Sudden unexpected death or episodes of viciousness have been associated with *atrioventricular nodal, or common bundle degeneration*, particularly in the *Doberman Pinscher*. Note that the presence of mineralized cartilage or osseous metaplasia in the central fibrous body in close proximity to conduction tissue is a normal finding in large breed dogs at all ages. The common bundle is fibrotic, degenerate, and in some cases replaced by fat. In most cases there is myointimal proliferation in arterioles in this region, possibly leading to ischemia of the common bundle. A similar phenomenon has been observed in other breeds, including the German Shepherd.

There is also a syndrome of sudden death in outwardly healthy, nonsyncopal *young German Shepherd Dogs* that is suspected to be hereditary in nature. Affected animals die unexpectedly during sleep or during rest following exercise. *Ventricular tachycardia* is the most common arrhythmia, the frequency of which increases during rest when the heart rate is slowest, and ends in ventricular fibrillation. The underlying defect is suggested to be regional paucity of sympathetic nerves in ventricular myocardium.

Hereditary stenosis of the common bundle has been observed in cases of syncope and sudden death in *Pug dogs*. Electrocardiographically, such dogs have intermittent sinus arrest and paroxysmal second-degree atrioventricular block. The sinus node, the atrioventricular node, and the bundle branches are normal. The paroxysmal atrioventricular block could be related to the lesion in the common bundle, but the sinus pauses are probably the result of excessive parasympathetic activity. Affected dogs are abnormally sensitive to small amounts of acetylcholine.

Deafness in the Dalmatian dog is associated with an abnormal blotchy coat color, and such animals may die suddenly. A proportion of affected dogs exhibit episodes of sinus pauses. In one that was available for necropsy, the right atrium was fibrotic and atrophied. This was accompanied by marked narrowing of the coronary arteries, including those of the sinus node. These clinical and pathologic findings are similar to those seen in congenital deafness in humans.

The presence of an atrophic and fibrotic atrium in the above case is the outstanding feature of the syndrome of **persistent atrial standstill** (atrioventricular muscular dystrophy), which occurs most commonly in *English Springer Spaniels* and has been described in *Siamese cats*. The atrium is grossly dilated and the walls are thin, transparent, and pink. Microscopically, there is myocyte atrophy, fibrosis, with a variable mononuclear cell presence. In some cases, atrophy of skeletal musculature is also evident. The syndrome is similar in many respects to a form of muscular dystrophy in people termed Emery-Dreifuss disease.

Sick sinus syndrome occurs in Miniature Schnauzers, West Highland White Terriers, and Dachshunds, and is familial in Miniature Schnauzers. Prolonged sinus pauses cause syncope.

Defects of the conduction system of **Alaskan sled dogs** that died suddenly during the Iditarod race included marked fibrosis or fatty infiltration of the sinus node, AV node, AV bundle, and bundle branches, and focal scarring of the left ventricle. These pathological changes may have led to fatal dysrhythmias.

Equine grass sickness (equine dysautonomia) is suspected to be a clinical form of botulism. The neurodegenerative changes noted in terminal parasympathetic ganglionic neurons in the heart, which include chromatolysis and vacuolation, may account for the tachycardia noted in this disease.

Ventricular preexcitation, a rare cause of weakness, syncope, or congestive heart failure in dogs and cats, can result when sinus node impulses bypass the normal conduction system via *accessory pathways* (bundle of Kent, James fibers, Mahaim fibers, or intranodal tract) to cause premature ventricular activation.

NEOPLASMS OF THE HEART

Primary neoplastic disease of the heart in all domestic species is rare, with the possible exception of hemangiosarcoma in the right atrium of dogs (see Vascular neoplasms, this chapter). In contrast, *metastasis to the myocardium from primary tumors of other organs is relatively common.* Primary tumors of the aortic body (chemodectomas) and of ectopic thyroid and parathyroid may arise at the base of the heart in dogs (Fig. 1.49) (see Vol. 3, Endocrine glands).

Hemangiosarcoma, a tumor of high-grade malignancy, may either arise as a primary in the myocardium, or metastasize to the myocardium, most commonly from the spleen or the skin. Characteristics of the tumor are described under Vascular neoplasms.

Other primary cardiac tumors are rare, and include *rhabdomyoma, rhabdomyosarcoma, myxoma, myxosarcoma, chondrosarcoma, osteosarcoma, granular cell tumor, fibroma, fibrosarcoma, lipomas, pericardial mesothelioma, and undifferentiated sarcoma.*

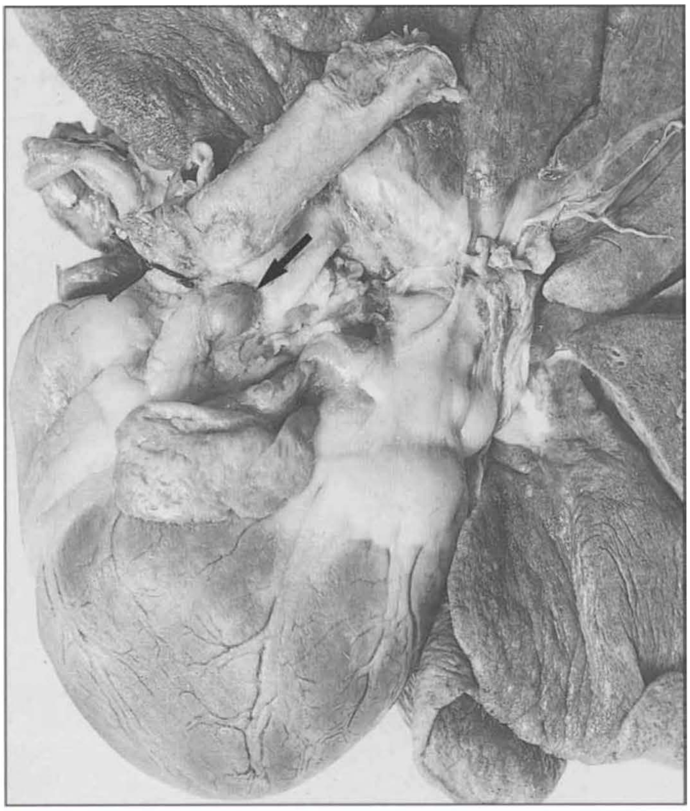

Figure 1.49 Cardioaortic chemoreceptor tumor in a dog. Tumor is within pericardial sac in the adventitia of the pulmonary artery (arrow).

Rhabdomyomas *are anomalous formations (hamartomas) of myocardial fibers seen as one or more circumscribed but nonencapsulated nodules within the myocardium.* It has been suggested that swine cardiac rhabdomyomas are not hamartomas but may represent congenital dysplasia of the perinatal cardiac myocytes with myofibrillar degeneration. Rhabdomyomas are rare in animals, but are most common in pigs, and have been observed in cattle, sheep, and dogs; a breed predisposition has been noted in red wattle pigs. Grossly, the nodules are gray and may be found anywhere in the heart. Those projecting into a chamber are very susceptible to hemorrhage and necrosis, and may become cystic (Fig. 1.50). Histologically, the cell type is predominantly mature myocardiocyte in type in a variant of rhabdomyoma, but cells in rhabdomyomas are more typically large, vacuolated, glycogen-rich, with scant myofibrils, and resemble Purkinje cells; cells with fine cytoplasmic strands extending from the nucleus to the peripheral cytoplasm are referred to as "spider cells." Fibrosis can be extensive, and the connective tissues may be impregnated with iron and calcium salts.

Myxomas are the most common cardiac tumor in adult humans, but are rare in domestic animals; they have been reported in the dog, cat, and cattle. They are believed to arise from multipotent vasoformative cells. They may originate from the endocardium of any of the four cardiac chambers or from the heart valves. Gross appearance is often multilobular, soft, and gelatinous. Histologically, myxomas are covered by endothelium on their surface, and are hypocellular, consisting of stellate or globular cells, blood vessels, and smooth muscle cells within an abundant myxoid matrix. Blood flow may be interrupted by these intracavitary space-occupying masses, and although they do not metastasize, they may generate emboli.

Primary cardiac **chondrosarcoma** occurs rarely and most probably arises from cartilaginous or like tissue that is present in the cardiac skeleton. Of the few that have been described, one arose in the right atrium with the others arising in the atrioventricular valves. As the tumors produce little cartilaginous matrix, a positive reaction to the presence of S100 protein is required to confirm the chondrocytic origin of the neoplastic cells.

A **granular cell tumor** or *granular cell myoblastoma* has been described in the right atrium of a dog. Granular cell tumors are rare in animals but have been reported to occur in a variety of organs including the lung, brain, meninges and tongue. The tumor has a distinctive light and electron microscopic appearance consisting of spindle-shaped to large polygonal cells containing prominent cytoplasmic granules within lysosomes. The cells are considered to be of neural origin as nerve-specific S100 protein is present within the cytoplasmic granules.

Neurofibromas (Schwannomas) *are either isolated or multiple benign neoplasms of peripheral nerves* (Fig. 1.51). Cattle are most frequently affected, with the most common sites being peripheral nerves, brachial plexus, autonomic ganglia, intercostal nerves, and cardiac nerves. The disease is usually detected only at slaughter. When the heart is involved, the tumors are single or multiple, round or nodular masses, either on the epicardial surface or within the myocardium. The microscopic appearance is of interwoven bundles or whorls of elongated cells (Fig. 1.52). There may be palisading of nuclei and variable amounts of collagen present. The principal cell is probably of Schwann or perineural origin.

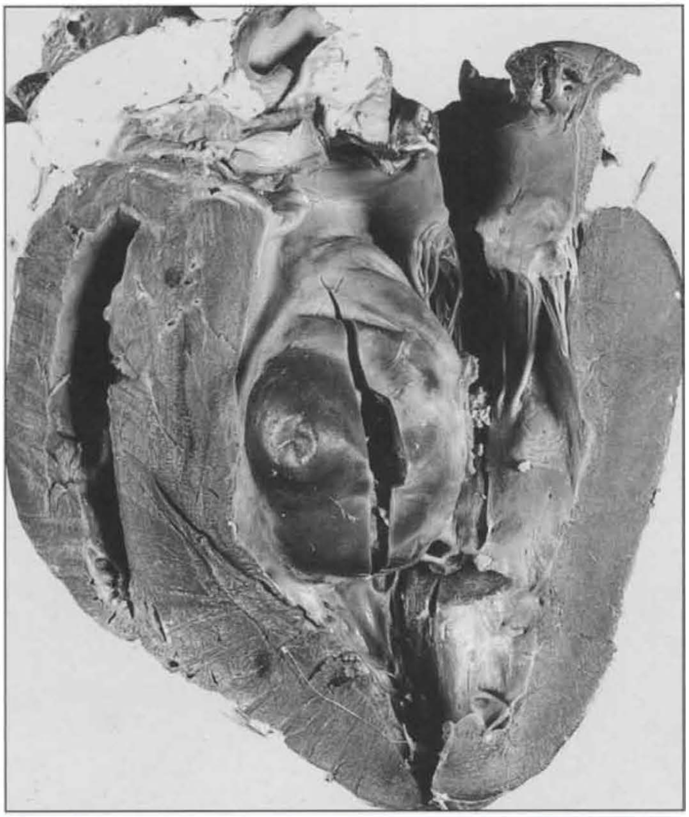

Figure 1.50 Cystic degeneration of a **rhabdomyoma** in the left ventricle, bovine.

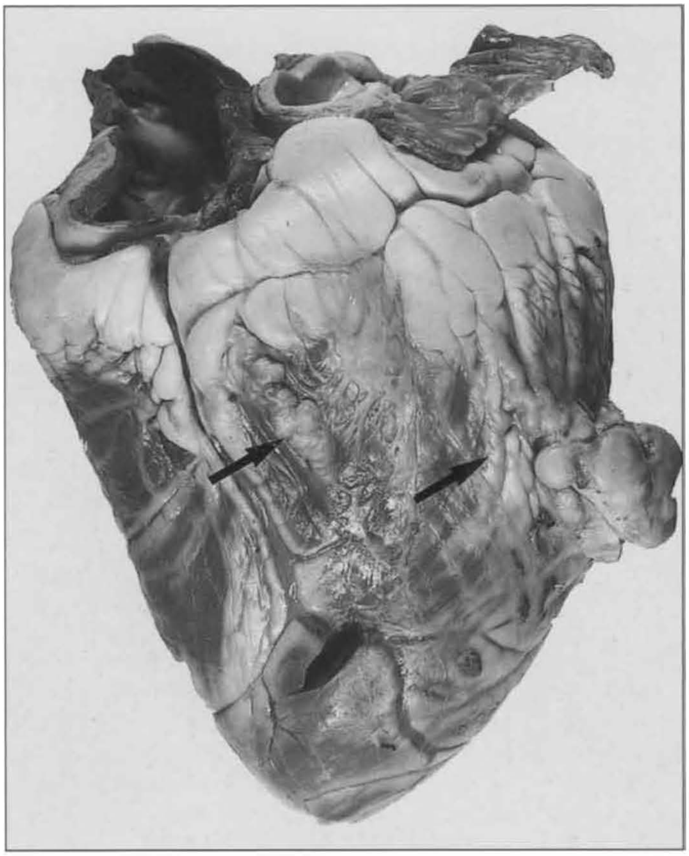

Figure 1.51 **Neurofibroma**, bovine. There are corded (arrows) and nodular enlargements of epicardial nerves.

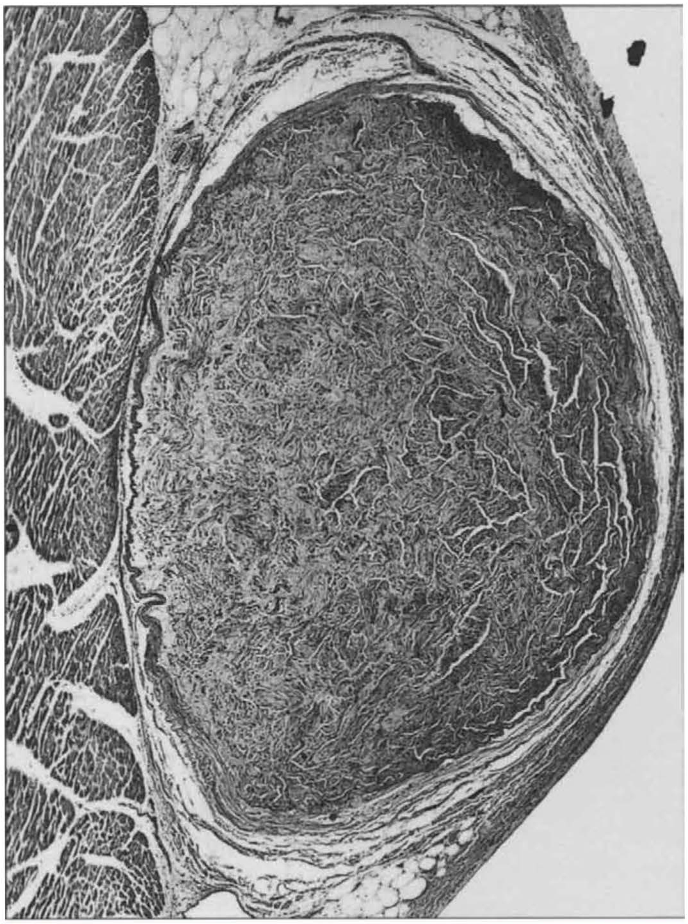

Figure 1.52 Section through nerve in Fig. 1.51.

Lymphoma *is the most common metastatic neoplasm involving the heart* (Fig. 1.53A, B), and occurs most commonly in the cow and the dog. It may be nodular or diffuse, although the distinction is arbitrary because there is overlap of the two forms. In the *nodular form*, there are foci, primarily in the atria (particularly the right atrium), which may be up to 5 cm or more in diameter. The nodules are covered by endothelium and are therefore smooth. When beneath the epicardium, they may be difficult to distinguish from epicardial fat. They are prone to central necrosis, and this resembles necrotic adipose tissue. On section, the wall of the atrium is more diffusely thickened, is moderately soft to cut, and has a pale appearance. If squeezed, milky fluid exudes from the cut surface. Globular masses like those beneath the epicardium are also found under the endocardium projecting into the cardiac cavities. In the *diffuse or infiltrating form*, the myocardium appears irregularly thickened and gray-white, with the ventricular walls being especially involved. These foci or areas of infiltration blend with normal myocardium and hence are difficult to distinguish from foci of myocardial degeneration or myocarditis. If they cause some thickening of the myocardium, such lesions are to be first regarded as lymphoma and indicate the need for careful search for primary lesions elsewhere in the body. Lymphoid neoplasms are considered in detail in Vol. 3, Hematopoietic system.

Diseases of the vascular system

GENERAL CONSIDERATIONS

The vascular system may be arbitrarily divided into the arterial system, the microcirculation, the venous system, and the lymphatic system. Impaired function of the vascular system can be generalized, as occurs in shock, or may be more localized as when decreased supply of oxygenated arterial blood to tissue causes ischemia, or impaired venous drainage causes congestion, or decreased lymphatic drainage of tissue fluids causes lymphedema.

The **arterial system** is subdivided into *large elastic arteries, medium and small muscular arteries, and arterioles,* with gradual transitions between these divisions. Arterial vessels are characterized histologically by walls composed of three layers: the internal, middle, and external tunics; or *tunica interna* (intima), *tunica media* (media), and *tunica externa* (adventitia).

The **intima** consists of endothelium; subendothelial connective tissue, which contains collagen, elastin, proteoglycan (ground substance), fibroblasts, and smooth muscle cells; and the internal elastic membrane. The thickness of the intima decreases as the vessel size decreases, until the subendothelial layer eventually disappears. The internal elastic membrane is not readily distinguishable in elastic arteries because of its continuity with medial elastic tissue, but is very prominent in muscular arteries, and disappears at the level of the smaller arterioles.

The **media** is the thickest layer of the vessel wall, and it consists of concentric layers of smooth muscle cells and elastic fibers, and the external elastic membrane. The media consists of fenestrated elastic laminae in elastic arteries, with smooth muscle cells lying between laminae. Intercellular ground substance is especially prominent in the tunica media of elastic arteries in the horse. *The elastic laminae diminish and smooth muscle predominates as vessels become more distant from the heart.* The media of muscular arteries is up to 40 muscle cells thick, whereas the media of arterioles is 1–3 cells thick. Definitions of the upper limit of arteriolar diameter range from 300 μm if fixed by perfusion to 100 μm if allowed to contract, but there are no sharp distinctions between small arteries and large arterioles. The thickness of the media as seen in routine material is greatest in relation to the luminal diameter in small arteries and arterioles, and it is these vessels, particularly arterioles, which participate actively in blood pressure regulation and also bear the consequences of hypertension. Contraction of muscular arteries and arterioles upon an animal's death forces blood from the lumina, and causes longitudinal folding that appears as scalloping of the internal elastic membrane when seen in cross-section. The external elastic membrane is best defined in the large elastic arteries, and becomes indistinct in muscular arteries.

The **adventitia** consists of a feltwork of elastic and collagen fibers continuous with the surrounding connective tissue. The interlacing network of collagen fibers in the adventitia limits expansion of the elastic arteries. Elastic fibers decrease in the adventitia with decreasing vessel size. *Vasa vasorum* and *nervi vasorum* supply the adventitia and the outer half of the media. *The intima and inner half of the media are avascular* and dependent upon diffusion from the vascular lumen, and are thus more subject to degenerative changes than the outer media.

The **microcirculation** *is the exchange system in which gases, nutrients, and waste products are transferred between the blood and the extravascular tissues.* The microcirculation consists of vessels of less than 100 μm in diameter: namely, *arterioles, terminal arterioles (metarterioles, precapillary sphincter areas), capillaries, postcapillary venules, and venules.* This classification overlaps microcirculation and macrocirculation (arteries and veins), but is useful conceptually as will be seen in disorders such as disseminated intravascular coagulation that affect primarily the microcirculation. Arterioles open through precapillary sphincters or through metarterioles into capillaries in most tissues, or into sinusoids in the liver. Capillaries are low-pressure tubules, of about 8 μm in diameter, composed of endothelial cells surrounded by a basal lamina; the endothelial cells are connected by tight junctions that allow rapid passage of small molecules such as glucose. The basal lamina is a molecular sieve that prevents passage of larger protein molecules. Capillary endothelial cells possess few endoplasmic organelles, but often contain pinocytotic vesicles. *Capillaries* may be: *continuous,* the most common type; *fenestrated* (60 to 80 μm fenestrae closed by thin diaphragms), as in the gastrointestinal tract and endocrine glands; or *porous* (without diaphragms closing the pores) as in renal glomeruli. Fenestration of the endothelial cells allows increased permeability. During tissue healing, cords of endothelial cells grow into the tissues by mitosis, develop lumina, and become functional capillaries. Undifferentiated perivascular cells, or *pericytes,* are ensheathed by glycocalyx that is continuous with the capillary basal lamina. Mitosis of pericytes is easily stimulated and they may be transformed into fibroblasts or smooth muscle cells. *Sinusoids* are less uniform than capillaries and more permeable because there are large openings between the endothelial cells and a discontinuous basal lamina.

Veins are termed *small, medium, or large* or, alternatively, *venules, collecting veins, and great veins*; all have large lumina in relation to their wall thickness. Classification of veins by wall characteristics is difficult because the layers in their walls may be absent or difficult to distinguish. Venules of greater than 30 μm in diameter have an incomplete muscular media and thin adventitia. Venular endothelium is normally more permeable than that of capillaries and is also more sensitive to vasoactive amines, the action of which can cause leakage. In the lymph node paracortex, *postcapillary venules,* which are nonmuscular venules with prominent endothelium, are important sites of lymphocytic traffic. The media is of increasing thickness in medium and large veins, and the internal elastic lamina becomes more prominent. However, *the adventitia is the thickest layer in veins, whereas the media predominates in arteries.* Backflow of blood in veins is prevented by the presence of *semilunar valves,* which are invaginations of the intima into the venous lumen. Venous valves are not present in venae cavae or hepatic portal vein. Paucity of valves in veins of the head and face may contribute to incidental venous congestion in these areas.

Lymphatic capillaries originate in loose connective tissue, and consist of very permeable walls and endothelial cells that may lack, or have a discontinuous, basal lamina. In larger lymphatics, *valves* are present, the basal lamina is continuous, and walls consist of three ill-defined layers; an internal elastic lamina is usually absent. The thin-walled veins and lymphatics are more susceptible to compression and occlusion, are more often involved by inflammation in adjacent tissue, and are more liable to neoplastic invasion than are the thicker-walled arteries.

Endothelium and smooth muscle, the main components of vessel walls, play important roles in all types of vascular disease. A wealth of information is accumulating about the important properties and reactive capabilities of these seemingly simple cells. For example, in addition to maintaining a permeability barrier between blood and tissues, *the endothelium is recognized as the largest paracrine organ in the body.* It produces anticoagulants, procoagulants, fibrinolytic agents, prostanoids, connective tissue components, adenosine, and a host of other substances. Vascular homeostasis is maintained by complex interactions among endothelial cells, leukocytes, and platelets, each of which produce vasodilators and vasoconstrictors and can interact to inhibit or promote thrombosis.

Vascular **endothelial cells**, as well as forming the thromboresistant monolayer lining of the vascular system, mechanically insulate the circulating blood from the highly thrombogenic subendothelial materials. The thromboresistance of the endothelium is normally maintained by a balance between antithrombotic and thrombotic factors; stimulation of excessive prothrombosis can lead to clotting and thrombosis, whereas excessive antithrombosis can lead to ineffective hemostasis and bleeding. *Antithrombosis* is normally accomplished through:

- binding and inhibition of thrombin via activation by thrombomodulin of protein C and protein S, via accentuation of antithrombin activity by heparin-like molecules, and via the presence of alpha$_2$ macroglobulin;
- inhibition of platelet aggregation through elaboration of prostacyclin (PGI$_2$), a potent inhibitor of platelet aggregation and a vasodilator, and by ADPase-mediated conversion of pro-aggregating ADP to adenine nucleotide platelet inhibitors; and
- promotion of fibrinolysis by synthesis of tissue plasminogen activators.

Procoagulant activities include:

- the presence of minute amounts of tissue thromboplastin in endothelial cells, further production of which can be stimulated by endotoxin and by cytokines such as interleukin-1 and tumor necrosis factor;
- synthesis and secretion of von Willebrand factor, needed for adherence of platelets to subendothelial components, and secretion of platelet activating factor, an activator and aggregator of platelets; and
- inhibition of fibrinolysis through release of plasminogen activator inhibitors.

In addition to their role in hemostasis, endothelial cells participate in *modulation of blood flow and vascular reactivity* by production of endothelium-derived relaxing factor (nitric oxide); endothelin, a vasoconstrictor; angiotensin converting enzyme, which converts angiotensin I to angiotensin II; and prostacyclin. Endothelial cells modulate the actions of various vasoconstrictors (catecholamines, serotonin, arginine, vasopressin) and vasodilators (histamine, leukotrienes, adenine nucleotides), and in concert with the endothelium-derived factors can thereby allow blood vessels to rapidly adapt to changes in hemodynamic conditions.

Endothelial cells aid in the *regulation of inflammation and immunity* through production of interleukin-1 and various adhesion molecules, which moderate adhesion and hence emigration of leukocytes. The most important adhesion molecule pairs are the selectins, the immunoglobulins ICAM-1 and VCAM-1, and the β2 and β1 integrins. Endothelial cells also aid in *regulation of cell growth* by production of growth stimulators (platelet-derived growth factor, colony-stimulating factor, and fibroblast growth factor), and production of growth inhibitors (heparin, transforming growth factor-β). Endothelial cells produce basement membrane, and are capable of contraction. The endothelium is a semipermeable membrane that can also transport metabolites including proteins through the cytoplasm via pinocytotic vesicles. *Weibel-Palade bodies*, rod-shaped cytoplasmic organelles that store von Willebrand factor, serve as ultrastructural markers of endothelial cells.

Subendothelial connective tissues consist of various types of collagen, elastin, proteoglycans, fibronectin, laminin, and thrombospondin. Of these, fibrillar collagen is the most potent stimulus for platelet adhesion and activation; collagen also activates the intrinsic pathway of coagulation. *Fibronectin*, or "molecular glue," normally functions to stabilize cell-to-cell and cell-to-substrate attachments, but also becomes cross-linked to fibrin and helps to anchor hemostatic plugs.

Mild endothelial injury, as occurs in the course of inflammation, may be apparent histologically as hypertrophy of endothelial cells ("reactive" cells). As well, increased vascular permeability may lead to insudation of plasma proteins, including fibrinogen, into the subendothelial area, and hence contribute to vascular hyalinosis. Since the intima and inner media depend upon diffusion of metabolites from the vascular lumen for their nutrition, such subendothelial deposits may impair the viability of smooth muscle cells and contribute to degeneration, or *fibrinoid necrosis*, of vessel walls. Thus, the endothelial barrier must be preserved to maintain a normal environment for medial smooth muscle cells. Necrosis of endothelium, which may be caused by a wide variety of agents, leads to exposure of subendothelial collagen, a potent inducer of coagulation and platelet aggregation, and hence thrombosis. Endothelial cells at the edges of denuded areas will proliferate and migrate to repair the endothelial defect or to form an endothelial covering over (endothelialize) a mural thrombus. Severe microvascular damage, as occurs due to lipoperoxidation of endothelial membranes in vitamin E/selenium deficiency in pigs, can result in hemorrhage and organ failure.

Vascular smooth muscle cells are important both as effectors of vasoconstriction and dilation, and as cells capable of synthesizing basement membrane, collagen, elastin, and proteoglycans of the extracellular space. In response to growth factors derived from platelets and monocyte/macrophages, smooth muscle cells of the media migrate through fenestrae of the internal elastic lamina to the subendothelial area where, as "myointimal" cells, they proliferate and are responsible for organization or collagenization of deposits, including thrombi. Examples of endoarterial organization and arterio-occlusive disease are discussed later in this chapter. In common with other muscle cells, *medial smooth muscle cells respond to an increased workload by hypertrophy.* Medial hypertrophy is a prominent consequence, as well as a cause, of pulmonary hypertension. Sustained vasoconstriction, as is induced by ergot (*Claviceps purpurea*) or fescue grass (*Festuca arundinacea, Festuca eliator*) poisoning, can lead to gangrene of the extremities; fescue toxicosis in cattle (summer syndrome) is caused by infestation of the grass by the endophyte *Neotyphodium (Acremonium) coenophialum*, which produces the ergopeptide alkaloids, ergovaline, ergosine, and ergonine. Along with the other components of the vessel wall, smooth muscle cells may be involved in degenerative and inflammatory changes, as described below, and contribute to fibrinoid necrosis of the wall.

Normal aging changes of vessels include intimal thickening due to proliferation of myointimal cells and accumulation of their products, deterioration of medial elastic fibers, medial fibrosis and loss of medial smooth muscle, and accumulation of ground substance in the media. These slowly progressive changes are usually of little consequence given the large functional reserve of the vascular system, but do lead to loss of resilience of the vessel walls and may cause vessel wall thinning, stretching, and hence increased tortuosity.

ARTERIES

Congenital anomalies

Minor variations occur among individuals of a species in the course and distribution of arteries, but these are of little significance except possibly in surgical techniques.

Arteriovenous fistula, the communication of an artery and vein that bypasses the capillary system, is a defect that *may arise developmentally or be acquired* subsequent to physical trauma, inflammatory necrosis involving adjacent vessels, neoplastic infiltration, or rupture of an arterial aneurysm into a vein. Fistulas occur in dogs, cats, horses, and cattle, but are uncommon. Clinically, fistulas most commonly occur in the extremities and appear as a pulsating, fluctuant swelling in which there is a palpable thrill and a machinery-like bruit on auscultation. In general, arteriovenous fistulas cause decreased peripheral resistance and increased venous return to the right heart. When 20–50% of the cardiac output is shunted through the fistula, high-output cardiac failure can occur. The veins involved are usually thick-walled ("arterialized"), may be dilated and extremely tortuous, and may have intimal sclerosis. *Hepatic arteriovenous fistula* (congenital hamartoma) occurs in dogs and cats, and can cause portal hypertension, portocaval shunts, and ascites.

Thebesian veins connect the cardiac chambers, between the trabeculae carneae, with the myocardial sinusoids and capillaries. They may also connect with coronary arterioles to form direct connections between the coronary arterioles and the cardiac chambers. Areas of myocardium in which the Thebesian vein system is richly persistent are randomly distributed and the true nature of the defect may be overlooked because of the tortuous aneurysmal dilation of the affected coronary artery. Injection studies are necessary to demonstrate the extent of the anastomosis.

Degeneration of arteries

Arteriosclerosis

Arteriosclerosis literally means "hardening of the arteries," and is more fully defined as *chronic arterial change consisting of hardening, loss of elasticity and luminal narrowing resulting usually from proliferative and degenerative, rather than inflammatory, changes of the media and intima.* The term atherosclerosis is applied to lesions of arteriosclerosis in which degenerative fatty changes also occur. Atherosclerosis is the most common and important type of arteriosclerosis in humans, and the terms can thus be used interchangeably with little loss of meaning when discussing this species. *In domestic animals, arteriosclerosis is common, but of little importance, and atherosclerosis is rare.*

Arteriosclerosis develops slowly in animals, its extent or incidence being greater in older animals. The disease may become so widespread in individual animals that microscopically normal vessels may be difficult to find. The sclerotic vessels are usually not accompanied by significant disturbances of blood flow, although ischemic change, especially of brain and heart, may be seen. Well-developed lesions may be good sites for thrombus formation in animals when thrombogenic circumstances prevail. Arteriosclerosis uncomplicated by focal degeneration in the sclerotic plaques and with no or minimal lipid deposition is the lesion usually found in older horses, ruminants, and carnivores. There is a predilection for the abdominal aorta and points of arterial branching, but it is also seen in peripheral and pulmonary arteries and in the thoracic aorta. The extensiveness of the lesions is very variable, so that there is no clear differentiation between a permissible aging change and a pathologic process. The nature of the insult (or insults) to the vessel walls that result in sclerosis is not known, although there are numerous possibilities. Hemodynamic factors probably contribute, especially to development of plaques about the orifices of arterial branches.

Arteriosclerotic plaques produce a slight thickening and wrinkling of the intima, or more or less distinct white, oval or linear elevations, and they can be found microscopically in many animals in which they are not visible to the naked eye. Their presence in peripheral, including coronary and cerebral, vessels, can be correlated with arteriosclerosis of the abdominal aorta.

The initiating lesion(s) and the evolution of plaque formation are not fully elucidated. Microthrombi composed chiefly of platelets are deposited at natural sites of turbulence or of endothelial denudation, and may initiate the lesion. Platelets secrete platelet-derived growth factor (PDGF), epidermal growth factor, transforming growth factor-β, and other mitogens; PDGF stimulates migration and proliferation of smooth muscle cells. Alternatively, the initial change in the vessel wall may occur as the result of a nondenuding insult to the endothelium; endothelial cells themselves produce several mitogens, including PDGF. Histologically, the internal elastic membrane shows an early distinctive change, being irregular in outline, partially duplicated, and fragmented or discontinuous. Smooth muscle cells migrate into the intima from the media to function as do fibroblasts outside of arteries; these intimal smooth muscle cells produce most of the connective tissue matrix of the intimal plaque, including collagen, elastic tissue, and proteoglycans. In young plaques, or the deeper portions of older ones, the smooth muscle cells ("*myointimal cells*") are numerous and intimately mixed with collagen, elastic fibrils, basement membrane, and proteoglycans as the so-called *musculoelastic layer*. In large and older plaques, a more superficial elastic hyperplastic layer may be recognized by a more compact arrangement of collagen and elastica with relatively few cells. This lamination of plaques is not always clearly evident, and its development may depend on the age of the lesion as well as on the segment of vessel involved, whether chiefly muscular or chiefly elastic.

Atherosclerosis

Atherosclerosis is of little practical importance in domestic animals, but is primarily of interest for the development of animal models of the human disease. The atherosclerotic susceptibility of animals varies; *rabbits, chickens, and pigs are atherosensitive, whereas dogs, cats, cattle, goats, and rats are atheroresistant*. Swine and nonhuman primates are usually considered to be the best animal models of human atherosclerosis.

In **humans**, *atherosclerosis and its complications of myocardial infarction, stroke, and peripheral vascular disease are major causes of morbidity and mortality in the western world*. Atherosclerosis affects the large elastic arteries (aorta, iliac) and the large and medium muscular arteries (carotid, coronary, femoral). The essential lesion is the *atheroma or fibrofatty plaque*, which is a focal, raised, intimal plaque with a core of lipid (cholesterol and its esters largely) covered by a fibrous cap. Complications of plaques include mineralization, ulceration, superimposed thrombosis, intraplaque hemorrhage, and aneurysmal dilation. *Fatty streaks*, another type of fatty intimal lesion, are common in the aorta and large arteries of domestic animals, especially ruminants and swine, and humans. The streaks, which are soft, smooth, nonelevated lesions ranging from pinpoint size up to several square centimeters, are rarely visible grossly unless the aorta is stained with a fat stain such as Sudan IV, which stains the lesions bright orange. Streaks and plaques may coexist in the same area, but fatty streaks also occur in areas in which plaques do not occur; thus, the role of fatty streaks in the genesis of atherosclerosis is unresolved.

Multiple pathogenetic influences can contribute to the development of plaques. The various events and theories of development of atherosclerosis have been unified in the "*response to injury*" *hypothesis*. Endothelial injury or dysfunction can occur as the result of hyperlipidemia, with the cholesterol present in low-density (LDL) and very-low-density lipoproteins (VLDL) seen as a primary culprit. Additional risk factors are hypertension, smoking, obesity, inactivity, and diabetes mellitus. Immunologic mechanisms, toxins, and viruses may also damage endothelium. Endothelial injury leads to platelet adhesion, monocyte adhesion and infiltration, and smooth muscle migration and proliferation, as discussed above under arteriosclerosis. The feature added in atherosclerosis is insudation of lipid, which is seen as extracellular lipid or as intracellular lipid in "foam cells." The lipid-laden foam cells that are characteristic of both fatty streaks and atheromatous plaques may be either altered macrophages or smooth muscle cells; macrophages predominate in streaks, whereas smooth muscle cells predominate in the fibrous cap of plaques. Endothelial cell dysfunction is emerging as an endocrinopathy that may contribute to the effects of atherosclerosis through impaired ability of endothelial cells to produce endothelial-derived relaxing factor and through increased production of endothelin.

Atherosclerosis develops commonly only in the **pig** amongst domestic species. Fatty streaks and atheromatous plaques develop in the aorta, extramural coronary arteries, cerebral and iliac arteries, as in man, and the plaques may cause considerable stenosis of vessels in swine 8–12 years old. The extent of lipid deposition can be influenced by feeding extraordinary diets containing much lipid, including cholesterol, but the atheromas rarely reach the degree of development seen in humans, and they do not lead to occlusive thrombus formation, which apparently requires softening and ulceration of the atheromatous plaque. The initial deposition of lipid occurs in the proliferated smooth muscle cells, which show signs of degeneration and which may become foam cells. Macrophages also appear, containing lipid, and fat may be demonstrable extracellularly, presumably released by degenerate cells. Deposits of cholesterol and mineral, not extensive, may be associated with softening of larger atheromatous plaques. However, except in pigs fed high-fat diets, lipid is usually a minor component of the predominantly fibromuscular plaques.

Of the domestic animals, the deposition of cholesterol and other lipids in the arteries in more than trace amounts occurs only in **dogs** (Fig. 1.54), and then almost always in association with *hypothyroidism or diabetes mellitus*. In dogs, hypercholesterolemia is chiefly related to hypothyroidism, but even in thyroidectomized, cholesterol-fed, hypercholesterolemic experimental dogs, only occasional dogs classed as "hyperresponders" developed atherosclerosis, perhaps as a result of an increased proportion of cholesterol-rich VLDL. A breed predisposition to atherosclerosis in miniature schnauzers may be the result of idiopathic hyperlipoproteinemia.

The deposition of lipids begins in the middle and outer layers of the media and occurs more extensively perhaps in the small muscular arteries than in the large elastic ones; if present, aortic lesions occur as intimal plaques. The veins are normal. The vascular changes can be severe enough to be seen on gross inspection. The vessels are enlarged, less pliable than normal, and their walls are thickened and ill defined because a hyperplastic adventitia merges irregularly with surrounding tissues. Projecting into the lumens of the vessels on cross-section are tiny yellow-brown nodules. In vessels large enough to be opened longitudinally, there are numerous small yellow flat elevations that may be confluent.

The media may be greatly increased in thickness by the accumulation of lipid, most of which is in foam cells, but some is present in identifiable muscle cells of the media or free in the interstitium as droplets or crystals (Fig. 1.55). The deposition of lipid in the internal layers of the media leads to disruption of the internal elastic lamina and involvement of the intima. The amount of lipid deposited can be, relatively, very great and lead to eccentric enlargement of the vessel. Associated with the lipidosis, and possibly as a response to it, there is progressive proliferation of fibrous connective tissue. Beginning with the formation of fine fibrils in and about the areas of lipid deposition, the fibrosis is progressive and may eventually completely transform the structure of the wall. The connective tissues become hyaline and relatively acellular and may be heavily impregnated with salts of calcium and iron, present as granules, large clumps, or crystalline plaques.

Atheromatosis of the degree described above in dogs is rare. Clinical consequences of severe atherosclerosis appear to be infrequent in dogs, even though the vessels most severely involved are

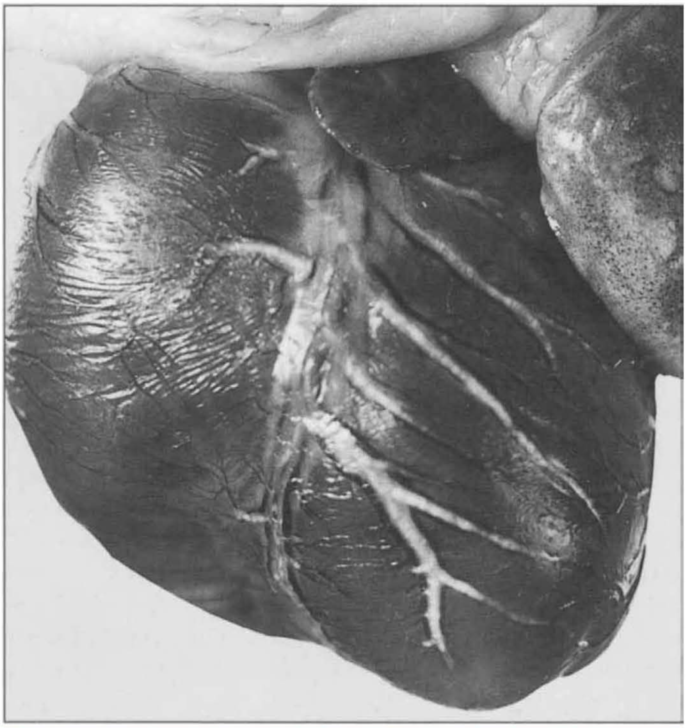

Figure 1.54 Irregular thickening of coronary arteries due to **atherosclerosis** in a dog.

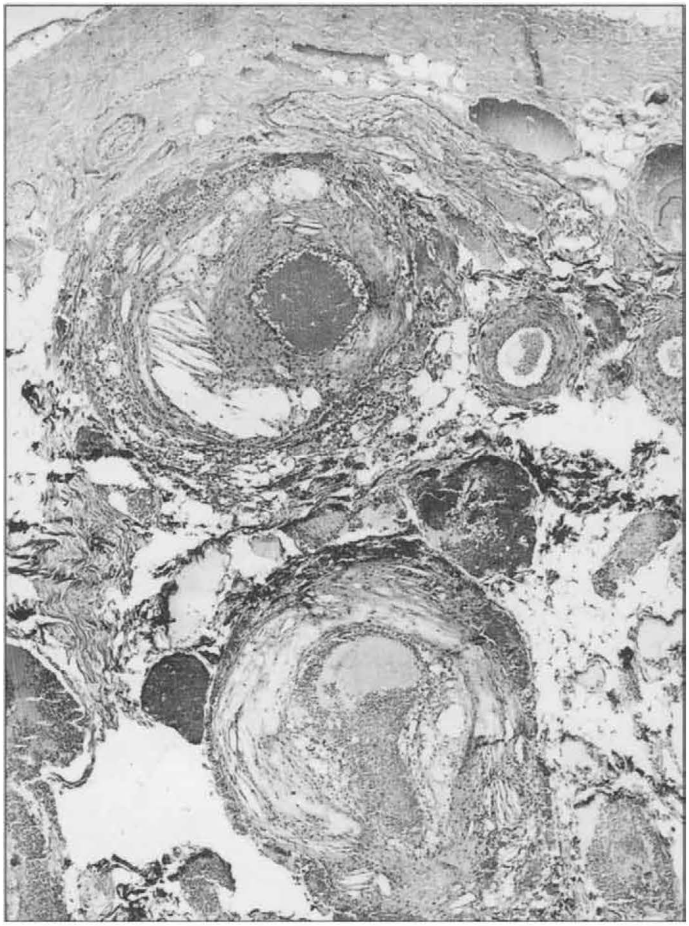

Figure 1.55 Atherosclerosis of extramural coronary arteries in a dog.

those of the heart, brain, and kidney. Occasionally, however, as in humans, rupture of the atheromatous area into the lumen with thrombosis or even widespread lipid embolism has been observed.

The morphology of atherosclerosis differs in dogs and in humans; *lipid is present in the intima but primarily in the media and adventitia of atherosclerotic canine arteries*, but is present primarily in the intima in man. The term "*xanthomatosis*" has been applied to the canine condition in the past, but its use is inadvisable as it may cause confusion with the human condition of primary xanthomatosis (type II hyperlipoproteinemia), in which there is premature atherosclerotic coronary artery disease, but also xanthomatous infiltration of the myocardium, dermis, and other organs with an associated granulomatous reaction. A similar condition in other animal species is referred to as xanthomatosis, and is characterized by the presence of lipid-laden foam cells in subcutaneous or intracutaneous accumulations known as *xanthomas*. A familial hyperlipoproteinemia occurs in lipoprotein lipase deficient cats, and results in the formation of xanthomata in a variety of organs; atherosclerosis is not a feature of this condition.

Arteriolosclerosis

Arteriolosclerosis describes a heterogeneous group of arteriolar lesions that may be predominantly hyaline or predominantly hyperplastic. The major cause of these changes in vessels in humans is hypertension, but the pathogenesis of the lesions in domestic animals is often not understood. Endothelial damage is likely the primary event in these conditions. *Hyaline degeneration* – the microscopic appearance of amorphous, brightly eosinophilic material in vessel walls – can occur as the result of increased vascular permeability that allows insudation of various plasma components; it includes the amyloid deposits of renal glomeruli and elsewhere, and the fibrin and necrotic smooth muscle of "fibrinoid" necrosis. Fibrinoid necrosis may predate and initiate inflammatory cellular infiltration, after which the reaction would be termed arteritis. Thickening of the arteriolar wall may cause luminal narrowing and hence ischemia of the region supplied.

Systemic hypertension, or *persistently elevated systemic blood pressure*, is an important disease of humans, and occurs as *primary or essential hypertension* and as *secondary hypertension*. Both forms of hypertension are typically benign in their clinical course; *accelerated or malignant hypertension* develops in about 5% of affected individuals. Both primary and secondary hypertensions have been reported in dogs and cats; the primary form is rare and the secondary form is apparently uncommon, though hypertension may often go unrecognized. The diagnosis of hypertension could well become more frequent as noninvasive techniques for measurement of blood pressure, such as Doppler ultrasonic sphygmomanometry, come into common use. *Renal disease, likely the most common cause of hypertension in dogs and cats*, may be either a cause or an effect of hypertension, thus making difficult the definition of the occurrence of a hypertensive vascular lesion as a primary or a secondary event. Primary hypertensive lesions can lead to decreased renal perfusion, activation of the renin–angiotensin–aldosterone system, and hence more hypertension, but, on the other hand, primary chronic renal disease can lead to inadequate excretion of sodium and water, blood volume expansion, and hence secondary hypertension. In either case, *hypertension is self-perpetuating* as medial hypertrophy and hyalinization of renal arteries lead to more nephrosclerosis, more hypertension, and more pressure-induced vascular damage.

Hypertension, which would be classed as secondary, is said to occur in more than 60% of dogs with chronic renal disease, and may also occur in association with pheochromocytoma, hyperadrenocorticism, hypo- and hyperthyroidism, and diabetes mellitus. In cats, hypertension occurs in association with chronic renal disease, hyperthyroidism, and chronic anemia. Systemic and local hypertensions reportedly accompany acute and chronic laminitis in horses; hypertension is suggested to occur in acute and chronic laminitis in cattle. The hypertension of feline hyperthyroidism is reversible on resolution of the primary condition. *The presenting sign in canine and feline hypertension may be blindness due to hypertensive retinopathy*; ocular lesions include retinal vascular tortuosity, intraocular hemorrhage, and retinal detachment, the results of retinal arterial degeneration. In the face of hypertension, retinal and choroidal arterioles constrict; sustained vasoconstriction may lead to ischemic necrosis of the arteriolar smooth muscle, increased vascular permeability, hyalinization, edema, and hemorrhage. Left ventricular hypertrophy commonly occurs in hypertension in response to increased demand for cardiac output plus increased peripheral vascular resistance.

Pulmonary hypertension – *persistent elevation of pulmonary arterial blood pressure* – can occur both as the cause and as the result of pulmonary arterial disease (see Vol. 2, Respiratory system; and, in this chapter, Arterial hypertrophy, and Dirofilariasis (heartworm disease), p. 87).

Widespread arterial degeneration commonly occurs in dogs with **uremia**, and is most frequently noted in small muscular arteries and arterioles of the gastric submucosa, tongue, colon, gallbladder, urinary bladder, and kidneys. Less frequently affected are arteries of the small intestine, myocardium, and other organs. The arterial and arteriolar lesions, in concert with degenerative capillary lesions, produce ischemic injury, and contribute to grossly observed lesions of uremia such as uremic gastric infarction. The arterial lesions of acute renal insufficiency consist of subendothelial deposition of fibrin, disruption of the internal elastic lamina, necrosis of medial smooth muscle, mineralization, and sometimes a neutrophilic reaction. These lesions may be segmental or circumferential in the vessel wall. This arterial reaction is primarily degenerative rather than inflammatory, and is similar to **hyaline arteriolosclerosis** of benign nephrosclerosis (patchy ischemic atrophy) in humans. In chronic renal insufficiency, medial hypertrophy and adventitial fibrosis produce thickening and whorling of renal interlobular and intralobular arteries and afferent arterioles. These changes are similar to **hyperplastic arteriolosclerosis** of humans, which is characterized by concentric fibrosis and smooth muscle proliferation in the intima (*onion-skinning*); these hyperplastic changes, in combination with fibrinoid necrosis of the media of arterioles, are features of malignant hypertension.

Hyalinosis is commonly observed in the splenic arterioles of dogs and pigs, affecting most frequently those of the lymphatic nodules. This change is more severe in dogs with a variety of diseases including diabetes mellitus and chronic renal disease, and thus may be of hypertensive origin. A hypertrophic hyalinization is regularly observed in the uterine and ovarian arteries in pregnant and postpartum animals; the elastic tissue is increased in amount, the intima is markedly thickened and hyaline, and the muscularis may be atrophic.

Hypertrophic hyalinization, or hyalinosis, is observed in old dogs, affecting principally the **intramural coronary arteries** (Fig. 1.32) and small meningeal and cerebral vessels. The hyalinization is not clearly of clinical significance in the brain but *may cause multifocal intramural myocardial infarction* (MIMI) and, in concert with valvular endocardiosis, lead to congestive heart failure. The hyaline deposits consist predominantly of fibrin or glycosaminoglycans or, less commonly, amyloid. Other lesions encountered in the intramyocardial arteries include musculoelastic intimal thickenings, intimal cushions, and microthrombi; these lesions occur at sites of turbulent blood flow, namely bifurcations and branchings.

Sclerosis of intramural coronary arteries, predominantly of the left ventricle, occurs in dogs with congenital subaortic stenosis and occurs in the right ventricle of dogs with pulmonic stenosis. Intimal thickening due to fibroelastic and smooth muscle proliferation can result in myocardial infarction and scarring. The intimal proliferation may occur in response to decreased coronary perfusion pressure and increased intramural tension during systole.

Arteriolar hyaline degeneration is seen in swine as part of the pathological picture in meninges in organomercurial poisoning, in various organs in edema disease, and chiefly in the heart in hepatosis dietetica and mulberry heart disease. The progression of arterial lesions in **edema disease** (Fig. 1.56) is from mural edema, to hyaline degeneration, to medial necrosis and intramural and perivascular hemorrhage, at which stage acute severe hypertension develops, likely as a result of increased vascular resistance, and hypertension in turn exacerbates vascular damage; adventitial proliferation follows in survivors. Certain strains of *Escherichia coli* produce edema disease toxin (Shiga-like toxin-II variant, SLT-IIv), which preferentially targets vessels of the gastric and colonic submucosa and the cerebellar folia, perhaps because of concentration of a toxin receptor, such as globotetraosylceramide, at these sites. **Cerebrospinal angiopathy** in swine is characterized by lesions in arterioles, primarily in the brainstem, which include subendothelial hyaline deposits, degeneration or fibrinoid necrosis of the media, and perivascular eosinophilic droplets. The vascular lesions cause demyelination and malacia, and hence nervous signs, and are probably manifestations of subclinical edema disease (Fig. 1.57).

Mineralization

Mineralization (calcification) occurs quite frequently in the arteries of animals, either as a dystrophic or metastatic process. **Dystrophic mineralization**, or *mineralization of dying or dead tissue*, occurs in areas of inflammation, degeneration, and thrombosis, and not necessarily in association with preexisting arteriosclerosis. **Metastatic mineralization** occurs as the *result of hypercalcemia and/or hyperphosphatemia*. The distinction between dystrophic and metastatic mineralization may be artificial; in vitamin D toxicosis for example, some maintain that degeneration occurs prior to mineralization as a result of direct vitamin D toxicity, and that hypercalcemia and mineralization are secondary events. Although the cardiovascular system is particularly susceptible to mineralization, mineralization of other soft tissues, such as the renal tubular and pulmonary alveolar basement membranes, endocardium and myocardium, and gastric mucosa, usually occurs concomitantly with vascular mineralization.

Vitamin D poisoning occurs in a variety of circumstances, and *leads to mineralization of vessels and other tissues in association with hypercalcemia and/or hyperphosphatemia*. The disease can be endemic in herbivores, cattle most often, that have consumed plants (such as *Solanum malacoxylon, S. torvum, Trisetum flavescens, Cestrum diurnum*) that contain 1,25-dihydroxycholecalciferol or a related compound. Horses and pigs are occasionally poisoned by inadvertent overdoses of vitamin D in feed. Accidental poisoning of dogs and cats with a *cholecalciferol (vitamin D_3)* rodenticide is common.

Mineralization occurs in dogs with hypercalcemia due to pseudohyperparathyroidism, in some dogs in association with chronic renal insufficiency, and in hypomagnesemic cattle. Mineralization also occurs spontaneously in animals of advanced age and, *in cattle especially, in a variety of chronic debilitating diseases such as Johne's disease*. In sporadic cases, the causes of mineralization are generally unknown and may be nonspecific.

Calcium and phosphorus are deposited in association with extracellular vesicles adjacent to elastic fibers and, in the smaller vessels, may produce a complete, concentric ring of medial mineralization; this is the domestic animal equivalent of *Monckeberg's arteriosclerosis (medial calcific sclerosis)* of humans. Mineralized lesions in the aorta and pulmonary artery are usually in the form of flat plaques and are often very striking grossly; complete encirclement is seldom seen. The button-like protuberances that are seen in the aorta about the orifices of smaller branches are not primarily aortic but, instead, concentric lesions in the small efferents that project when the opened vessel undergoes elastic recoil. The plaques in the large vessels are brittle and the smaller arteries are transformed into rigid tubes that can be fractured easily. Metaplastic ossification may occur (Fig. 1.58).

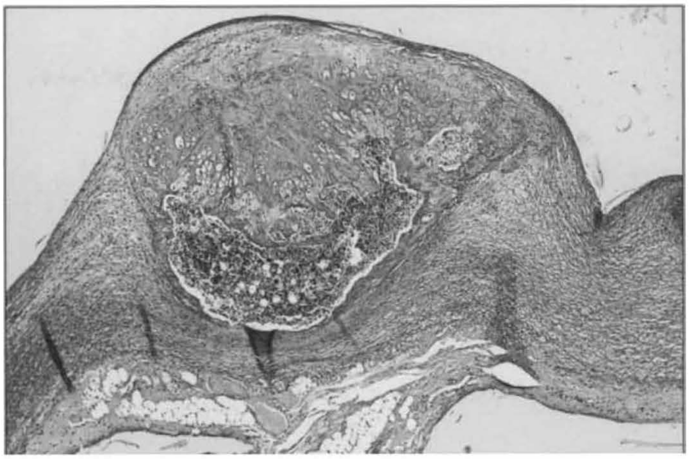

Figure 1.58 Cartilaginous and osseous metaplasia in arteriosclerosis of the aorta in a dog. Note hematopoietic tissue.

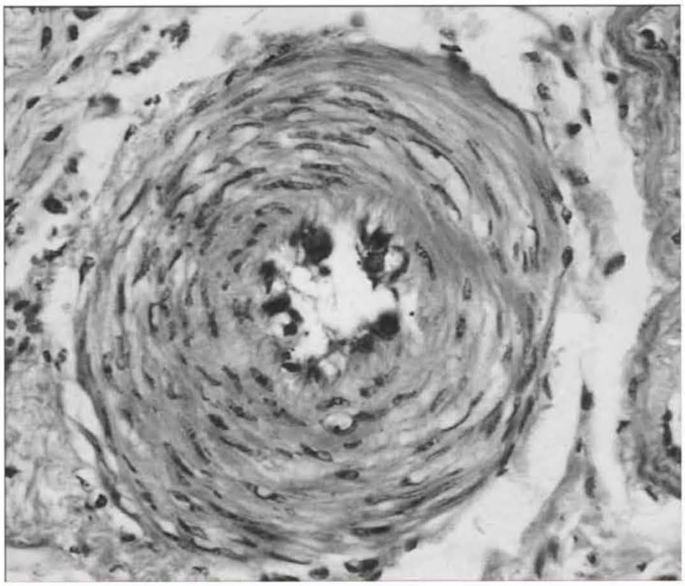

Figure 1.59 Intimal bodies in a submucosal artery of the intestine in a horse.

Intimal bodies *occur commonly in small arteries and arterioles of horses*, particularly in the submucosa of the intestines, but in other organs as well. Intimal bodies appear in section as multiple irregular mineralized masses covered by endothelium and usually protruding into the arterial lumen (Fig. 1.59). They occur in horses of all ages, are not associated with strongyle infection, and *have no apparent functional significance*. These bodies apparently arise from degeneration and mineralization of subendothelial smooth muscle cells and intercellular material.

The deposition of iron salts with calcium (**siderocalcinosis**) is observed commonly in horses, the incidence or severity of the change increasing with age. Vessels of all types are involved and sites of predilection include the globus pallidus and internal capsule in the brain. Mostly, the deposits are without notable consequence, but secondary malacia may occur. It is also possible that malacia of other cause may exacerbate the cerebrovascular siderosis.

The *mineralized nodules in the intima of the aorta in the horse* are probably all healed lesions of verminous arteritis (*Strongylus vulgaris* migration).

Arterial rupture, aneurysms

Rupture of arteries as a result of physical trauma is common; spontaneous ruptures are not. The aortic lesions produced by *Spirocerca lupi* in dogs occasionally lead to rupture. *Rupture of a uterine artery* is a cause of fatal hemorrhage in aged mares at parturition and is associated with low serum copper levels. Mycotic ulceration of the internal carotid or maxillary artery in horses can lead to fatal guttural pouch hemorrhage.

Rupture of the aorta *is well known, but certainly uncommon, in the horse.* The ruptures occur during periods of excitement and activity, such as racing or in stallions while breeding, and are probably related to increased intra-aortic pressure. A predisposing aortic lesion has not been definitely identified, but fragmentation, degeneration, and mineralization of elastic fibers may contribute to weakening of the wall. "Cystic medial necrosis," the presence of pools of ground substance within the elastic media, has been suggested to be an underlying cause, but this change is present in the aortas of many normal horses. Intimal thickening and medial fibrosis of vasa vasora may predispose to aortic medial necrosis and rupture. Tears occur in the ascending aorta at any level from the aortic valvular ring to the level of the brachiocephalic trunk (Fig. 1.60), and range from 0.5 to 1 cm tears in the right coronary sinus to large transverse or three-cornered tears in the cranial wall of the aorta. Hemorrhage may occur into a number of different sites: *hemopericardium*, the most common sequel to aortic rupture, leads to sudden death; hemorrhage into, and disruption of, the atrioventricular node or bundle of His also leads to sudden death; dissection through the ventricular septum and into the right ventricle (*aortocardiac fistula*) causes progressive right heart failure; dissection of blood along the aortic wall may lead to formation of an *aneurysm*, which may in turn rupture.

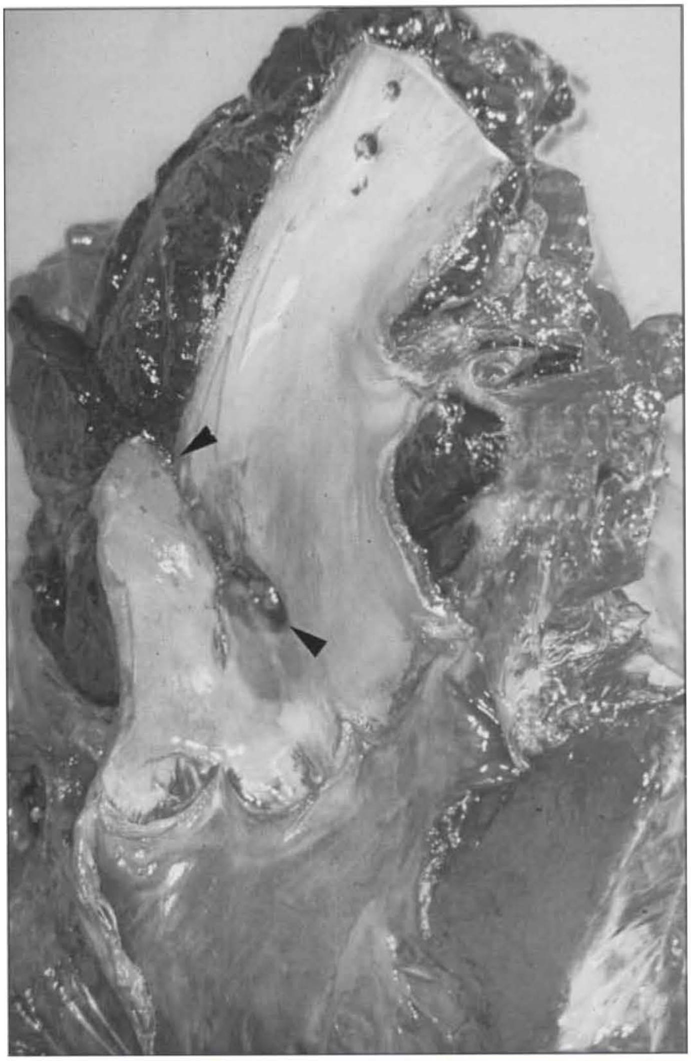

Figure 1.60 Rupture (between arrowheads) **of the ascending aorta** of a horse, which led to hemopericardium and fatal cardiac tamponade.

Spontaneous rupture of the *pulmonary artery* also occurs in horses, but is even less frequent than aortic rupture.

Rupture of the aorta, pulmonary artery, or coronary artery occurs experimentally, though not as a natural event, in *copper-deficient swine*, and has been extensively investigated because of similarities with *Marfan syndrome*, an inherited disorder in fibrillin metabolism in man and cattle in which dissecting aortic aneurysms occur. Degeneration of elastica appears to be the basis of the vascular lesions of copper deficiency, and is due to a deficiency of a copper-containing enzyme, lysyl oxidase, which is responsible for cross-linking of collagen and elastin. Similarly, feeding β-aminoproprionitrile to pigs, rats or turkeys causes dissecting aortic aneurysms and skeletal changes, an experimental model known as *lathyrism*, but is due to inhibition, rather than deficiency, of lysyl oxidase.

An **aneurysm** *is a localized abnormal dilation of any vessel.* Aneurysms are of most importance when they affect the aorta; they occur most commonly in humans as a complication of atherosclerosis, but are infrequent occurrences in domestic animals other than turkeys. On the basis of their gross appearance, aneurysms may be classified as *berry, saccular, fusiform, or dissecting.* In a **dissecting aneurysm**, blood enters the wall of an artery through an intimal tear, dissects between medial layers, and creates a cavity within the arterial wall. *Dissecting aortic aneurysm* (dissecting hematoma, or acute aortic dissection) is one manifestation of aortic rupture in horses, and may precede fatal aortic rupture. Dissecting aneurysms occur in the coronary and renal arteries of young, male, racing greyhounds, possibly as a result of arteriosclerosis and hemodynamic stresses, and can rupture fatally. Dissecting aneurysms may be of consequence by causing stenosis of the aortic lumen, as well as by rupturing. **True aneurysms** *are composed of all, or most, of the layers of the vessel wall.* Dilation of the cranial mesenteric artery may occur in the course of verminous arteritis in horses; the arterial wall is often greatly thickened, but the dilation could be termed an inflammatory rather than a true aneurysm. **False aneurysms** result from rupture of an artery or aneurysm and are essentially hematomas communicating with an arterial lumen; their walls are formed by the surrounding fibrous tissue.

Arterial thrombosis and embolism

The three major predispositions to thrombosis are:

1. *injury to endothelium*, e.g., via infectious, toxic, or immunologic mechanisms;
2. *altered blood flow*, as occurs with stasis or turbulence; and
3. *hypercoagulability* of the blood, which may result from increased concentrations of activated procoagulants, increased numbers or stickiness of platelets, or decreased concentrations of inhibitors such as antithrombin (see nephrotic syndrome).

The relative contribution of each of the above three features of Virchow's triad may vary. Endothelial injury, by itself, is the major cause of thrombosis, especially in the heart and arteries. Stasis must usually be combined with endothelial damage and/or hypercoagulability to induce thrombosis.

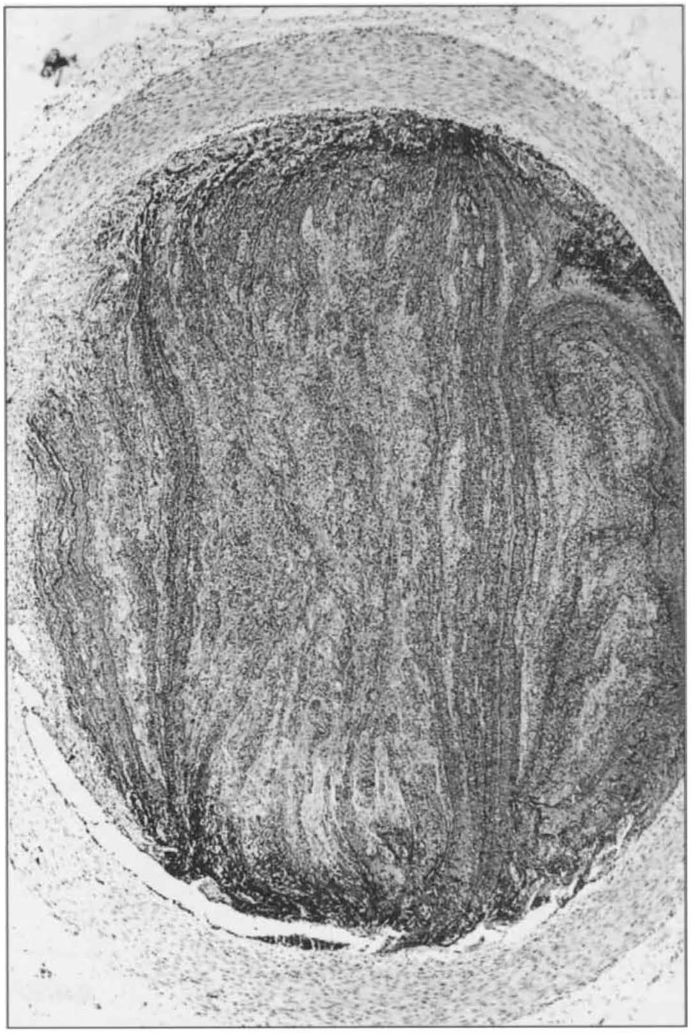

Figure 1.61 Laminations in an **arterial thrombus**, with organization from the intima and markedly reduced eccentric lumen, in aortic-iliac thrombosis in a calf.

Thrombi are of importance because they occlude the vessel at the site involved (Fig. 1.61), and because pieces of the thrombus break off giving rise to *emboli* that may occlude vessels distal to the site of thrombosis. Arterial occlusion is of significance in organs with an end-arterial blood supply, such as the kidney, because of the absence of collateral circulation and the development of infarction. Simultaneous occlusion of a large number of pulmonary arterioles or arteries by thrombi can lead to right heart failure (cor pulmonale) and death. Even in areas with extensive collateral circulation, the development of this circulation may be impaired by release of vasoactive substances such as serotonin and/or prostaglandins from the thrombus.

Specific causes and examples of thrombosis abound. As discussed below, thrombosis is a common complication of arteritis. Specific examples of thrombosis, namely aortic-iliac thrombosis in horses and disseminated intravascular coagulation, are discussed below.

Thromboembolism occurs in a variety of conditions. In verminous arteritis in horses, emboli arise from thrombi in the cranial mesenteric artery and cause intestinal ischemia, and possibly infarction. *Saddle thromboemboli of the aortic trifurcation in cats* arise from the dilated left atrium in cases of cardiomyopathy and cause posterior paresis of acute onset; *the clinical signs of aortic trifurcation obstruction, referred to as the five p's, are: pain, paresis, pulselessness, poikilothermy, and pallor.* Arterial thromboembolism occasionally occurs as a result of congenital cardiac defects and the formation of intracardiac thrombi. Emboli commonly arise from the cardiac valves in cases of vegetative bacterial endocarditis. Thrombi that develop in animals undergoing extended anesthesia can result in fatal pulmonary micro-thromboembolism, a common occurrence in humans, but a condition that is seldom recognized in domestic animals. *Pulmonary thromboembolism* may well complicate a variety of conditions, such as cardiac or renal disease, physical trauma, disseminated intravascular coagulation, hyperadrenocorticism, and neoplasia, but be underdiagnosed as a cause of morbidity.

Thrombosis is by far the most common antecedent to embolism, but *emboli other than thromboemboli occasionally occur.* Venous **air** embolism is a rare complication of pneumocystography, laparoscopy, or cryosurgery; an air trap develops in the right ventricle and may cause fatal blockage of circulation. **Foreign bodies**, such as pellets or bullets, may be embolic and occlude major vessels such as the aorta. Larval and adult **parasites**, such as strongyles and heartworms, may be embolic in the arterial system, especially if killed by therapy, and may cause arterial occlusion plus a granulomatous response. Emboli of **neoplastic** cells can result in distant metastases. **Fibrocartilaginous** embolism can result in necrotizing myelopathy in dogs, pigs, and humans. Fractures of bones, especially of those of the pelvis, and trauma of soft tissues can result in **fat** embolism; death may occur due to embolization of the central nervous system. Embolic fat may also originate from rupture of fat-laden hepatocytes.

Aortic-iliac thrombosis in horses

Aortic-iliac thrombosis causes *exercise intolerance and hind-leg lameness* (intermittent claudication) in affected horses. The condition is seen most frequently in racing Thoroughbreds and Standardbreds, especially young males. The oldest lesions are located at the aortic quadrifurcation and in the distal portions of the femoral and internal iliac arteries (Fig. 1.62), and consist of partially or completely occlusive masses of well-organized and well-vascularized fibrous tissue, occasionally containing hemorrhagic or degenerate areas (Fig. 1.63). Proximal to these organized masses, large unorganized thrombi are often present. The tunica intima is obliterated by the occlusive masses, except for the internal elastic lamina, which usually remains intact. The tunica media is largely unaffected, except for ischemic necrosis of the media in greatly distended arteries or under thick plaques. The pathogenesis of the lesions is unknown. The lesions may result from organization of strongyle-related thromboemboli, or from progressive enlargement and organization of spontaneously developing fibrous intimal plaques.

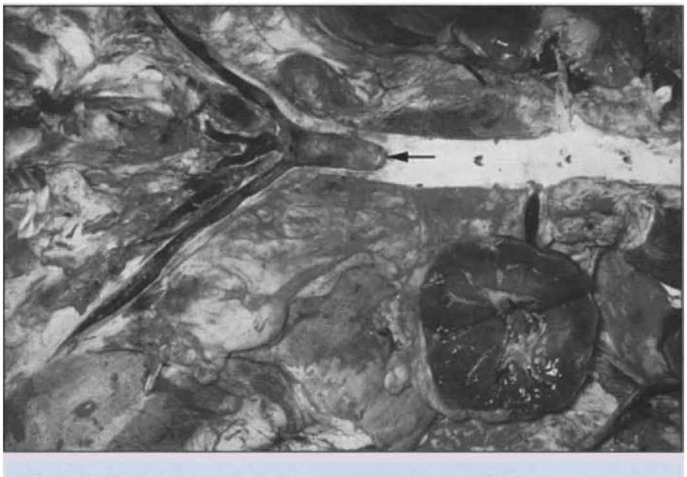

Figure 1.62 A large organized thrombus is present in the terminal aorta (arrow) and the internal and external iliac arteries in a horse with **aortic-iliac thrombosis**.

Disseminated intravascular coagulation

Disseminated intravascular coagulation (DIC) is a common and important intermediary mechanism of disease, but is not a disease in itself. It may be defined as a pathological activation of the coagulation system that leads to *generalized intravascular clotting* involving particularly arterioles and capillaries. The process may be *acute, subacute, or chronic*, and may be *localized or generalized*. Macrothrombosis does not usually develop in this disorder. The terms "consumption coagulopathy," "defibrination syndrome," and "consumptive thrombohemorrhagic disorder" are also used because of the massive consumption of coagulation factors which occurs and which may be sufficiently severe that a hemorrhagic diathesis results.

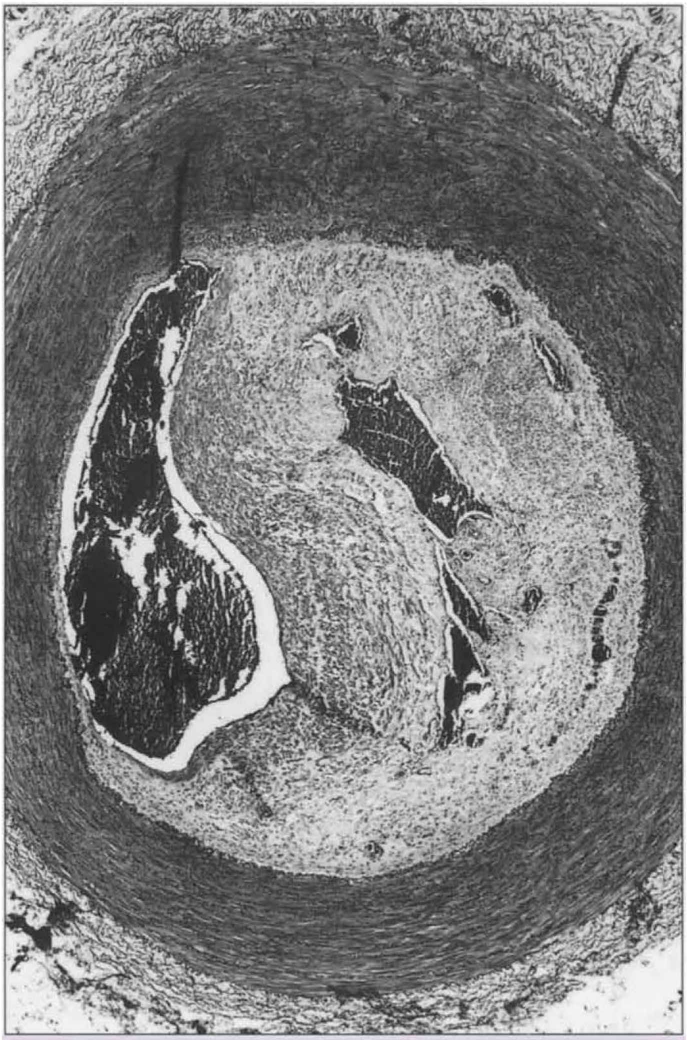

Figure 1.63 Aortic-iliac thrombosis in a horse. Lumen of artery is almost occluded by an organized, recanalized fibromuscular mass.

A wide array of agents and conditions will initiate coagulation (Table 1.7), basically either by causing *widespread endothelial damage* and thus exposing thrombogenic subendothelial collagen, or by directly *activating the coagulation cascade* via the intrinsic or extrinsic pathway. Exposure of monocytes, macrophages, and endothelial cells to disease agents or mediators will cause expression of tissue thromboplastin on the cell surfaces and activation of the extrinsic pathway of coagulation, and is likely a predominant pathway of DIC. As well as leading to expression of intravascular tissue factor, inflammation promotes coagulation by eliciting the expression of leukocyte adhesion molecules on intravascular cell surfaces, and by down-regulating the fibrinolytic and protein C anticoagulant pathways. Thrombin can in turn promote inflammatory responses, leading to further vascular injury. Stasis of blood flow and plasma hyperviscosity are other factors that may contribute to DIC.

Many of the agents listed in Table 1.7 may initiate DIC by more than one route. For example, gram-negative bacterial endotoxin can cause: endothelial damage (either directly or via mediators such as interleukin-1 and tumor necrosis factor), which exposes subendothelial collagen and leads to activation of platelets and Hageman factor; activation of the complement cascade and hence platelet activation; direct activation of Hageman factor and hence the intrinsic pathway; and leukocyte damage which results in thromboplastin

Table 1.7 Agents or conditions known to induce disseminated intravascular coagulation in animals

Bacteria	• Gram-negative (endotoxin) • Gram-positive
Helminths	• *Angiostrongylus vasorum* • *Dirofilaria immitis*
Protozoa	• *Babesia* spp. • *Sarcocystis* spp. • *Theileria* spp. • *Trypanosoma* spp.
Rickettsia	• *Rickettsia rickettsii* (Rocky Mountain spotted fever)
Viruses	• *African swine fever virus* • *Aleutian disease virus* of mink • *Bluetongue virus* • *Canine adenovirus 1* (infectious canine hepatitis) • *Classical swine fever virus* • *Epizootic hemorrhagic disease virus* of deer • *Feline infectious peritonitis virus*
Neoplasia	• Carcinoma • Hemangiosarcoma • Leukemia
Other	• Aflatoxicosis • Antigen–antibody complexes – incompatible blood transfusion • Gastric dilation-volvulus • Heat stroke • Hyperlipemia in ponies • Hyperosmolality • Immunologic endothelial injury • Ingestion of red maple leaves • Nephrotic syndrome • Proteolytic enzymes – pancreatitis, snakebite • Shock, vascular stasis, prolonged anesthesia, acidosis • Tissue necrosis – hepatic, pneumonia, postsurgery, burns

release. Viral infections are postulated to induce DIC by viral- or antiplatelet antibody-mediated platelet aggregation, by causing endothelial damage, and by causing Hageman factor activation by immune complexes. Also, in feline infectious peritonitis for example, hepatic necrosis impairs macrophage clearance of activated clotting factors and may potentiate the coagulation defect. Another important pathophysiologic event that accompanies activation of coagulation is activation of the kallikrein-kinin system; generation of kinins contributes to increased vascular permeability, hypotension, and shock.

When coagulation is initiated, activated Hageman factor simultaneously converts plasminogen to plasmin. Plasmin cleaves fibrinogen/fibrin to produce fibrinogen/fibrin degradation products that inhibit thrombin activity, fibrin polymerization, and platelet aggregation. A negative feedback system normally exists between thrombosis (coagulation) and fibrinolysis (anticoagulation) in which thrombin helps convert plasminogen to plasmin to cause fibrinolysis and hence limit thrombosis. In addition, a dynamic equilibrium exists between production of tissue plasminogen activator and production of plasminogen activator inhibitors by endothelial cells.

The clinical manifestations of DIC are protean and vary with the organ(s) in which thrombosis predominates and the severity of a hemorrhagic diathesis. Clinical presentations include shock, organ failure, hemorrhage, or hemolysis depending upon the relative activation of thrombin and plasmin and hence the dominance of thrombosis or hemorrhage. Hemorrhage is usually only seen in animals that survive acute episodes with thrombosis and shock, or in those reacting to a moderate procoagulatory stimulus. Perhaps the most common result of acute DIC is *shock*, which is due to reduced venous return to the right heart, plus systemic and pulmonary arterial hypertension due to thrombosis. Special examples of DIC include:

- the **generalized Shwartzman-like reaction** (GSR) (bilateral hemorrhagic renal cortical necrosis, induced experimentally by timed injections of endotoxin), which is seen as a cause of oliguric renal failure in septicemic or endotoxemic postpartum cows,
- **hemorrhagic adrenal necrosis** (Waterhouse–Friderichsen syndrome) seen in septicemic calves,
- **microangiopathic hemolytic anemia** (MHA) (an intravascular fragmentation anemia) seen in septicemic calves,
- **acrocyanosis and gangrene** seen in the extremities of calves recovering from septicemia,
- the **hemolytic-uremic syndrome** (HUS) in which coagulation is combined with microangiopathic hemolytic anemia and acute renal failure; a similar syndrome is seen in Greyhound dogs with idiopathic cutaneous and renal glomerular vasculopathy ("Alabama rot").

Animals that die with DIC may have petechial to ecchymotic hemorrhages on mucosae and serosae and in the skin, and may have variable thrombotic or hemorrhagic involvement of internal organs. Histologically, microthrombi may be associated with congestion, edema, hemorrhage, and necrosis. *Microthrombi are usually seen most easily in capillaries of brain, renal glomeruli, adrenals, lungs, and myocardium*, but may occur in any organ. They consist primarily of fibrin (*hyaline thrombi*), platelets (*granular thrombi*), or of fibrin degradation products (*hyaline globules or "shock bodies"*); pulmonary alveolar hyaline membranes are also said to be a form of hyaline microthrombi. Because fibrinolysis is an ongoing process that continues after death, *most microthrombi are lysed within three hours of death* and may not be found if postmortem examination is delayed. With routine hematoxylin and eosin staining, microthrombi appear as homogeneous pink masses in dilated small blood vessels. Identification of microthrombi is aided by the use of special stains such as Martius-scarlet-blue, which stains fibrin red, or phosphotungstic acid hematoxylin, which stains fibrin purple. Even with special stains, incompletely polymerized fibrin is difficult to demonstrate. Red cells that impinge on fibrin strands in the microcirculation may fragment; these red cell fragments (*schistocytes*) may be detected within blood vessels in histologic sections and may thus serve as indicators of DIC.

Arterial hypertrophy

Hypertrophy of arteries may affect one or all components of the arterial wall. *High-altitude disease of cattle*, described below, is a result of hypoxia-induced pulmonary arterial constriction and hypertrophy that lead to pulmonary hypertension and eventual right heart failure (cor pulmonale). *Various cardiac anomalies* cause pulmonary arterial hypertension and hyperperfusion, which result in pulmonary arterial hypertrophy and additional pulmonary hypertension (see below). Arterial hypertrophy occurs in *collateral vessels* in response to the extra load they carry after occlusion of the artery that usually supplies an area. A specific form of hypertrophy occurs in the *pulmonary arteries of cats* and is described below. Systemic arterial involvement in the hypertension associated with chronic renal disease is described above.

"High-altitude disease" of cattle

This disease is caused by pulmonary hypertension that results in dilation and hypertrophy of the right ventricle with the ultimate development of cardiac decompensation and congestive cardiac failure. Edematous swelling of the venter, as is typical of congestive heart failure in cattle, is responsible for the synonym "*brisket disease*." The syndrome in cattle resembles in many respects the chronic mountain sickness of humans resident at high altitude, and represents failure of the cardiorespiratory system to adjust to the hypoxia of higher altitudes. There are species differences in the hypertensive response to hypoxia; sheep and dogs are hypo-responders, humans are intermediate, whereas cattle and pigs are hyper-responders and are prone to develop hypertensive heart failure at altitudes of about 2500 meters and above. There are also variations within species, and some cattle react dramatically to degrees of hypoxia that only mildly inconvenience others. Young cattle are more susceptible than adults, and the morbidity rate is highest in animals exposed to high altitudes for the first time. In animals imported from low altitudes to about 3500 meters, the incidence of severe pulmonary hypertension approaches 50%, whereas in herds maintained at such altitudes for many generations, high altitude disease may not affect more than 2%. The different morbidity rates are probably attributable to natural selection in the resident population.

Cattle exposed to critical altitudes, or experimentally to comparable degrees of hypoxic stimulation, develop a several-fold increase in pulmonary arterial pressure and pulmonary vascular resistance that may gradually be reduced to near normotensive levels when the animals are returned to low altitudes. A distinctive feature of the pulmonary vasculature in cattle is the inherently well-developed muscular media of the arteries and veins with diameters as small as 20 μm, which implies an unusual potential for vasomotor activity. *Hypoxia-induced vasoconstriction leads to work hypertrophy of the muscular media of pulmonary arteries and arterioles, and hence hypertension*, and may be compounded by reaction hypertrophy that occurs in response to increased arterial pressure. In cattle affected with high-altitude disease, there is uniformly prominent hypertrophy of the muscular media of pulmonary arteries and arterioles, and usually adventitial proliferation around pulmonary arteries of all sizes. The hypertension may also cause endothelial damage, thrombosis, intimal proliferation, and medial mineralization, especially in elastic pulmonary arteries.

Cardiac anomalies and pulmonary arterial hypertension

Increased pulmonary arterial pressure (*hypertension*) and increased blood flow (*hyperperfusion*) occur with certain cardiac anomalies in which there is left-to-right shunting of blood, such as a large ventricular septal defect or patent ductus arteriosus. Pulmonary arterial hypertension, which may even lead to reversal of the shunt and cyanosis (*Eisenmenger's syndrome*), produces pulmonary arterial constriction and hypertrophy, increased pulmonary vascular resistance, and sustained pulmonary hypertension by means of a number of arterial responses. These responses range from persistence of the

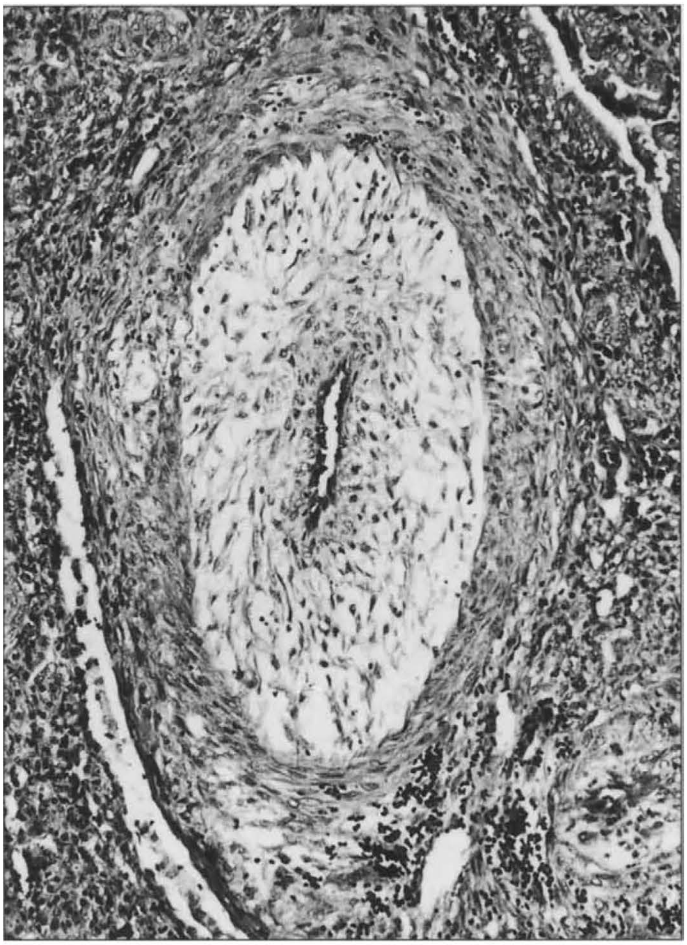

Figure 1.64 Idiopathic **intimal hyperplasia** in blood vessel in the lung of a kitten.

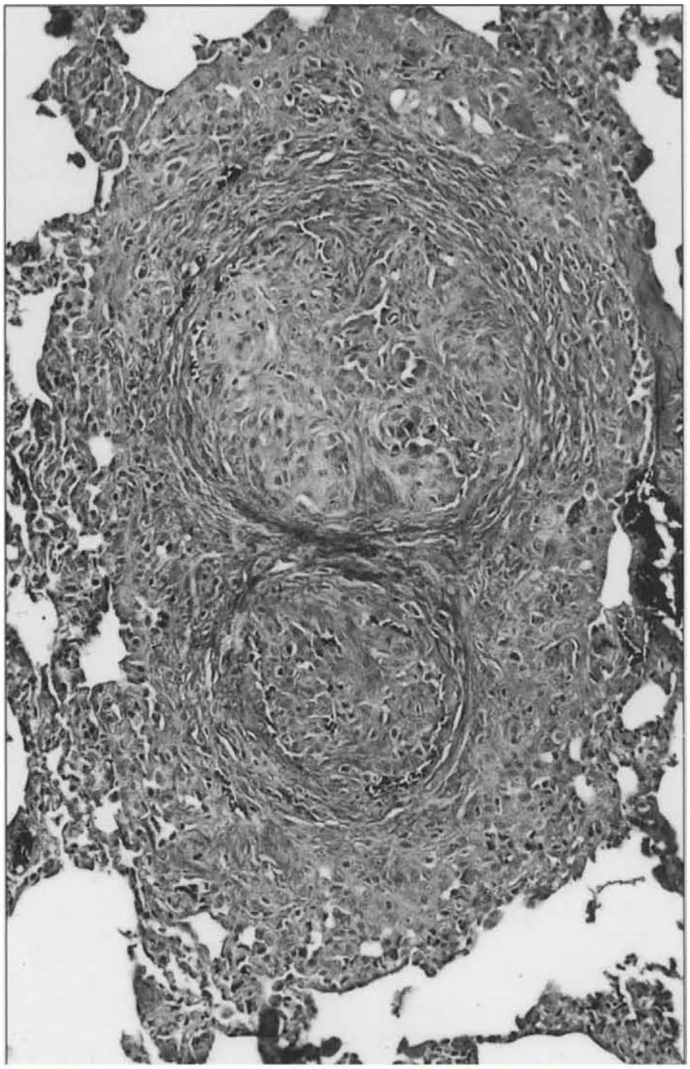

Figure 1.65 **Pulmonary arterial hypertension** in dog with a cardiac anomaly. Two pulmonary arteries with intimal fibromuscular hyperplasia, medial and adventitial hyperplasia. (Courtesy of JS Nimmo-Wilkie.)

normal thick muscular wall configuration of fetal life, to lesions that are the acquired response to hypertension (Fig. 1.64). *These acquired lesions include prominent medial hypertrophy, intimal proliferations that may be obliterative, disruption of elastic laminae, adventitial fibrosis, and plexiform lesions* (vascular occlusion by myointimal proliferations containing irregular vascular channels). These changes may be mediated by increased expression of various mediators, such as matrix metalloproteinases and endothelin-1. In the early, cellular phase of the lesion, migration of medial smooth muscle cells through the internal elastic lamina and into the intima, possibly in response to a chemical attractant such as endothelial cell-derived growth factor, is followed by their conversion to myofibroblasts and production of ground substance, collagen, and elastin, which produces marked intimal thickening (Fig. 1.65). Aged mature lesions become less cellular, myofibroblasts revert to smooth muscle cells, and thin elastotic septa separate wide vascular channels; these channels may be thrombosed. As the pulmonary vascular lesions progress, the arteries may dilate and their walls undergo fibrinoid degeneration. Together these lesions constitute "**plexogenic pulmonary arteriopathy**," which in its more severe manifestations is an end-stage irreversible arterial condition that is associated with a poor prognosis, even if the underlying cardiac anomaly can be corrected surgically.

Medial hypertrophy of the pulmonary arteries of cats

Pulmonary medial hypertrophy and hyperplasia commonly occur in cats, but are of no clinical significance even when very severe and generalized. The change is seen with equal frequency in germ-free and conventional cats, displays no age, sex, or breed predilection, and appears to be *normal anatomic variation* in cats. The cat lungworm, *Aelurostrongylus abstrusus*, has been suggested as an etiologic agent, but while the parasite may produce similar lesions, it is not necessary for the development of the lesion. Pulmonary hypertension does not result from the vascular change, right ventricular pressure does not increase, nor does the right ventricle hypertrophy. The most severely affected vessels may be grossly visible on the cut surface of the lung and through the pleura when the lungs are collapsed, and are even palpable in some cases. The histologic spectrum of arterial changes ranges from mild sporadic or generalized hypertrophy of the tunica media, to marked medial hypertrophy and hyperplasia with concomitant intimal proliferation and severe luminal encroachment. Thrombosis has not been observed, but adhesion of endothelial surfaces across the lumen does occur providing sinuous channels and an appearance similar to that of an organized, recanalized thrombus. Frequently, the arterial hypertrophy is accompanied by fibromuscular hyperplasia in the pulmonary parenchyma and around alveolar ducts.

Vasculitis

Vasculitis, or inflammation of a vessel, is characterized by the presence of inflammatory cells within and around the blood vessel wall with concomitant vessel wall damage as indicated by fibrin deposition, collagen degeneration, and necrosis of endothelial and smooth muscle cells. The fibrillary, homogeneous, or granular eosinophilic material observed by light microscopy and referred to as "**fibrinoid**" consists of fibrin, immunoglobulins, complement, and platelets; degenerate collagen and smooth muscle also contribute to increased eosinophilia of the vascular wall. Thrombosis may occur because of endothelial injury and initiation of coagulation. The above changes in the blood vessel wall distinguish vasculitis from perivascular infiltration with inflammatory cells. Neutrophils, lymphocytes, or macrophages may predominate in vasculitis, and the predominant cell type may be used to classify the vasculitis. Neutrophilic vasculitis may be further subdivided into **leukocytoclastic**, in which fragmented neutrophil nuclei or "nuclear dust" are present, and **nonleukocytoclastic**, in which there is little nuclear dust. The predominant cell type may vary over the course of the vasculitis, as the condition becomes chronic or resolves.

Vasculitis is an important component of a wide variety of inflammatory diseases, both **infectious** and **noninfectious** (Table 1.8), although its origin remains idiopathic in many cases. Vascular degeneration that lacks a significant inflammatory cell component occurs in a number of toxic and metabolic conditions, such as mercury poisoning and mulberry heart disease, and has been excluded from the classification. The terms *vasculitis* and *angiitis* are used interchangeably

    - Purpura hemorrhagica
    - Rheumatoid arthritis
    - Rabies vaccine reaction
    - Staphylococcal hypersensitivity
    - Systemic lupus erythematosus
- Nonimmune-mediated
    - Drug reaction, e.g., itraconazole, ivermectin, trimethoprim-sulfadiazine/sulfamethoxazole
    - Uremia

and may be used in preference to the more specific term *arteritis*, because arteries, capillaries, and veins may be involved simultaneously in some conditions. Also, the wall of the vessel may be obscured or obliterated by inflammatory changes, precluding definitive classification. The consequences of vasculitis depend upon the size, numbers, and types of vessels affected, and upon the degree of obstruction caused, as noted under thrombosis. We will discuss vasculitis in general and specific forms of arteritis in this section; *phlebitis* and *lymphangitis* are discussed with Veins and Lymphatics, respectively.

Vasculitides may be *classified* according to the size of the blood vessels involved (large, medium, small), the histologic characteristics of the lesion, or clinical effects. However, many cases overlap in their morphologic and clinical manifestations, and are simply termed "*systemic necrotizing vasculitis*." Improvement in the classification of necrotizing vasculitides will require further characterization of causes and of the spectrum of immune-mediated changes in vessels. Until such time, the use of accurate morphological descriptions of vascular lesions is preferable to placing vasculitides, especially those of known cause, in such ill-defined categories as "polyarteritis nodosa." The wide range of lesions observed probably reflects the variety of antigens or other agents involved, the intensity and chronicity of antigenic exposure, the relative contributions of immune-complex versus delayed-hypersensitivity reactions, the genetic variation among individuals, and the stage of development at which the lesion is observed.

Vasculitis may be of considerable significance in the pathogenesis of a condition, usually because of the occurrence of thrombosis, ischemia, and infarction (Fig. 1.66). As well as having local effects due to thrombosis and infarction, arteritis may affect distant organs, as occurs when obliterative pulmonary endoarteritis leads to congestive heart failure in dogs infected with *Dirofilaria immitis*. (The term *endo*arteritis is used in preference to *end*arteritis to avoid implying that end-arteries are primarily affected.) Arteritis of *hematogenous origin* occurs in the course of septicemias and bacterial endocarditis. The primary injury may be to the endothelium and intima or it may, when the organisms localize in the vasa vasorum, affect first the adventitia and outer lamellae. The arteritis in pigs with septicemic salmonellosis, erysipelas, or classical swine fever is conspicuously expressed as erythematous areas of purple discoloration on the ears, perineum, snout, and venter, which, if the animal survives, may become necrotic and slough. Lesions with this basis may also occur in other organs, and indeed are often seen as infarcts in the spleen in erysipelas and classical swine fever. In affected portions of vessels, the endothelium swells and proliferates, and vessel walls undergo acute fibrinoid necrosis. The formation of thrombi in these areas in turn gives rise to infarcts and necrosis. Vasculitis arising by *extension of inflammation and infection from adjacent tissues* may occur, especially if the original inflammatory process is suppurative or necrotizing. It is encountered most often in bacterial pneumonias, adjacent to abscesses, in purulent meningitis, in local lesions of aspergillosis and mucormycosis, and in acute metritis especially if complicated by necrobacillosis. Fungi of the family *Mucorales* have a distinct affinity for arteries and produce necrotizing, thrombotic arteritis.

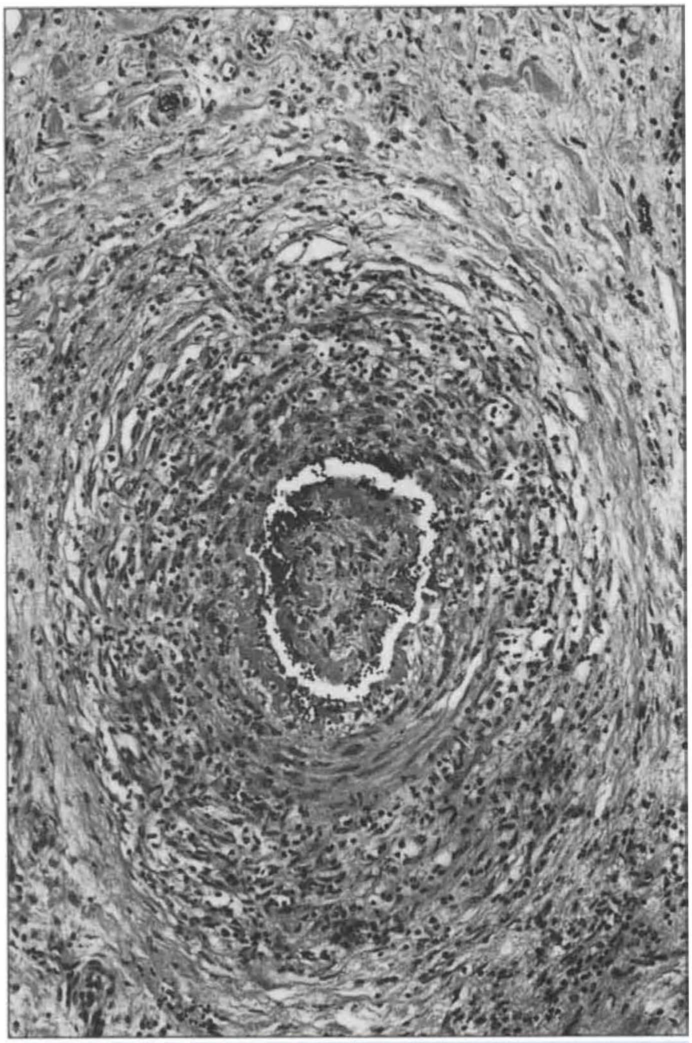

Figure 1.66 Panarteritis and thrombosis in the kidney of a pig.

Vasculitis may develop from within the vessel as a result of *endothelial injury* by infectious agents and/or immune reactions. Endothelial damage and exposure of subendothelial collagen leads to activation of Hageman factor, and hence activation of complement, kinin, and plasmin systems, and to increased vascular permeability and inflammation. Infectious agents may cause endothelial damage either directly or through the actions of various toxic products, such as endotoxins of gram-negative bacteria, or exotoxins of bacteria such as *Corynebacterium pseudotuberculosis*. *Mannheimia (Pasteurella) haemolytica* endotoxin (lipopolysaccharide, LPS) can directly damage endothelial cells; such damage may be reduced or increased by the activity of neutrophils, depending on the concentration of LPS present. The mechanism of LPS-mediated damage may involve prostaglandins or production of oxygen radicals by endothelial cells. In the absence of LPS, *M. haemolytica* leukotoxin may contribute to endothelial damage. In the case of *Actinobacillus pleuropneumoniae*, rather than endotoxin causing endothelial damage, cytotoxicity is apparently caused by a 104 kD hemolysin. *Histophilus somni* lipooligosaccharide has been shown to cause cytotoxicity and apoptosis of bovine endothelial cells through the generation of reactive oxygen and nitrogen intermediates. Many viruses are endotheliotropic, for example, the viruses of equine arteritis, infectious canine hepatitis, canine distemper, African swine fever, and classical swine fever (Table 1.8).

Immune reactions appear to be less important primary causes of vasculitis in domestic animals than in man, but they may contribute to vasculitis caused by an infectious agent, as occurs in malignant catarrhal fever. *Type III hypersensitivity reactions*, or Arthus reactions, cause necrotizing vasculitis by the deposition of immune complexes in vessel walls, usually in association with the endothelial basement membrane. The complexes fix complement, and complement fragments attract neutrophils that release lysosomal enzymes and oxygen radicals (superoxide anion, hydrogen peroxide, hydroxyl radical, hypochlorous acid) in the process of phagocytosing immune complexes, and hence cause necrosis. As the Arthus reaction matures, neutrophils diminish and mononuclear cells, including plasma cells, predominate. The morphology of immune-complex-mediated vasculitis can be modified by the relative concentrations of immune reactants or secondary mediators; increases in antibody or complement concentrations can change an Arthus-like reaction to a Shwartzman-like reaction. Immune complexes can be found in vessel walls in a variety of conditions, including systemic lupus erythematosus, Aleutian disease of mink, and feline infectious peritonitis. However, even though immunoglobulins or immune complexes are found in the walls of affected vessels, this is not definitive proof that the immune reaction caused the vasculitis. Conversely, the absence of immune complexes from a vessel wall lesion does not rule out immune-complex vasculitis, because immune reactants can disappear rapidly. The underlying lesion in *porcine dermatitis and nephropathy syndrome* (PDNS) is necrotizing systemic vasculitis, which has a predilection for skin and kidney, and is thought to have an immune-complex origin; *Porcine circovirus 2* antibody titers were excessively high in PDNS pigs in a case-control study.

Cell-mediated type IV, or delayed hypersensitivity, reactions may be involved in some types of vasculitis in which there is lymphocytic predominance, such as the arteritis of malignant catarrhal fever and of Border disease. In malignant catarrhal fever, the vasculitis is characterized by accumulations of principally lymphocytes and fewer macrophages in the adventitia and intima of affected small and medium arteries and veins of the alimentary tract, eye, kidney, liver, lung, and brain; neutrophils and plasma cells are rare. Lymphocytes may later invade the media, though adventitial infiltration continues to predominate, and there may be medial myocyte necrosis with variable amounts of fibrinoid degeneration and endothelial hyperplasia; thrombosis may be seen in advanced cases. There is a possibility of, but little direct evidence for, direct viral cytolysis in malignant catarrhal fever.

Vasculitis in humans has been associated with a variety of **drugs** (see *hypersensitivity vasculitis* on p. 72). Hypersensitivities to itraconazole, ivermectin, allergy immunotherapy (hyposensitization) injections, and ibuprofen have been reported in dogs.

Genetic predisposition to vasculitis occurs in a number of dog breeds, e.g., Beagle ("Beagle pain syndrome"), Greyhound ("Alabama rot"), Chinese Shar-Pei ("Shar-Pei fever"), German Shepherd, Bernese Mountain Dog. Vasculitis may be precipitated by vaccination or infection.

Arteritis may be found as an *incidental "background" lesion* in clinically normal animals. For example, mild idiopathic arteritis and intimal thickening occurs in extramural coronary arteries in 5–10% of young Beagle and mongrel dogs, which can complicate the interpretation of lesions in dogs used in arterial toxicity studies. A more severe, febrile syndrome, variously named *Beagle pain syndrome*, *canine juvenile polyarteritis syndrome*, or *idiopathic canine polyarteritis*, occurs in Beagles and other breeds. In this syndrome, necrotizing arteritis affects the coronary, mediastinal and cervical spinal arteries, resulting in thrombosis, infarction, and hemorrhage as well as progressive atrophy of temporal and cervical muscles; amyloidosis occurs in some chronically affected dogs. The syndrome appears to be immune mediated; some affected dogs have antineutrophil cytoplasmic antibodies (ANCA) and other immunologic irregularities similar to Kawasaki disease in humans.

An idiopathic vasculopathy occurs in kenneled and racing *Greyhound dogs*, involving skin and occasionally kidneys. Deep, slowly healing cutaneous ulcers occur as the result of fibrinoid arteritis, thrombosis, and hemorrhagic infarction. Renal lesions include acute necrosis of glomeruli and of afferent arterioles, glomerular capillary thrombosis, and acute tubular necrosis. The pathogenesis of the condition is thought to involve a genetic predisposition to an unidentified infectious agent.

Polyarteritis nodosa (panarteritis, or periarteritis nodosa)

The term "polyarteritis nodosa" has been applied to a *heterogeneous group of arteritides*, which occur sporadically in all species of domestic animals, on the basis of similarities with *classic polyarteritis nodosa in humans, in which small and medium-sized arteries undergo severe necrotizing inflammation, often in a sharply segmental (nodose) pattern*, and with a predilection for branching points. As all layers of the arterial wall are involved, the lesion is also referred to as "*panarteritis*." Arterioles, capillaries, and venules are not involved, and glomerulonephritis is not present.

The only agent thus far associated with the condition in man is hepatitis B antigen, which is found in 25–40% of individuals with necrotizing vasculitis; high mortality occurred in the human disease before the advent of corticosteroid therapy. Polyarteritis nodosa has been reported in dogs having rheumatoid arthritis and systemic lupus erythematosus; separation of the vasculitis component from disease syndromes is of problematic value. Also, as noted above under *vasculitis*, a more appropriate term for idiopathic vasculitides is probably **systemic necrotizing vasculitis** rather than polyarteritis nodosa, which has tended to become a catchall term.

A wide variety of clinical and pathologic manifestations occur in polyarteritis nodosa as described in man and domestic animals. Although occasionally associated with the death of an animal, lesions are also noted in otherwise normal animals at slaughter. Renal, coronary, hepatic, and gastrointestinal vessels are perhaps most commonly involved (Fig. 1.67A, B). *Arterial lesions at all stages of development, namely acute, healing, and healed, may occur simultaneously in one individual and even within the same vessel.*

The acute lesions are often typical of immune-complex-induced arteritis, and inflammation and necrosis of the arterial wall may be segmental or circumferential. Thrombosis may occur and lead to infarction and hemorrhage. As the reaction progresses, neutrophils are replaced in the media by mononuclear cells, and fibroplasia may result in grossly visible fibrous thickening of the wall. The vascular lumen may be obliterated by organization of a thrombus plus intimal proliferation. The term "*periarteritis*" has been used in the past to describe a stage in the vascular reaction in which mononuclear cells surround the vessel, but the term is now little used.

Microscopic polyangiitis (*hypersensitivity vasculitis, microscopic polyarteritis, leukocytoclastic vasculitis*) affects smaller vessels in humans, namely *arterioles, capillaries, and venules* in skin, mucous membranes, lungs, brain, heart, gastrointestinal tract, kidneys, and muscle. Suspected causes include many common drugs, e.g., penicillin; microbes, e.g., streptococci; heterologous proteins; and tumor antigens. The reaction often occurs 7–10 days after exposure to the stimulus; remission usually follows removal of the agent. Lesions typical of leukocytoclastic vasculitis are seen. Since larger arteries are spared, macroscopic infarcts are uncommon. Hypersensitivity vasculitis appears to be the basis of some cases of *hemorrhagic purpura in horses*; other causes of subcutaneous edema and mucosal hemorrhages, such as equine viral arteritis, equine infectious anemia, and equine ehrlichiosis, must also be considered. Trimethoprim-sulfadiazine and trimethoprim-sulfamethoxazole have caused *hypersensitivity vasculitis in dogs*.

Viral vasculitides

Equine viral arteritis

This disease is caused by ***Equine arteritis virus*** (EAV), an RNA virus of the family Arteriviridae, genus *Arterivirus*, which is pathogenic only for horses and is cytopathic in equine kidney culture. Although serologic surveys indicate that infection with EAV is common in North America and Europe, *clinical disease is uncommon*. Most strains of EAV are avirulent, and mortality is rare in natural outbreaks. Long-lasting immunity follows recovery. Transmission of virus occurs primarily by *respiratory and venereal routes* during the acute phase of infection; venereally infected mares can infect nonimmune mares by aerosol transmission. Long-term carrier stallions play an important role in perpetuation and dissemination of the virus; a carrier state has not been demonstrated in mares or foals.

The **clinical disease** is characterized by: fever; variable anorexia and depression; leukopenia; edema of the ventral body wall and limbs, especially the hindlimbs; skin rash, most commonly on the neck; serous, later mucopurulent, oculonasal discharge with rhinitis and conjunctivitis; and periorbital/supraorbital edema. Dyspnea, coughing, ataxia, and diarrhea are less frequent. Pregnant mares often *abort* during or shortly after the febrile period, probably due to myometritis and decreased progesterone production by a hypoxic placenta. Specific lesions are present occasionally in aborted fetuses, and include necrotizing vasculitis, especially of the placenta, and inflammatory foci in various organs. Newborn foals may succumb to interstitial pneumonia.

The virus is pathogenic to endothelial cells and causes ***panvasculitis****, that is, inflammation of veins, lymphatics, and arteries.* Following initial replication of the virus in macrophages, endothelial cells are invaded beginning three days after experimental aerosol infection. As inflammation progresses and neutrophils damage the internal elastic lamina, medial cells are invaded. The most severe edema occurs at days 6 and 7 when phlebitis, lymphangitis, and capillary damage are most pronounced. Arterial necrosis peaks at day 10, when edema has largely disappeared. The vascular lesions will resolve if the horse survives. Antibody appears to play little role in the pathogenesis of the disease, in contrast to the immune-complex component of some other viral vasculitides.

The **gross lesions** of the disease, in addition to the changes observed clinically, consist principally of hemorrhages and edema. Petechial hemorrhages are found on all serous membranes, in the substance of the lungs and the gastric mucosa. Larger hemorrhages may be present in the adrenals. There is excessive fluid which contains much protein and some strands of fibrin in all serous cavities. As much as 10 L may be present in the pleural and peritoneal cavities. The connective tissues and mesenteries of the body cavities are saturated with edema fluid and the wall of the gut may be thickened by edema. Enteritis, hemorrhagic or diphtheritic in character and usually more severe in the large than in the small intestine, is regularly present. The lungs are more-or-less severely edematous.

Characteristic **microscopic lesions** occur focally or segmentally in the media of small muscular arteries (Fig. 1.68). The muscle cells undergo necrosis and are replaced by hyaline or fibrinoid material. There is edema of the wall and adventitia and infiltration of leukocytes, chiefly lymphocytes, the nuclei of which undergo fragmentation with necrosis. The endothelium and intima may have been repaired so that thrombosis is unusual; thrombosis may however occur in the intestine and lungs. *The arterial lesions occur in many organs but are perhaps most consistently present in the gut and adrenals.* Infarction is most common in the intestines, particularly in the cecum and colon. Massive necrosis of lymph nodes also occurs. Extensive necrosis of the adrenals may result from direct viral injury and infarction.

Diagnosis is made through detection of seroconversion (serum neutralization, ELISA), or identification of the virus (virus isolation, polymerase chain reaction, immunohistochemistry) in the presence of compatible lesions. *Differential diagnoses* for EVA include diseases caused by other viruses (*Equid herpesvirus 1, Equine adenovirus, Influenza A virus, Equine infectious anemia virus, African horse sickness virus, Hendra virus, Getah virus*), plus purpura hemorrhagica, septic shock, and poisoning by the toxic plant hoary alyssum (*Berteroa incana*).

African horse sickness

African horse sickness (AHS) is a vector-borne disease of solipeds, and occasionally of dogs and camels, caused by ***African horse sickness virus*** (AHSV), family Reoviridae, genus *Orbivirus*, that is closely related to bluetongue virus. The disease is endemic in sub-Saharan Africa, from where it spreads to southern Africa and occasionally northern Africa. It has also extended on occasion through the Middle East as far as India, and apparently with climate change, the vector has become established in southern Europe. *Its importance lies in the extreme lethal potential of the infection in susceptible horses and the very wide distribution of the competent insect vectors.*

The vectors of AHSV are primarily *Culicoides* biting midges, particularly *Culicoides imicola*. Transmission by mosquitoes or ticks is of minor importance. The AHSV requires an ambient temperature of ≥15°C to replicate and be transmitted by *Culicoides*. Historically, in enzootic areas south of the Sahara, outbreaks of disease occurred in seasons when nocturnal biting insects were active, outbreaks subsiding shortly after the first frosts. It is possible that, in climatically suitable areas, transmission might occur throughout the year. Annual recrudescence poses the question of reservoirs for over-winter persistence; the natural reservoir remains unknown, although the zebra is most likely. Even in districts where AHS occurs annually, the distribution tends to be limited to low-lying areas such as valleys, swamps, and areas of summer rain.

Horse sickness is primarily a disease of the horse and its close relatives, but a wide range of species is susceptible to the virus experimentally, including goats, guinea pigs, mice, ferrets, and rats. The horse is the most susceptible to infection and to illness; the mortality rate in susceptible populations of horses may be as high as 95%. The mortality rate in mules (about 80%) is less than that in horses but greater than that in the Egyptian donkey. The South African donkey and the zebra are resistant. The role of dogs, and other scavenging carnivores, in the disease cycle is not known. The disease is not contagious by contact, but dogs may acquire it from eating infected horseflesh. Infection detected by viral isolation or serologically can be common in dogs in some circumstances, but vector transmission from dogs is unlikely.

In many parts of Africa, the use of the horse, mule, and donkey is dependent on the control of AHS, but this control has been difficult to attain. The primary obstacle has been the multiplicity of antigenic types of AHSV. There are at present *nine major antigenic types*. These types have a basic antigenic relationship which may be demonstrated in the horse, but the relationship is not sufficiently close to provide solid immunity amongst types. Indeed, although all strains investigated can be fitted into one of the major types, the antigenic diversity of strains within a single type is such that very few strains are identical. This is certainly the situation in enzootic areas where a large number of different strains may be isolated during an outbreak. On the other hand, there has been close antigenic relationship between the viruses recovered during the epizootic outbreaks that occurred outside the reservoir-host range where the transmission was from horse to horse. This suggests that, although the AHSV is extremely mutable, mutations do not readily occur when the disease is transmitted from horse to horse. Recovered horses are immune to homologous challenge, and possess some immunity to heterologous challenge.

Four clinical forms of AHS are described: *pulmonary (peracute), mixed (acute), cardiac (subacute), and AHS fever (mild) forms*, from most to least severe. Most cases are of the mixed form, perhaps reflecting variations in the susceptibility of the host, the virulence of the virus, or the tropism of virus for different parts of the vascular system.

The **peracute or pulmonary form of the disease** – the most common form in epizootics – has an incubation period of 3–5 days. Fever occurs suddenly and is of short duration followed by the acute onset of respiratory distress. Death may occur in a few hours from *pulmonary edema*, and frothy fluid fills the respiratory tract and may flow from the nostrils.

The **subacute or cardiac form** is usually associated with infections that are not fully virulent or are encountered in animals in which infection by heterologous strains has stimulated some immunity. The incubation period is 7–14 days with clinical signs of fever lasting 3–6 days. As the fever subsides, edematous swellings appear in the temporal or supraorbital fossae and the eyelids. The swellings extend to the lips, cheeks, tongue, intermandibular space, and throat. Swelling from subcutaneous fluid may affect the upper neck and sometimes the chest and shoulders. Terminally, petechial hemorrhages usually occur on the conjunctiva and ventral surface of the tongue. The mortality rate may be as high as 50%, and is attributed to *cardiac failure and pulmonary edema*.

As observed above, many cases are **mixtures of the pulmonary and cardiac form**. Initial pulmonary signs of relatively mild degree may be followed by characteristic swelling of the head and death from cardiac failure, or the cardiac form may be followed by sudden onset of dyspnea and pulmonary edema.

The mild clinical form of the disease, **AHS fever**, may not be noticed in outbreaks. It is characterized by remittent fever lasting for a week or so. This is the form of the disease to be expected in animals with immunity to heterologous strains and in resistant species such as donkey and zebra. The mortality rate is about 70%.

The **pathogenesis** of the signs and lesions is related to sites of viral replication. Virus is found early and develops to highest titer in spleen, lymph nodes, lung, and the large intestine; the titer in myocardium is low. Viral infection causes degeneration and loss of endothelium in myocardial and pulmonary capillaries, with resulting increased vascular permeability, edema, hemorrhage, and microthrombosis. Vascular permeability of pulmonary capillaries may be increased through the action of inflammatory mediators released by activated intravascular macrophages. *Myocardial lesions* are seen microscopically in the cardiac form of the disease and are less severe in the pulmonary form. These consist of hemorrhage, edema, and focal myocardial necrosis (of hypoxic origin) with inflammatory infiltrates and slight proliferation of connective tissue.

The **gross lesions** observed at autopsy depend largely on the clinical form of disease. In the *pulmonary form*, the most characteristic changes are edema of the lungs and hydrothorax. In very acute cases, alveolar edema and mottled hyperemia of the lungs are seen, whereas in cases with a somewhat more protracted course extensive interstitial and subpleural edema are also present, but hyperemia is less evident. There may be diffuse alveolitis in some animals (Fig. 1.69A, B). Other lesions commonly observed are periaortic and peritracheal edematous infiltration, diffuse or patchy hyperemia of the glandular fundus of the stomach, hyperemia and petechial hemorrhages in the mucosa and serosa of the small and large intestines, subcapsular hemorrhages in the spleen, and congestion of the renal cortex. All the lymph nodes are enlarged and edematous, especially those in the thoracic and abdominal cavities. The pericardial sac may contain variable amounts of fluid, and numerous petechial hemorrhages occur in the pericardium. Cardiac lesions are usually not conspicuous, but epicardial and endocardial petechial hemorrhages may sometimes be evident.

In the *cardiac form*, the most characteristic lesions are the edematous infiltration of the subcutaneous, subfascial, subserous and intermuscular tissues. Only the head and neck may be involved, but in more severe cases the edema also involves lower parts of the neck, brisket, and shoulders. *Hydropericardium* is a constant finding, the pericardial sac often containing 2 L or more of fluid. The epicardium and endocardium show numerous, almost confluent ecchymotic hemorrhages. These are particularly conspicuous along the course of the coronary vessels, beneath the bicuspid and tricuspid valves, and in the papillary muscles adjacent to the insertions of the chordae tendineae. The lungs are usually normal or only slightly engorged and the thoracic cavity rarely contains an excess of fluid. The lesions in the gastrointestinal tract are generally similar to those found in the pulmonary form, except that submucosal edema tends to be far more pronounced. Ascites is unusual.

In the *mixed form*, the lesions are a combination of those observed in the pulmonary and cardiac forms. In fact, *most of the fatal cases of AHS can be considered to be of the mixed form*, with lesions typical of either the pulmonary or the cardiac form predominating.

The infective dose of AHS virus for **dogs** is large, and high infective titers are not known to be gained except by ingestion of infected horseflesh. The course of the disease in dogs is similar to the pulmonary form in horses with fever and severe respiratory distress. The mortality in dogs showing respiratory signs is very high. At autopsy, the lungs are edematous and may have some superimposed bronchopneumonia. There is much froth in the airways, copious hydrothorax in which the fluid gels on exposure, and saturation of mediastinal tissues. Histological changes are not helpful in diagnosis or understanding of pathogenesis.

The clinical signs of AHS are usually characteristic, although AHS might be confused with equine encephalosis, anthrax, equine infectious anemia, equine babesiosis, purpura hemorrhagica, equine viral arteritis, equine viral rhinopneumonitis, or trypanosomiasis.

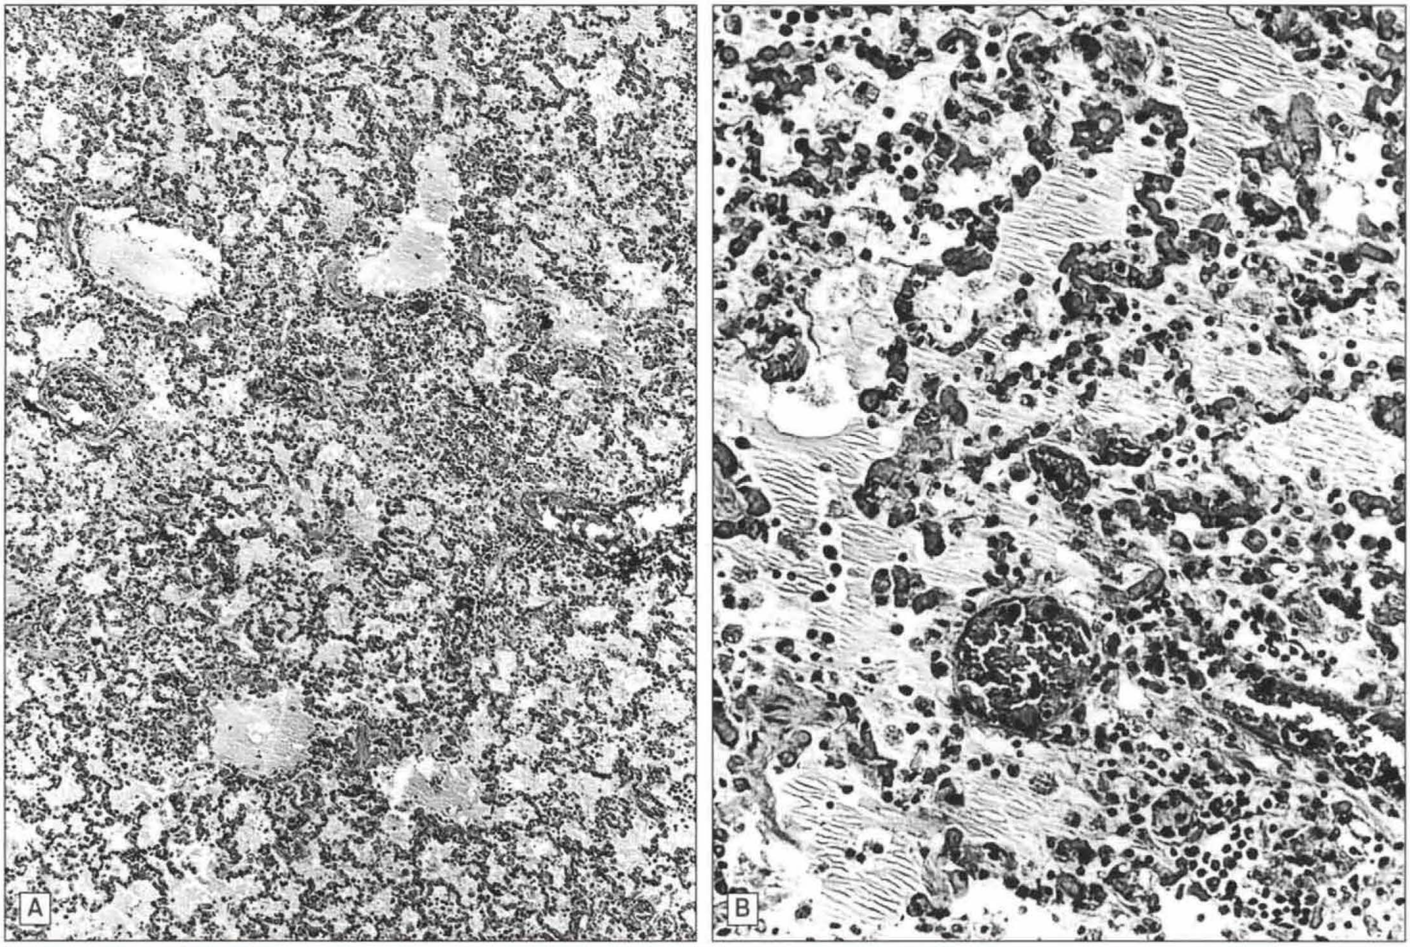

Figure 1.69 African horse sickness. A. Diffuse pulmonary edema with mononuclear cells in alveoli. **B.** Higher magnification of (**A**).

Diagnosis requires virus isolation, virus identification (ELISA, virus neutralization, PCR), or serology (ELISA, complement fixation, immunoblotting).

African swine fever

African swine fever (ASF) is an acute-to-chronic, febrile, viral disease of swine, characterized by high fever, cutaneous hyperemia, abortions, edema, and hemorrhage in internal organs, particularly lymph nodes. ***African swine fever virus*** (ASFV) infects only members of the Suidae family and is a harmless companion of the warthog (*Phacochoerus aethiopicus*) and the bush pig (*Potamochoerus porcus*). However, the virus is a constant and major threat to domestic pigs. Originally limited to sub-Saharan Africa, the disease has appeared in southern and western Europe, the Caribbean, and Brazil, but remains endemic only in Sardinia outside Africa. *International spread of ASF is primarily through infected pork products in garbage fed to pigs.* Once a focus of infection is established, spread is most likely to occur by direct or indirect contact. In Africa, the transmission of the virus from wild Suidae to domestic pigs is primarily by the argasid tick *Ornithodoros moubata*, a true biological vector and a reservoir of the virus in nature. Additional arthropod vectors exist.

The causative agent, ASFV, is an enveloped DNA virus, family Asfarviridae, genus *Asfivirus*. It is a relatively resistant virus that may survive in the environment or in uncooked pork products for prolonged periods. There are several antigenically different strains of ASFV that also vary in their cultural characteristics and their ability to hemadsorb. Viral virulence is classified as high, moderate, and mild. In an area free of the disease, ASF is typically seen as a peracute or acute disease with high morbidity and mortality, but as virulence diminishes with time, subacute, chronic, and inapparent forms become increasingly evident. Survivors remain persistently infected.

The immunological response of swine to strains of ASFV is unusual and is incompletely understood. Susceptible animals infected with African field strains develop precipitating and complement-fixing, but rarely neutralizing or protective, antibodies. The animals remain viremic and usually die within 7–10 days. Pigs that recover are resistant to infection with the homologous virus. In the case of infection with highly virulent ASFV, even though 10 days may have elapsed since infection, pigs typically die before development of anti-ASF immunoglobulin, probably because of the demise of antigen-presenting cells in lymph nodes, spleen, and liver.

There is no cross-protection conferred by infections by *Classical swine fever virus* (CSFV) and ASFV. Failure of swine that are immune to CSFV to survive challenge with ASFV is the critical test for establishing the diagnosis of ASF in a suspected outbreak. The ability of most isolates of the virus to produce hemadsorption when grown in tissue culture contrasts with the CSFV, and this feature allows ready differentiation of most strains of the two viruses.

The ASFV replicates in and activates monocytes and macrophages of various lymphoid tissues and organs, resulting in release of cytokines such as interleukin-1 and tumor necrosis factor-α, and hence causes widespread cell death through apoptosis of T and B lymphocytes in lymphoid tissue and of endothelial cells in arterioles and capillaries, accounting for the lesions of the acute disease. Activation of pulmonary intravascular macrophages and release of cytokines incites pulmonary edema, neutrophil sequestration, and formation of microthrombi in septal capillaries. It also appears that the virus modulates signaling pathways in macrophages, hence interfering with the expression of host immunomodulatory genes; this evasion of host defences allows infections to be persistent.

The **peracute form** of ASF is *a severe acute viral hemorrhagic fever* characterized by a 1–3 day course of pyrexia, hyperpnea, and cutaneous hyperemia, with morbidity and mortality approaching 100%. The usual clinical course of ASF is acute. Following an incubation period of 4–10 days, there is a reduction in appetite, pyrexia, marked cutaneous reddening, dyspnea, and severe leukopenia. Pregnant sows may abort. The clinical signs in the less severe forms of the disease are variable. The signs may be a mild expression of those seen in the acute disease and may be confused easily with other diseases. There are recurring periods of pyrexia, dyspnea, growth retardation, and emaciation. Death may occur during one of the periods of pyrexia. *It is important to realize that the clinical signs of chronic ASF may be indistinguishable from those seen in classical swine fever (CSF).*

The ASFV tends to affect the same organs and tissues as does the CSFV. The anatomical differences tend to be quantitative and dependent on the more fulminating nature of ASF; *only splenomegaly and hematoma-like visceral lymph nodes are particularly characteristic of ASF* (Fig. 1.70). The vascular lesions that can develop rapidly, namely hemorrhage and edema, are apt to be more severe in ASF than in CSF, whereas the lesions that develop more slowly, such as infarction, tend to be absent.

The pig dead from **acute ASF** shows few or no signs of recent wasting. Gastrosplenic and renal lymph nodes are usually intensely hemorrhagic, and ecchymotic hemorrhages may be present on the serous membranes. The spleen is usually enlarged and may be markedly enlarged and friable; infarction cannot usually be recognized grossly. *Pulmonary edema*, not common in CSF, is present frequently in pigs with ASF. The pulmonary septa are thickened by a yellow gelatinous infiltrate. Pulmonary hemorrhage is also common. The gallbladder is often edematous, and the vessels of the wall are engorged and conspicuous. Both petechiae and ecchymoses are present on the serosal and mucosal surfaces. In some outbreaks of the disease, there are extensive pancreatic hemorrhages and necrosis. The renal changes are similar to those of CSF and consist of subcapsular petechiae (Fig. 1.71). The stomach often contains ingesta, but the mucosa is apt to be inflamed and eroded. Changes in the

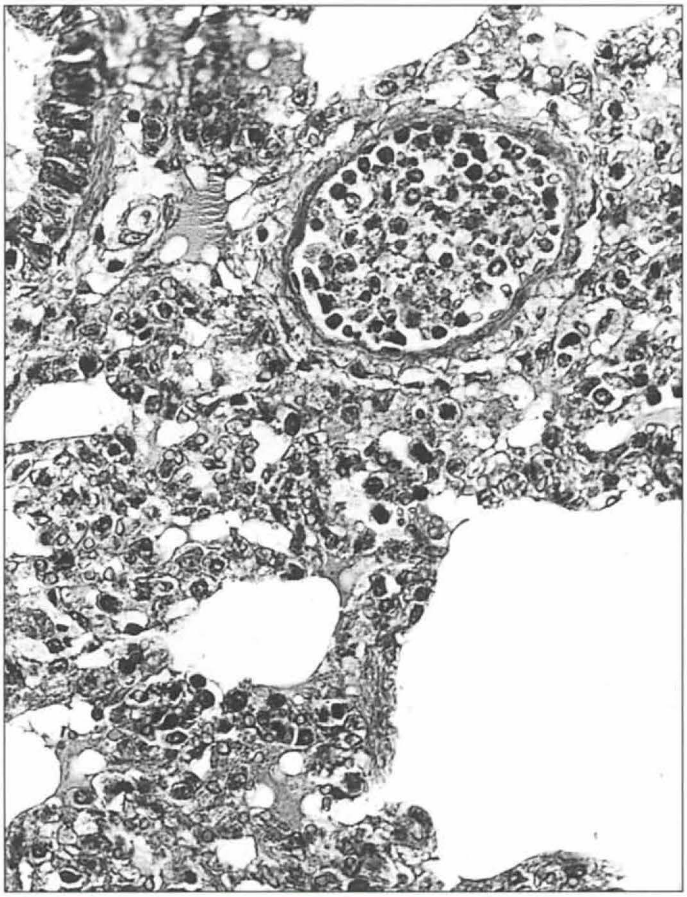

Figure 1.72 Cellular thrombus in pulmonary vessel, and alveolar thickening in **African swine fever.**

small intestine may be absent or consist of segmental areas of congestion and mucosal petechiation. More severe intestinal changes may be found in the large intestine; these may include large areas of hemorrhage, severe congestion, and ulceration. Lesions suggesting "button ulcer" are very rare in this disease, presumably because few animals survive long enough for their development.

The postmortem appearance of **subacute and chronic cases of ASF** varies considerably. In the subacute cases that die after 3–4 weeks of illness, there may be lymph node and renal hemorrhage, an enlarged, but not congested spleen, lobular consolidation of cranial lung lobes, and intestinal mucosal hemorrhage. Prominent features of the chronic form include fibrinous pericarditis and pleuritis; splenic and lymph node enlargement; lobular consolidation of the lungs, which may progress to necrosis and mineralization of an entire lobe; skin lesions ranging from raised hyperemic plaques to necrotic areas; swollen joints; and arthritis. The meningoencephalomyelitis and periportal hepatitis observed in the acute disease persist in the chronic disease. Lesions in *aborted fetuses* are inconsistent but include petechiation of placentas, skin, and myocardium, mottled lungs and liver, and anasarca.

Histologically, infection by a highly virulent strain of ASFV causes extensive necrosis of cells of the mononuclear phagocyte system, whereas infection with a moderately virulent strain causes little necrosis. *The histologic findings in acute ASF are very similar to those of CSF, but there are important differences.* A major difference is that ASFV does not infect epithelium. Necrosis with karyorrhexis in lymphoid tissue everywhere is often very obvious in ASF; frank necrosis is quite rare in CSF, although mature lymphocytes are apt to be absent in lymphoid tissue. Renal tubular degeneration with amorphous casts in the medulla is frequent in ASF, but rare in CSF. In ASF, necrosis of periportal hepatocytes and infiltrating lymphocytes is common, whereas microscopic hepatic lesions are usually absent in CSF. The vascular cuffs in the brain in ASF contain much more necrotic debris than do the lesions in CSF. *The degeneration of vascular endothelium and the fibrinoid arterial changes are identical.* Vascular endothelial damage in the lung may cause thrombosis (Fig. 1.72) of vessels and thickening of alveolar walls. Pigs dead of acute ASF may have glomerular capillary thrombosis; surviving pigs may develop focal segmental glomerulonephritis.

Since there is no treatment or effective vaccine against ASF, rapid diagnosis is critical to disease control. A **diagnosis** of ASF is confirmed by detection of ASFV antigen in tissues by direct immunofluorescence, detection of ASF antibody by indirect immunofluorescence or ELISA, detection of virus genome by PCR, and virus isolation. *Differential diagnoses* include classical swine fever (from which ASF cannot be differentiated by clinical or necropsy examination), erysipelas, salmonellosis, pasteurellosis, and other septicemias.

Classical swine fever (hog cholera)

Classical swine fever (CSF) is a highly contagious viral disease of swine; it may occur as acute, subacute, chronic, or inapparent syndromes. Acute CSF is a disease of high morbidity and mortality caused by a virulent strain of virus; low virulence virus may cause inapparent disease. Classical swine fever is said to have developed de novo in Ohio, USA, in the early 1800s. It subsequently spread to almost all countries and is also known as *swine fever, Schweinepest, peste du porc, and peste svina.* The ***Classical swine fever virus*** (CSFV) produces disease only in swine. The disease has been eradicated from Australia, Canada, the UK, and the USA, but it remains a problem in Central and South America and several European countries.

Classical swine fever is caused by a *Pestivirus*, a member of the family Flaviviridae. Other members of the genus include *Bovine viral diarrhea virus* (BVDV) and *Border disease virus*. CSFV and BVDV are closely related antigenically, and although pestiviruses other than CSFV are thought to be harmless to pigs, *natural BVDV infection can cause clinical signs and necropsy lesions indistinguishable from those of chronic CSF*. Under appropriate circumstances, all three pestiviruses may produce transplacental infection, and hence persistent infections and congenital anomalies. The CSFV is an enveloped, single-stranded RNA virus that replicates intracytoplasmically. Most strains do not produce a cytopathic effect in porcine cell cultures. The enveloped nature of the virus makes it sensitive to lipid solvents and to desiccation. However, the virus may persist for prolonged periods in uncooked pork products.

Antigenic variation exists among strains of CSFV, and field strains vary widely in virulence. The interaction of a particular strain of virus and the host provides a range of disease syndromes. Strains of CSFV are usually classified as being of *high, moderate, or low virulence*, or as being *avirulent*. Highly virulent strains produce the features of the classical acute disease in pigs of all ages; the morbidity may reach 100%, with a mortality rate of up to 90%. Strains of moderate virulence induce subacute or chronic disease, and pigs may subsequently die or recover. In pigs infected postnatally, strains of low virulence produce few or no signs of disease and induce immunity, but may cause fetal abnormalities. Artificially attenuated strains used as vaccines are avirulent, even for fetuses. Virulence of CSFV may be unstable; virulence can increase by one passage through pigs.

Transmission of the disease is usually by direct contact of infected pigs or wild boar with susceptible pigs; CSF is endemic in wild boar in parts of Europe. The virus is present in urine, feces, and lacrimal and oronasal secretions of infected pigs, as well as semen of infected boars. With the less virulent strains, the virus may be excreted in the urine for periods up to 3 months. The major mechanism of spread of virus of low virulence occurs from continuous virus shedding by chronic or persistently infected asymptomatic pigs. Minor modes of transmission include fomites and arthropods.

Classical swine fever is characteristically an **acute disease** *of high morbidity and mortality*, most animals surviving only to 14 days after showing the first signs of illness, namely anorexia, depression, fever, and leukopenia. Persistent infection (that is, survival of greater than 30 days) is caused by CSFV strains of moderate or low virulence and may arbitrarily be divided into chronic and late-onset types. In **chronic CSF**, typical acute disease is followed by clinical improvement, the result of specific antibody formation, but later by immune exhaustion and chronic disease in which the pig is viremic and more susceptible to secondary bacterial infection. **Late-onset CSF** occurs in pigs that are persistently viremic and immunotolerant to CSFV as a result of fetal infection by CSFV of low virulence. The latest date for the development of a persistent infection appears to be about day 70 of gestation; by day 85 viral antigen may be detected in a few fetuses, but virus cannot be isolated. Signs that develop in viremic, but previously asymptomatic, pigs include anorexia, depression, leukopenia, conjunctivitis, dermatitis, diarrhea, runting, and posterior paresis. *The late-onset form of CSF is the porcine equivalent of mucosal disease in cattle*, in which BVDV infection of fetal calves results in persistently viremic, immunotolerant animals.

The **pathogenesis** of CSF is not fully understood, but involves the effects of the virus on the immune system (lymphoreticular cells and macrophages), the vascular endothelium, and epithelial cells. The effect of the monocytotropic CSFV on the immune system varies with the stage of differentiation; mature elements degenerate, whereas undifferentiated cells respond by proliferation. CSFV replicates in macrophages in lymph nodes and lymphoid tissues and can cause depletion of lymphocytes indirectly through expression of apoptotic cytokines, such as tumor necrosis factor-α. Similarly, intestinal epithelial necrosis appears be the product of release of chemical mediators from activated macrophages, rather than direct viral infection. Endothelial changes are primarily degenerative but some proliferative changes occur. *Damage to endothelial and other cells leads to thrombocytopenia, consumption coagulopathy, and in turn disseminated intravascular coagulation and hemorrhage.*

The classical or **acute** form of the disease, which affects pigs of all ages, commences by entry of the virus through the mucous membranes with initial replication in the tonsillar epithelium. This is followed by spread to the cervical lymph nodes with viremia within 16 hours of infection. The virus has a propensity to replicate in cells of the immune system, particularly in lymph nodes, bone marrow, and other lymphoid aggregates such as the spleen and Peyer's patches. After 3–4 days, the virus invades endothelial cells and epithelial cells including those of the pharyngeal mucosa, gastrointestinal tract, gallbladder, pancreas, salivary gland, uterus, adrenal, and thyroid. The clinical signs are not specific and do not provide good correlation with pathologic changes, although in the acute disease they may be sufficient for presumptive diagnosis where the disease is endemic.

Superficially, the eyelids are frequently adherent and sticky, and the carcass is dehydrated and soiled by terminal diarrhea. The irregular erythema that can be seen in the animal when alive is less obvious, but hemorrhages, particularly in unpigmented areas of skin, may be seen (Fig. 1.73). If present, they are most numerous on the abdomen and the inner aspects of the thighs.

Diagnostic lesions *may be sparse in CSF*, especially if peracute, and it may be impossible to establish the diagnosis on the basis of the gross lesions in a single animal. *The lesions most commonly present are hemorrhages in the periphery of the lymph nodes and renal petechiae.* The renal hemorrhages may be very few, and in all cases the kidney capsule should be removed and the surface examined in good light. Hemorrhages in the lymph nodes are more obvious; characteristically, only the periphery of the node is involved. In acute cases, this produces a distinctive bright red halo; if the case is more chronic, the halo may be the dirty brown of partially degraded hemoglobin. Less frequently, the hemorrhage in the node is diffuse. The nodal changes are generalized, but nodes most apt to show severe changes are the mandibular, colonic, hepatic, and iliac; changes in the renal lymph nodes are not useful in this context.

Splenic infarction is almost pathognomonic of acute CSF. Unfortunately, the tendency for infarcts to develop in the disease varies with the strain of the virus, with reports of incidence of 1–87%. When present, infarcts occur as single or multiple, dark red, pyramidal blebs 0.5–2 cm in diameter, usually along free edges but occasionally on the flat surface (Fig. 1.74). The spleen in CSF is not enlarged, as it is in septicemias, and is red-brown so that the infarcts contrast quite sharply with the meaty parenchyma. In addition to the hemorrhages of the kidney, petechiae are common in the urinary bladder

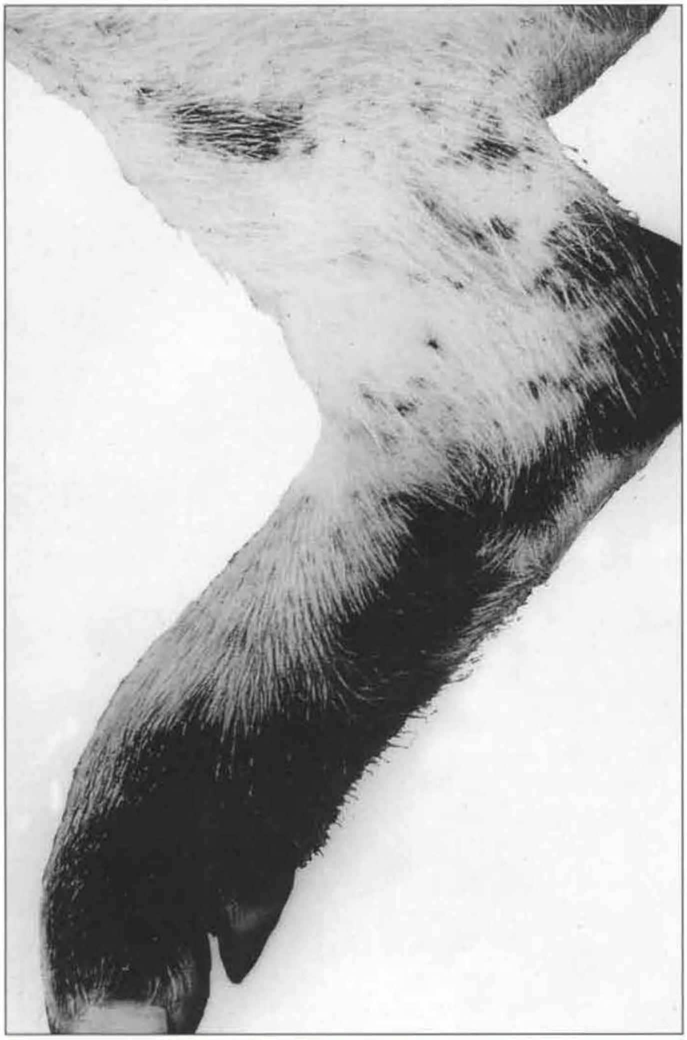

Figure 1.73 Diffuse and patchy subcutaneous hemorrhages in **acute classical swine fever**.

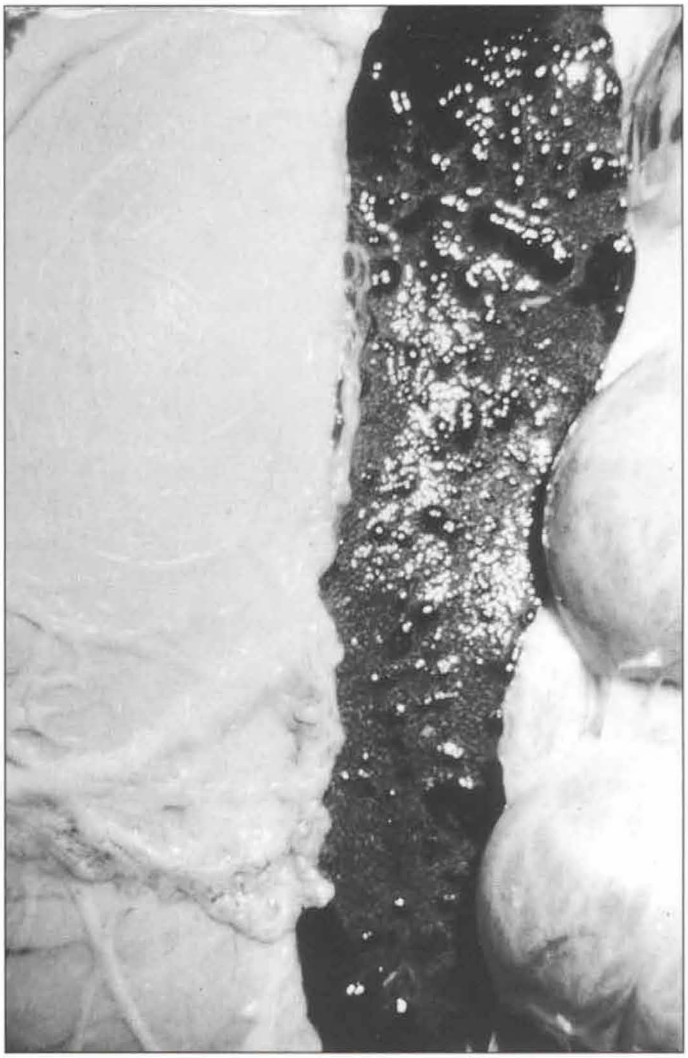

Figure 1.74 Multiple splenic infarcts in **classical swine fever**. (Courtesy of C Brown.)

(Fig. 1.75), the larynx (Fig. 1.76), the gastric mucosa, the lung, and the epicardium, in about that decreasing order of frequency. There is usually a small amount of straw-colored fluid in the pericardial sac. There may be hemorrhagic lobular pneumonia (Fig. 1.77).

Irregular, but sharply outlined areas of necrosis develop in the tonsils and posterior fauces (Fig. 1.78). The stomach of an animal dead of CSF is empty except for a small amount of watery mucus and ingesta. The fundic mucosa is congested, and mild or severe erosions may be present. Specific lesions do not occur in the small intestine, but the mesentery is usually congested. It is in the colon and cecum that the virus combines with the intestinal flora to produce craterous mucosal defects, "*button ulcers*," which are characteristic of the subacute or chronic stage of the disease. These lesions begin as sharply outlined circular areas of hemorrhage and necrosis (Fig. 1.79). The central area is yellow and dry. As the lesion ages, the rim, which is composed of necrotic epithelium, bacteria, and detritus, is raised above the surrounding mucous membrane and concentric rings form as if growth were cyclic. The center of lesions sinks giving a slight diskoid shape. If this necrotic tissue and debris is removed, a deep ulcer is revealed. Growth arrest lines may be seen in the ribs of chronically sick pigs. Gross lesions are not usually present in the brain, but the brain should be removed because it is there that the histological changes can be best appreciated.

Within the *brain*, all areas may be affected but the lesions are usually most conspicuous in the medulla, pons, mid-brain, and thalamus. The response is largely confined to the vessels and their supporting mesoderm. Many of the venules have eccentric cuffs, which are formed in part by transmural migration of monocytes. Mitotic figures and nuclear chromatin of necrotic cells are frequently present together in the cuff, as proliferation and necrosis are coexistent. Swelling and degeneration of the endothelial cells occur in the walls of the smaller vessels (Fig. 1.80). All changes from slight thickening to necrosis of the wall may be seen. The lumen is often compromised by these reactions. The response of the neural parenchyma appears to be entirely secondary to the vascular lesions; often it is nonexistent or confined to minimal neuronal degeneration, or it may consist of glial nodules formed about obstructed or destroyed capillaries. If severe cerebral edema develops, there may be widespread damage to the oligodendroglia. The vessels of the eyes, choroid plexuses, and the leptomeninges are similarly involved.

Vascular lesions usually are most severe in lymphoid tissue but may occur anywhere. The lesions vary from slight thickening of the capillary wall to

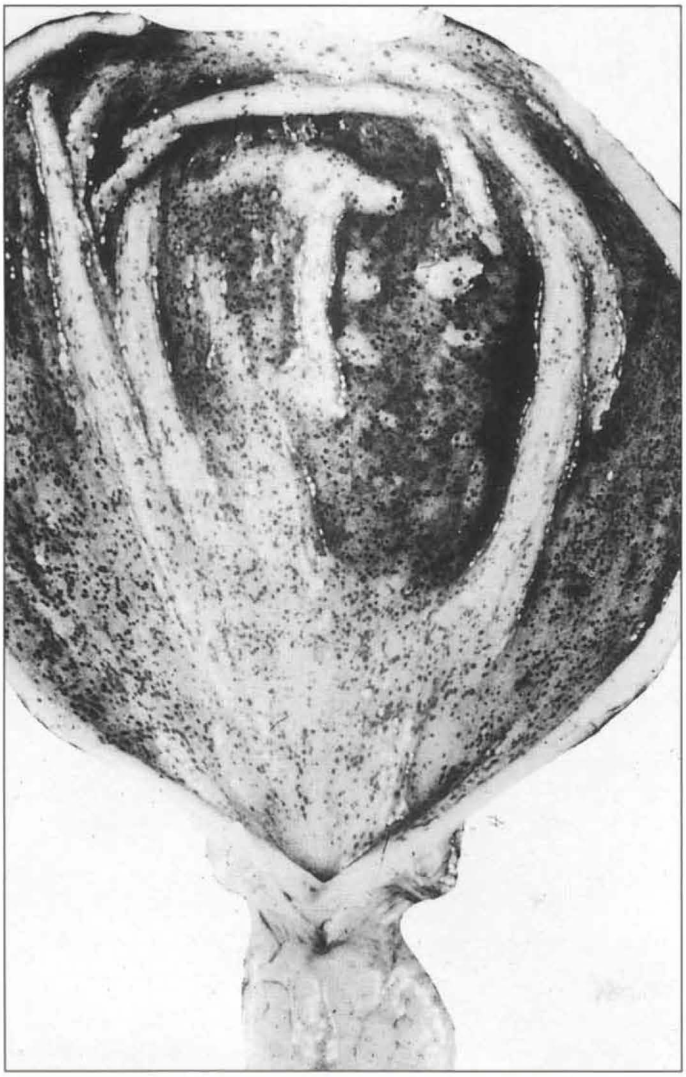

Figure 1.75 Hemorrhages in mucosa of urinary bladder in **acute classical swine fever**.

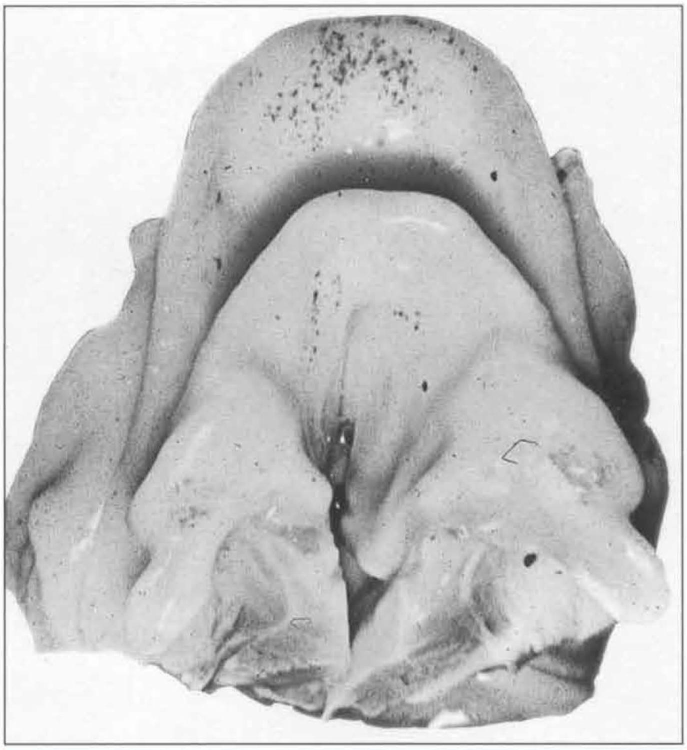

Figure 1.76 Laryngeal hemorrhages in **acute classical swine fever**.

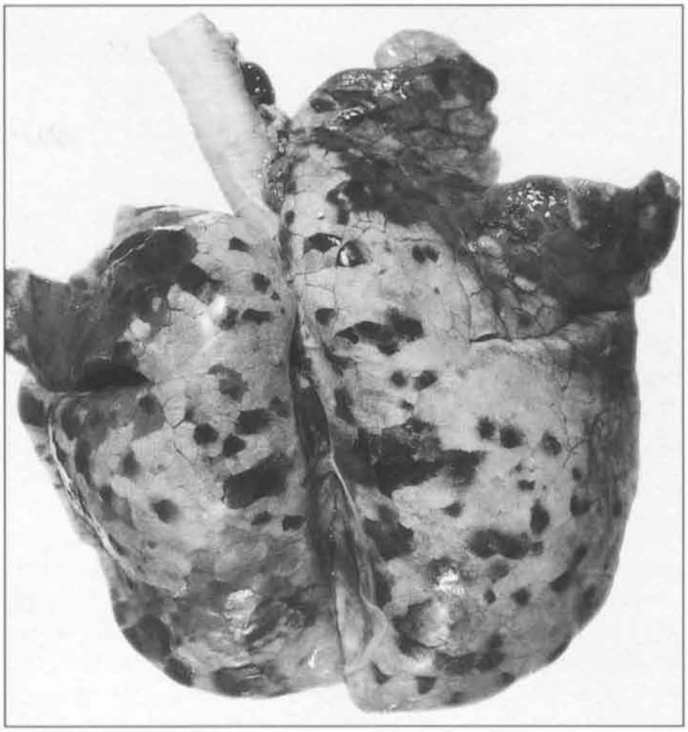

Figure 1.77 Hemorrhagic pneumonia with lobular distribution in **classical swine fever**. The cranial bronchopneumonia is probably not related.

fibrinoid necrosis of arterioles. As these changes develop, there is a tendency for extravasations to occur and for microthrombi to form.

Microscopic areas of *infarction* are common in the lymph nodes and skin, but only in the spleen, tonsil, gallbladder, and large intestine are these areas usually large enough to be grossly visible. In some cases, swelling and paleness of the capillary wall is obvious. The nuclei of these vessels are enlarged and the nuclear chromatin is dispersed as fine dust. Less often, the endothelial proliferation is so marked as to be the most conspicuous change. In general, in acute cases the degenerative changes are most prominent, whereas in chronic ones proliferative changes are more obvious.

In the periphery of *lymph nodes* (the equivalent of the medulla in other species), lesions vary from slight edema and proliferation of the reticuloendothelial elements to extensive hemorrhage. It is the intermediate stages that are the most common and in which the nature of the lesion is best visualized; in these, there is necrosis of the small vessels and secondary hemorrhages and parenchymal necrosis.

In the *spleen*, the most pronounced lesions are in the follicular arteries, particularly those at the apex of the pyramidal infarcts. The swelling and hyalinization of these vessels may be so severe as to occlude the lumen. Survival of tissue within the infarcted area will depend on how long the infarction preceded death. Even if the spleen is free of gross and microscopic infarction, vascular changes of the type seen elsewhere can usually be found. They are often

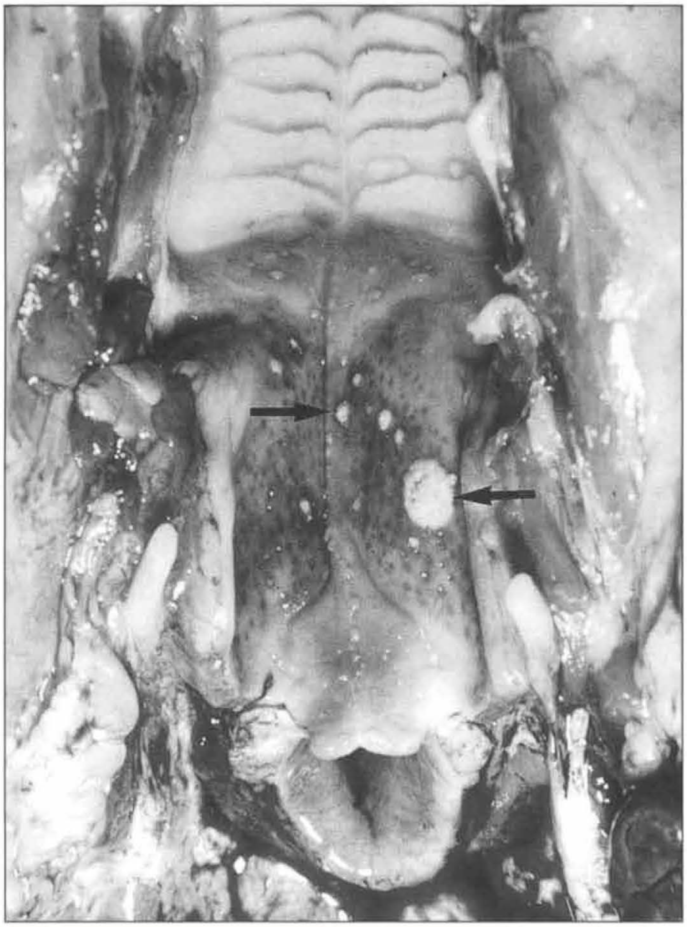

Figure 1.78 Necrosis of tonsils (arrows) in **classical swine fever**. (Courtesy of C. Brown.)

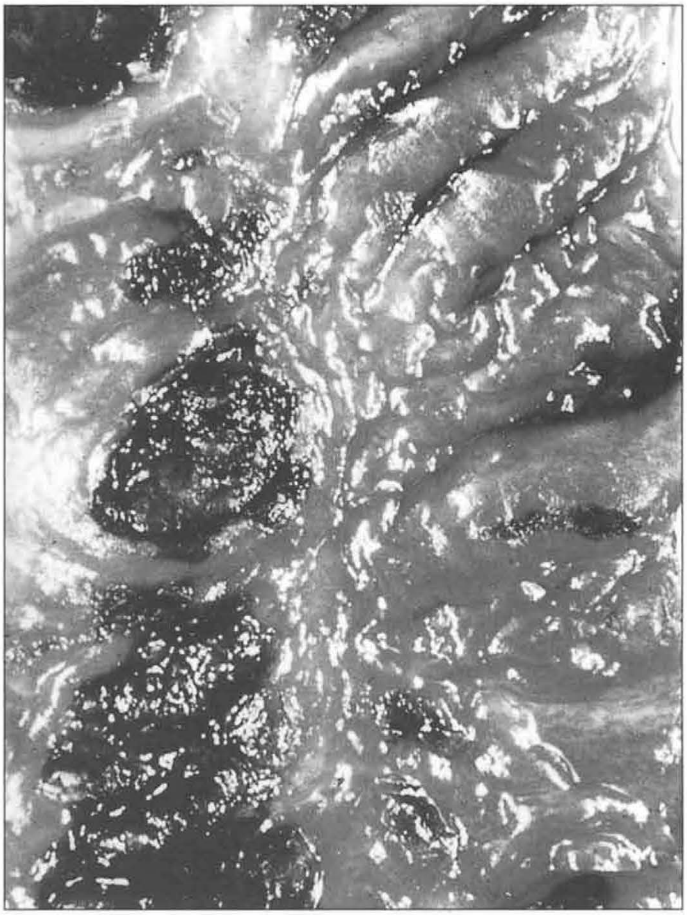

Figure 1.79 Hemorrhagic ulcers in the colon in **acute classical swine fever**.

associated with perivascular hemorrhage. In addition, there is reticuloendothelial hyperplasia and absence of mature lymphocytes.

The *kidney* tubules often show nonspecific degenerative changes. The subcapsular hemorrhages seen grossly are the result of increased vascular permeability and erythrodiapedesis. Immune-complex-mediated mesangioproliferative glomerulonephritis occurs, with deposition of IgM, IgG, and C1q in mesangial, subepithelial, and subendothelial sites, fusion of foot processes, infiltration of the mesangium by macrophages and later neutrophils, and the presence of viral particles in glomerular endothelial cells and podocytes.

In utero infections can result in a variety of effects, including abortion, mummified fetuses, and stillborn piglets. Fetal abnormalities such as ascites, petechiation of skin and other organs, hepatic nodularity, pulmonary hypoplasia, microcephalus, hydrocephalus, cerebellar hypoplasia, and hypomyelinogenesis may also be observed. Persistently infected pigs that survive may be runts and die 2–11 months after birth. These piglets have severe thymic atrophy and pale swollen lymph nodes; some may have focal colonic mucosal necrosis.

Serological **diagnosis** of CSF is difficult. Antibodies to CSFV and BVDV cross-react in many assays; they may be differentiated by specific virus neutralization tests. The prescribed tests in the OIE Manual are the neutralization peroxidase-linked assay, fluorescent antibody virus neutralization, and ELISA. CSFV antigen can be detected in live pigs by RT-PCR, and in formalin-fixed tissue by semi-nested RT-PCR or by in situ hybridization. *Differential diagnoses for CSF* include African swine fever (clinicopathologically indistinguishable), BVDV infection, porcine reproductive and respiratory syndrome (PRRS), postweaning multi-systemic wasting syndrome (PMWS), porcine dermatitis and nephropathy syndrome (PDNS), salmonellosis, erysipelas, acute pasteurellosis, other viral encephalomyelitides, streptococcosis, leptospirosis, and courmarin poisoning.

Bovine ephemeral fever

Bovine ephemeral fever (BEF), a non-contagious vector-borne viral disease of cattle and water buffalo, is characterized by sudden onset of fever, stiffness, and lameness, usually with high morbidity and low mortality, and with rapid spontaneous recovery within 3–4 days of the onset of clinical signs. The cause, ***Bovine ephemeral fever virus*** (BEFV), is in family Rhabdoviridae, genus *Ephemerovirus*. The disease is endemic in tropical regions of Africa and Asia and occurs as epidemics in subtropical and temperate regions of Africa, Asia, and Australia; it has not been reported from the Western Hemisphere, Europe, New Zealand, or New Guinea. In temperate climates, BEF is a disease of summer and autumn, and ceases abruptly at the first frost; the reservoir for overwintering or between epizootics is probably in wild ruminants. Infection usually confers lifelong immunity. The likely *vectors* are various species of *Culicoides* and mosquitoes.

Clinical disease ranges from almost imperceptible clinical signs to death, with considerable individual variation in an outbreak. Mild disease may be exacerbated by environmental stress, e.g., exposure causing dehydration. Disease is milder in young than in mature animals; in lean than in fat animals; in light steers and cows than in bulls; in dry cows than those in heavy lactation. The incubation period is usually 2–4 days. The fever may be biphasic, triphasic, or multiphasic; clinical signs are milder in early than in later phases of fever. Mildly affected animals may have fever, be lame or stiff for a day or two, and then recover completely. Neutrophilia with a left shift and concurrent lymphopenia, hyperfibrinogenemia, and hypocalcemia occur early in the course of disease. More severely affected animals are anorectic, have oculonasal discharge, may have muscle tremors, stiffness, lameness, and patchy edema of the face or jaw. Rumen motility ceases and the animal may be constipated. Animals in lateral recumbency are usually still able to rise. Lactation falls by an average of 50%, and does not usually recover to normal during that lactation. Cows in late pregnancy may abort. In very severe cases, there may be temporary or permanent paralysis of all limbs, inability to swallow, and drooling; in 1–4 days, loss of reflexes, coma, and death follow.

Whether the disease is mild or severe, recovery commences quite suddenly and is complete in 95–97% of uncomplicated cases, giving rise to the name "ephemeral fever." Although mortality is usually less than 1%, the most productive mature animals are often lost, plus there are losses of milk production, abortion losses, and temporary infertility in bulls. Other sequelae include fatal pulmonary emphysema, pneumonia, mastitis, and locomotor disturbances. The total economic loss in an outbreak can be severe.

The essential **gross feature** *of BEF is serofibrinous polyserositis*, which variously affects the synovial, pericardial, thoracic, and peritoneal cavities, and is the *result of increased vascular permeability*. The serosal membranes themselves are often edematous and may be hemorrhagic; the edema fluid in cavities often contains fibrin clots. Severely affected joints may be surrounded by brown or yellow gelatinous periarticular fluid that also extends along tendon sheaths and fascial planes. There may be patchy pulmonary edema, visceral and parietal pleuritis, epicarditis at the base of the heart, edematous lymph nodes in the febrile stages, and necrosis in some skeletal muscles; myonecrosis is likely the result of recumbency. Histologically, affected tissues are edematous and infiltrated by neutrophils, and may also be hyperemic and hemorrhagic. *Vascular changes* include endothelial swelling and hyperplasia, hyperplasia of pericytes, fibrinoid necrosis of arterioles, perivascular fibroplasia, and thrombosis of occasional vessels in muscles. Wallerian degeneration has been reported in the upper cervical spinal cord in cases with chronic paralysis, but may be secondary to trauma.

The **pathogenesis** of BEF is poorly understood, but is likely mediated through cytokines; the site of viral replication remains unknown. Neutrophils appear to play a central, but undefined, role; cattle in which neutrophils are experimentally depleted develop viremia but not clinical disease. Interferon α, interleukin 1, and tissue necrosis factor circulate in high titer during the acute phase of BEF.

The clinical signs observed in an epizootic are usually diagnostic. The **diagnosis** can be confirmed by virus isolation. Serological diagnosis may be complicated by cross-reaction with antibody to *Kimberley virus*, an arbovirus that induces production of low levels of serum neutralizing antibody to BEF virus but does not protect against BEF.

Rickettsial vasculitides

Heartwater (cowdriosis)

Heartwater is a tick-borne rickettsiosis of ruminants that is endemic in sub-Saharan Africa and that has been identified in several Caribbean islands. The common name, heartwater, is derived from the *pericardial effusion* that is typically present in small ruminants but sometimes absent in cattle. Heartwater is a major vector-borne disease of ruminants in Africa, third in importance only to East Coast fever and trypanosomiasis, but has a wider distribution than either of these. Mortalities due to heartwater are estimated to be 3 times greater than those due to babesiosis and anaplasmosis. The causative agent is ***Ehrlichia* (*Cowdria*) *ruminantium***, order Rickettsiales. Isolates of *E. ruminantium* cross-react strongly with *Ehrlichia equi,* and to a lesser extent with *E. canis,* in indirect fluorescent antibody tests. The *vectors* are 3-host ticks of the *Amblyomma* genus, principally *A. variegatum*, *A. hebraeum*, and *A. pomposum*. *Amblyomma maculatum* and *A. cajennense* are suitable vectors present on the American mainland. Transstadial transmission occurs in vector ticks; transovarian transmission is infrequent. When a tick feeds on an infected host, organisms apparently first infect and develop within gut cells. Subsequent stages of the organism continue their development in hemolymph and salivary gland, and are transferred to the vertebrate host during tick feeding.

The various strains of *Ehrlichia ruminantium* are antigenically similar, but differ considerably in their virulence. The various domestic hosts also differ in their susceptibility. Imported breeds of cattle, sheep, and goats are as a rule much more susceptible than indigenous breeds. There is also an important age difference in susceptibility. Calves and lambs less than three weeks of age are highly resistant to heartwater. This is a true age resistance, and it is independent of maternal immunity. Ruminants are most susceptible at about the stage of early maturity, and in the absence of treatment *mortality is expected to be about 60% in cattle and close to 100% in European breeds of sheep*, although this will depend on the virulence of the infecting strain.

There also appear to be differences in susceptibility among the African antelopes. The blesbok and black wildebeest are known to be susceptible to infection without showing signs of illness. Wildlife may act as reservoirs of infection, though this is not necessary as the tick itself is a reservoir; infection survives in adult ticks for over 15 months. Domestic ruminants that have recovered from the disease seldom remain as carriers of the circulating organism for more than 3 weeks after recovery, but it is not clear whether the agent remains in a masked form in tissues. *Immunity of variable duration follows recovery, often as premunity*; sterile immunity may persist for a year or more after disappearance of the organism. Immunity in natural infections is expected to be reinforced by reinfections.

The early development of the parasite is not completely understood, but probably takes place in reticulum cells and macrophages of lymph nodes and spleen in which initial bodies are demonstrable at about the fourth day of infection. Organisms are then released into the blood and parasitize vascular endothelial cells. The organism is demonstrable in capillary endothelium of brain 1–3 days after it is demonstrable in lymph nodes. *Ehrlichia ruminantium* parasitizes endothelial cells but is also present in the blood; the infection is readily transmissible by inoculation of blood collected during the febrile stage or shortly thereafter. *The colonies (groups, clusters, morulae) of microorganisms in endothelial cells lie characteristically in membrane-bound vacuoles in the cytoplasm at the poles of the endothelial cell nuclei.* Colonies and organisms are pleomorphic; colonies are formed by binary fission of organisms. Organisms range in size from 0.2 to >2.5 μm and are termed small, medium, or large; each is surrounded by a double membrane, and based on their internal morphology they may be termed *elementary (electron-dense), intermediate, or reticulate bodies*; usually only organisms of the same form are found within a vacuole. They can be found in sections and are present in all organs and in vessels of all calibers but are best sought in the capillaries of the cerebral cortex in squash-smear preparations or in imprints from the endothelium of a large vessel such as the jugular vein. Giemsa is the preferred method of staining.

The natural incubation period of heartwater is 2–3 weeks but varies considerably. In the peracute form of the disease, death occurs rapidly in convulsions without warning. The usual **clinical syndrome** in susceptible animals is acute, with a course of up to 6 days. There is high fever and its attendant signs, and dyspnea. As the course advances, nervous signs develop. These are especially prominent in cattle and consist of chewing movements, protrusion of the tongue, twitching of eyelids and blinking, unsteadiness of gait, circling, and a terminal convulsive phase in which there is prominent cutaneous hyperesthesia. Diarrhea is common in cattle but less common in sheep. Mild progressive anemia may develop, as may leukopenia (neutropenia, eosinopenia, and lymphocytosis) and hypoalbuminemia. In the subacute syndrome, the course is prolonged and leads either to slow recovery or to collapse and death. Animals with high natural resistance or partial immunity may show transient fever only.

The **pathogenesis** of the increased capillary permeability seen in heartwater is unclear; the severity of edema is often thought to be out of proportion to the numbers of infecting organisms. Production of a toxin has been suggested, but not proven; *Ehrlichia* stains negatively with Gram's stain, has a cell wall similar to that of gram-negative bacteria, and has been suggested to produce endotoxin. Complement and

the products of arachidonic acid metabolism may play a role in the generation of vasoactive substances.

The **gross anatomical changes** in heartwater are the same in each ruminant species but generally are less prominent in cattle than in sheep or goats; lesions may be inconspicuous or absent in treated animals. The disease does not alter the general condition of the animal appreciably. Typical gross lesions include effusion in body cavities, hydropericardium, edema of lungs, brain, mediastinum, and associated lymph nodes, and splenomegaly, though all of the lesions rarely occur simultaneously. The name of the disease is derived from the hydropericardium, but this is sometimes absent. The effusion, which is serous with some fibrinous strands, is more constant and copious in sheep than in cattle. The other serous cavities also contain excess serous fluid; there may be several liters in the pleural and peritoneal cavities of the ox and up to half a liter in sheep and goats. When exudation is copious, the mediastinum and retroperitoneal tissues are also edematous. The membranes remain clear and glistening. The lungs are severely edematous, especially in the peracute form. The lymph nodes of the head, neck, and cranial mediastinum especially are swollen and edematous. The spleen is almost invariably much enlarged in sheep and goats, being sometimes up to 6 times its normal size, but splenomegaly in cattle is only moderate. There is hyperemia with submucosal edema in the lower alimentary tract but it is most pronounced in the abomasum. Petechial hemorrhages are present in the endocardium, mucosa of stomach and gut, tracheobronchial mucosa, and lymph nodes.

Lesions in the *brain* are common (Fig. 1.81) and account for the nervous signs that characterize the disease, especially in cattle, and for the failure of animals to recover with chemotherapy. Gross changes are inconstant on inspection of the surface of the brain. Petechial hemorrhages may be present over the cerebellum, and the choroid plexus may be dull and thickened. On slicing, petechial, ecchymotic, and larger hemorrhages may be numerous in all parts of the brain. The microscopic lesions in the brain are reflections of parasitism and injury to small vessels, especially capillaries and venules. Colonies of *E. ruminantium* are visible in endothelial cytoplasm of untreated cases (Fig. 1.82). There is acute inflammation of the choroid plexus with fibrinous exudate in the stroma, congestion, hemorrhage, and accumulation of inflammatory cells about the vessels. Within the brain, vascular injury leads to perivascular or larger hemorrhages and accumulation of protein droplets in the perivascular space. Focal or larger areas of malacia surround the vessels and are in various stages of development from edematous disruption of white matter with glial activation to microcavitation.

The **diagnosis** of heartwater depends largely on the demonstration of organisms in endothelial cells in brain either in smears or section; brain biopsy can be used to establish the diagnosis in the living animal. The pCS20 PCR assay is the most reliable and specific assay for the detection of *E. ruminantium* in ruminants and *Amblyomma* ticks. Various antibody detection assays are available, e.g., indirect fluorescent antibody, polyclonal competitive ELISA, major antigenic protein (MAP-1) ELISA, Western blot, but often lack specificity because of cross-reactivity with closely related ehrlichiae.

Rocky Mountain spotted fever

Rocky Mountain spotted fever (RMSF), a febrile exanthema caused by ***Rickettsia rickettsii***, is an important rickettsiosis of dogs and humans; *R. rickettsii* or antigenically similar organisms infect a wide variety of mammals and birds. RMSF occurs in dogs throughout the Americas (and is known by various other names, e.g., Brazilian spotted fever), with most cases in North America occurring during the tick season (April to September). The *ticks* most commonly responsible for the transmission of RMSF are *Dermacentor variabilis* and *D. andersoni*; these ticks serve as vectors, reservoirs, and natural hosts for *R. rickettsii*. The rickettsiae are maintained in nature in a primary sylvan cycle, involving mostly small rodents. Dogs can develop a high and persistent rickettsemia, and are a potential public health danger; humans can be infected during tick removal by contact with hemolymph of engorged ticks or with tick excreta. Tetracycline therapy is effective, and dogs are immune after recovery.

Dogs are usually infected via the bite of infected ticks. *The rickettsiae invade and replicate within endothelial cells of small blood vessels*; endothelial damage is probably mediated by phospholipase A and a trypsin-like protease, of either rickettsial or host origin. There is little support for production of endotoxin or exotoxin by *R. rickettsii*. Endothelial damage leads to platelet activation and activation of coagulation and fibrinolytic systems; *thrombosis* in RMSF is thought to arise in reaction to endothelial damage. *Vasculitis* in RMSF is a product of endothelial swelling and necrosis with secondary contributions from the immune and phagocytic host responses mounted by lymphocytes and macrophages, but is not primarily caused by immune-complex formation or by cell-mediated mechanisms. The action of various mediators, such as those of the kallikrein-kinin system, in addition to direct endothelial necrosis, leads to increased vascular permeability and hence edema and multifocal hemorrhage.

Dogs less than two years old are predominantly affected. Purebred dogs, especially German Shepherds, appear to be more susceptible than are crossbreds. Following an incubation period of a few days, **clinical findings** in affected dogs include, in decreasing order of frequency, listlessness and depression, high fever, history or actual presence of ticks, anorexia, myalgia/arthralgia, lymphadenomegaly, vestibular deficits, dyspnea, conjunctivitis, paralumbar hyperesthesia, edema of face and extremities, petechiae or hemorrhagic diathesis, and vomiting and diarrhea. Vasculitis may be visible by means of ophthalmoscopic examination of retinal vessels.

Laboratory findings include anemia, leukopenia followed by leukocytosis, thrombocytopenia, prolongation of activated partial thromboplastin time, hyperfibrinogenemia, and increased concentrations of fibrin/fibrinogen degradation products. The thrombocytopenia is at least partly due to the development of anti-platelet antibodies. Serum biochemistry usually reveals hypoalbuminemia, increased alkaline phosphatase activity, and hypercholesterolemia. Increased concentrations of aldosterone and antidiuretic hormone may contribute to expansion of plasma and extracellular fluid volumes and hence edema. Edema of the medulla oblongata may contribute to cardiorespiratory depression. Death may occur in the acute stages of disease as the result of peripheral vascular collapse, hemorrhagic diathesis, and thrombosis, although fully developed DIC is an unusual event in RMSF in dogs. Necrosis of extremities may occur. Damage to the cardiovascular system, brain, or kidneys may cause death or permanent organ dysfunction; severely affected dogs may die with rapidly progressive meningoencephalitis.

Lesions seen at necropsy include edema of ears and muzzle; ulcerative glossitis; scrotal dermatitis; petechiation of mucous membranes, caudal abdominal skin, pleura, and gastric wall; hemorrhagic colitis; and hemorrhagic lymphadenopathy. *The prominent histologic lesion of RMSF is necrotizing vasculitis of small veins, capillaries, and arterioles*, with perivascular accumulations predominantly of lymphocytes and macrophages. This lesion is seen most commonly in skin, testes, alimentary tract, pancreas, kidneys, urinary bladder, myocardium, meninges, retina, and skeletal muscle. Acute meningoencephalitis may be present. There may also be acute splenitis, acute interstitial pneumonia, and multifocal necrosis of myocardium, adrenals, and liver. A moderate degree of glomerulonephritis may be present.

The most reliable *serologic test* for RMSF is the species-specific microimmunofluorescent method. High antibody titers develop to *R. rickettsii*, but usually decline after 3–5 months. Direct fluorescent antibody staining of a skin biopsy is positive in up to 80% of infected dogs; coccobacillary organisms are present in endothelial cells and vessel walls.

Verminous arteritis

We are here concerned with those parasites whose natural habitat is the lumen or the wall of arteries. Parasites that, accidentally or as part of their life cycle, migrate in tissues may, depending on the route they take, cause vasculitis in various organs. The chief offenders in this regard are the larvae of the genera *Strongylus* and *Ascaris*; the vascular lesions of *Ascaris* infestations are described under diseases of the intestine (Vol. 2, Alimentary system). *Angiostrongylus vasorum*, which inhabits the pulmonary arteries of dogs, is described with the lungworms. *Spirocerca lupi*, which passes part of its history in the adventitia of the thoracic aorta, is described in its final habitat, the esophagus.

Dirofilariasis (heartworm disease)

The dog is the only mammal commonly infected by ***Dirofilaria immitis*** *(heartworm), and is the only significant reservoir of infection.* In areas in which heartworm infection is enzootic in dogs, a number of other mammals may become infected, including domestic cats and wild felids, wild canids (coyotes, foxes, wolves), ferrets, sea lions, muskrats, horses and, rarely, humans. If *D. immitis* develops to maturity in hosts other than the dog, microfilaremia is usually low or absent, and heart failure is rare. Pulmonary dirofilariasis is of considerable importance in humans because the spherical, subpleural granulomas produced may be mistaken radiographically for primary or metastatic lung tumors, leading to thoracotomy and excisional biopsy for diagnosis. *Dirofilaria immitis* has a tropical and subtropical distribution in southern Europe, Asia, Australia, and North and South America, although its range has extended into more northern temperate zones in North America and southern temperate zones in Australia.

Adults of *Dirofilaria repens* occur in subcutaneous connective tissues of dogs and other carnivores (and rarely humans). Similarly, *D. tenuis* is found in the subcutaneous connective tissue of the raccoon in the southern USA. None of these three filariids usually develops to maturity in humans, but they may be found in cysts in various parts of the body, especially in the lungs. *Dirofilaria striata*, a parasite of bobcats (*Lynx rufus*), has been reported in dogs in Florida. The "Florida" *Dirofilaria* differs slightly from *D. immitis* and *D. striata.*

Adult D. immitis worms live in the pulmonary arteries and right heart, but they can develop in various other arteries and veins, and have been reported from a variety of unusual sites, including the eye and brain. Adult males are 12–20 cm long by 0.7–0.9 mm in diameter; females are 25–31 cm by 1.0–1.3 mm. The adult female worms are viviparous, and release microfilariae into the bloodstream; mosquitoes obtain microfilariae in blood meals. The first, second, and early third larval stages of *D. immitis* are obligate parasites of mosquitoes, predominantly of the genera *Aedes, Culex,* or *Anopheles.* Larvae develop to the infective stage in about 13 days in the malpighian tubules. They then migrate to the cephalic spaces of the head or to the proboscis of the mosquito and escape into a new host when the mosquito feeds. The infective larvae are about 1.2 mm long when they enter the host, and are about 5 cm long when they reach the right ventricle 3–4 months later. In the meantime, the parasites have wandered and grown in the connective tissue, chiefly those of the subcutis and muscles, finally leaving these to migrate to the heart via the veins. They mature in a further 3 months. Thus the prepatent period is from 6–8 months. Adults may live for several years and microfilariae can survive in a dog for as long as 2.5 years. Adult heartworms may be found in cutaneous nodules occasionally in dogs, and rarely in cats.

The **clinical diagnosis** of dirofilariasis in dogs depends upon the detection of microfilariae in the blood, preferably by the microscopic examination of centrifuged sediment of lysed blood (*modified Knott's test*), or by a filter technique. Microfilariae of *D. immitis* (290–315 μm long, straight body and tail, tapered head) must be differentiated from those of ***Dipetalonema reconditum*** (270–290 μm, curved body, blunt head, most have a buttonhook tail), the adults of which are nonpathogenic and are commonly found in the subcutaneous connective tissue of dogs; these microfilariae can also be differentiated by PCR or histochemical means. The average number of circulating microfilariae per adult female *D. immitis* decreases as the number of adult worms increases. *Hence the numbers of circulating microfilariae indicate neither the numbers of adult worms present nor the severity of heartworm disease in an individual dog.* Although microfilariae are present in the blood more or less continuously, there is a tendency to periodicity, with maximum numbers occurring in the evening and in the summer, coincident with maximal activity of mosquitoes. Microfilariae are pooled in internal organs, especially the lungs, in the daytime. Fetal pups may be infected by microfilariae from the bitch and have microfilaremia, but the pups do not harbor adult worms. Cats infected with *D. immitis* are typically amicrofilaremic, given low numbers of adult female worms or male-only infections, hence antigen- or antibody-detection tests are required for diagnosis.

Occult dirofilariasis, that is, *heartworm infection without microfilaremia*, occurs in 10–67% of infected dogs, primarily as a result of destruction of microfilariae by immune mechanisms ("immune-mediated occult disease"), but also as the result of prepatent infections, single-sex infections, and drug-induced sterility of adult heartworms. Clinical diagnosis of occult dirofilariasis then rests on the findings of the indirect fluorescent antibody test, antigen detection tests, and cardiopulmonary imaging. Circulating antibodies are usually detectable only in dogs without microfilaremia.

The **clinical signs** of canine dirofilariasis are usually those of *cardiovascular dysfunction*, such as cough and tiring on exercise, which may progress to congestive heart failure. Heartworm disease is usually seen in dogs that are older than five years and have had continuous or multiple infections. There is a rough correlation between the numbers of worms present and the severity of the disturbance, but there are exceptional cases, and severe signs may appear in dogs with only a few worms. Clinically normal dogs may harbor up to about 30 worms, and clinically affected dogs 50 to more. Dirofilariasis in cats usually causes cough and dyspnea, but may as well cause vomiting, neurological signs, and malaise; sudden death is another possible outcome.

Adult heartworms are normally found in the pulmonary arteries and right ventricle (Fig. 1.83), but may be found in the right atrium and venae cavae in heavy infestations. Young adult worms usually develop first in small pulmonary arteries, and progressively involve more proximal arteries as they grow. Adult worms may be found in the right ventricle if more than about 25 are present, and in the right

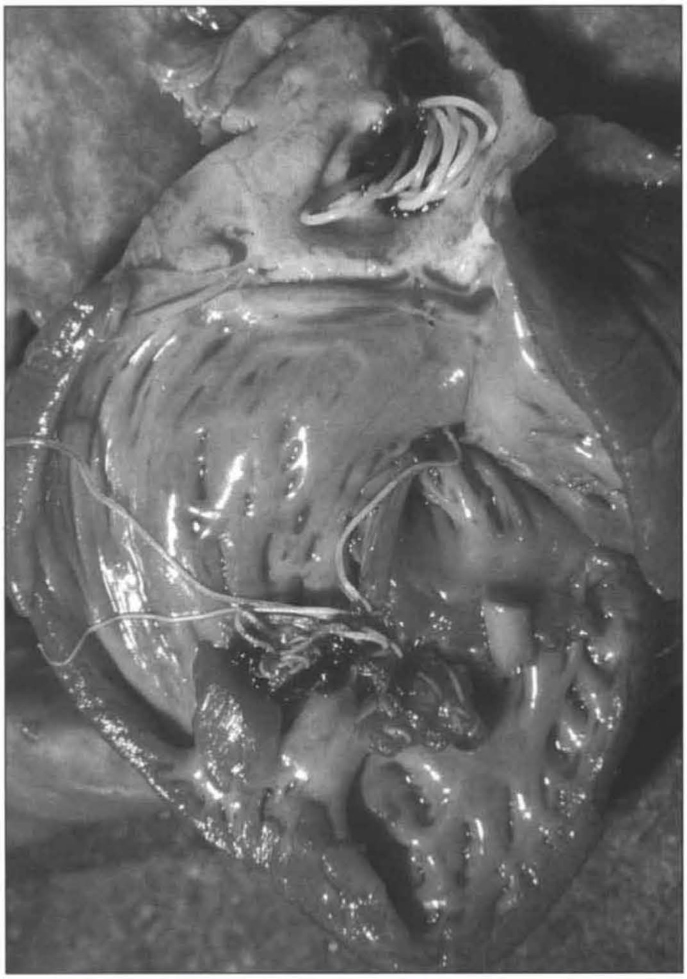

Figure 1.83 ***Dirofilaria immitis*** in right ventricle and pulmonary artery of a dog. (Courtesy of KG Thompson.)

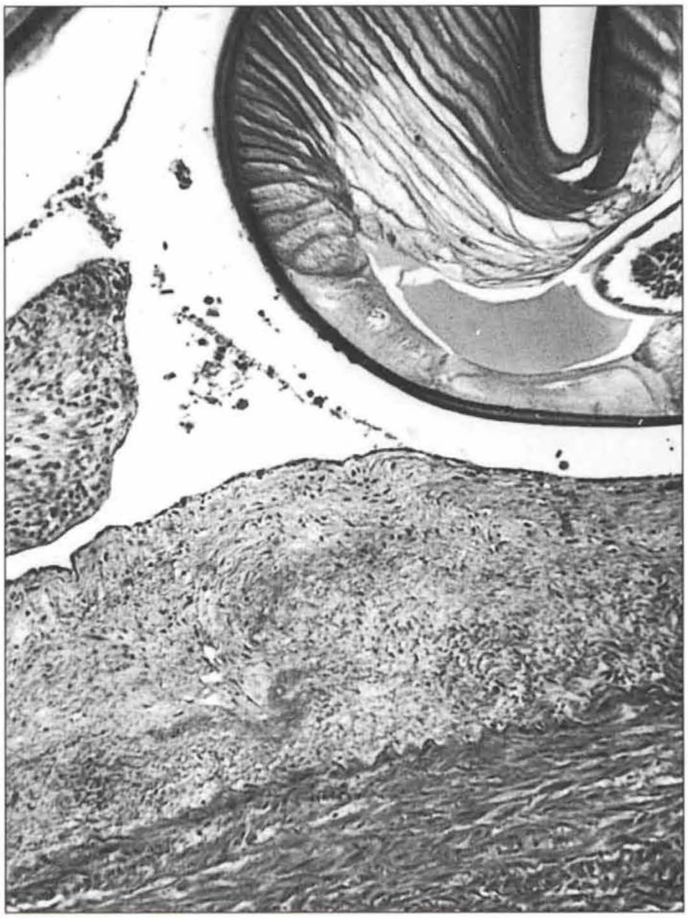

Figure 1.84 Sclerosis of pulmonary artery containing *Dirofilaria immitis* in a dog.

atrium and venae cavae if there are 50 or more worms. The caudal lobar pulmonary arteries are usually the most heavily infested vessels. Right heart failure develops as a consequence of *pulmonary hypertension*, which in turn is the result of pulmonary vascular sclerosis. Of secondary importance is mechanical interference of the worms with cardiac blood flow and valve function. Pulmonary sclerosis and hypertension slowly regress following removal of the adult worms.

Heartworm disease is primarily a pulmonary vascular disease, and is characterized by myointimal proliferations in small peripheral arteries initially, and later in the large lobar arteries, especially the right caudal lobar artery (Fig. 1.84). *The fibromuscular intimal proliferations in the larger vessels produce a grossly visible shaggy or roughened appearance, a change pathognomonic of heartworm disease.* The vascular reaction is to the immature and mature adult worms, and begins as an endoarteritis with infiltration of leukocytes, primarily eosinophils. Neutrophils are also present in the arterial wall, partly in response to the intracellular bacteria *Wolbachia* harbored by *D. immitis.* The leukocytic response subsides and is replaced by myointimal proliferation that produces irregular rugose to villus projections enmeshing the worms; the myointimal proliferation occurs at sites of direct contact with worms, is likely due to mechanical irritation and endothelial damage, and is possibly mediated by platelet-derived growth factor. *Thrombosis* may be associated with either live or dead worms, and *thromboembolism*, especially following adulticide therapy, may further exacerbate pulmonary hypertension; the presence of dead parasites initiates a granulomatous reaction in the vessel wall, which may extend into the pulmonary parenchyma. Thrombi may be organized and recanalized. Pulmonary infarction is an uncommon sequel to thromboembolism.

Pulmonary parenchymal changes that accompany the above vascular changes include periarterial granulomatous inflammation, hemosiderosis, diffuse interalveolar fibrosis, proliferation of alveolar epithelium, and fibrous pleural thickenings. Dead worms commonly incite *pulmonary granuloma formation.* Adulticide therapy causes embolization of worms and resulting thrombosis and granulomatous inflammation; resolution of these lesions is underway by 6 weeks post-treatment. Proliferative intimal lesions will progressively resolve after surgical removal of adult worms; resolution of advanced, fibrotic, obstructive arterial lesions is unlikely. Severe pulmonary arterial disease often results in chronic or low-grade DIC, and hence thrombocytopenia and hemoglobinuria. Microfilariae entrapped in the lung in a state of antibody excess are surrounded by neutrophils and eosinophils, producing *eosinophilic pneumonitis.* This allergic pneumonitis may be the precursor of *pulmonary eosinophilic granulomatosis*, which is characterized by 1–8 cm diameter nodules composed of eosinophils, lymphocytes, plasma cells, and macrophages, and devoid of microfilariae, plus peripheral blood eosinophilia.

Additional lesions of heartworm disease include those of *right heart failure*, such as chronic passive congestion of the liver, and occasionally ascites. *Membranoproliferative glomerulonephritis* occurs primarily due to glomerular deposition of immune complexes, either those formed in circulating blood in a state of antigen excess, or formed in situ in the glomeruli. The intensity of the immune-complex deposition varies directly with the intensity and duration of infection and the antibody response; the immune response may be to immature heartworms, microfilariae or adult heartworms. Physical damage to glomerular endothelium has been attributed to microfilariae. The result of glomerular disease in dirofilariasis is proteinuria, which is usually mild to moderate in severity. Renal failure and uremia are uncommon. Microfilariae are usually of little consequence to the dog, but when they die they may incite formation of microgranulomas in various organs, such as the lung, liver and kidney.

Aberrant migration of adult heartworms into the *systemic arterial circulation*, a rare event, results in thromboembolism and hence signs such as hindlimb lameness and interdigital ischemic necrosis.

The **vena caval syndrome** (venae cavae syndrome, liver failure syndrome) is a variant of heartworm disease seen usually in young dogs in which *large numbers of adult worms (100+) fill the right atrium and venae cavae*, likely as the result of retrograde migration from the pulmonary arteries. The syndrome is characterized by sudden onset of weakness, anorexia, bilirubinuria, hemoglobinuria, and anemia. Shock occurs because of obstruction and decreased venous return. The mass of worms may also interfere with valve function, causing tricuspid regurgitation, which together with pulmonary hypertension results in decreased left ventricular preload and congestive right ventricular failure. Hepatic congestion is very severe, hepatic lymphatics may be distended, and ascites may occur. Anemia develops due to right-atrial turbulence and shear-induced mechanical hemolysis, with perhaps microangiopathic hemolysis resulting from platelet activation and fibrin formation. Azotemia develops and death usually occurs in 1–3 days. Phlebosclerosis and thrombosis in the caudal vena cava and hepatic veins are similar to the reactions usually seen in the pulmonary arteries. Vena caval syndrome also occurs in cats, and untreated has a poor prognosis and high mortality rate in both dogs and cats; the treatment of choice is surgical removal of the heartworms.

Strongylus vulgaris in horses

Horses are commonly infected with both large and small strongyles (see Vol. 2, Alimentary system), but *by far the most damaging to the host is the large strongyle* ***Strongylus vulgaris***. While the adults of *S. vulgaris* share their large intestinal habitat with many other strongylids, *S. vulgaris* is the only strongylid to undergo development in the horse's arterial system.

The *usual route of migration* of *S. vulgaris* is as follows. Infective third-stage larvae are ingested, exsheath in the small intestine, penetrate the mucosa and submucosa of the small intestine, cecum, and colon within three days of infection, and molt to fourth stage larvae by day 7. The larval penetration of the gut can cause the formation of large subserosal hemorrhages, called *hemomelasma ilei*. The fourth stage larvae, which are about 1 mm long, penetrate submucosal arterioles, migrate in or on the intima of arterioles and arteries, being constrained by the internal elastic lamina from penetrating to the media, and reach the cranial mesenteric artery, the predilection site for further development, between day 11 and 21. After 3–4 months, the larvae molt to the fifth stage (immature adults, 10–18 mm long), return to the wall of the cecum and colon via the intestinal arteries, and are encapsulated in subserosal nodules before returning to the gut lumen as adults when the nodules rupture. The adults require another 6–8 weeks to reach sexual maturity. The prepatent period of *S. vulgaris* is thus about 6–7 months.

Virtually all horses are infected with Strongylus vulgaris and have arterial lesions due to larval migration, although the prevalence of *S. vulgaris* infection has been markedly diminished by benzimidazole and avermectin anthelmintics. A degree of resistance to verminous arteritis is slowly acquired under natural conditions, but horses of all ages remain susceptible to infection. **Lesions** range from the very common, but insignificant, *tortuous intimal tracks*, to the less common, but more serious, *occlusive thrombotic lesions*. Lesions of verminous arteritis are often incorrectly called "verminous aneurysms," but these dilations are usually thick-walled due to inflammation and scarring, rather than thinned. Saccular or fusiform aneurysms may occasionally result from weakening of the arterial wall. *Lesions occur most frequently in the cranial mesenteric artery and its extension, the ileocecocolic artery*. This apparent larval predilection has been suggested to fit a random-walk model in which the larvae sense blood vessel curvature, rather than direction of blood flow, migrate longitudinally along arteries, and are essentially trapped in the cranial mesenteric artery because of its perpendicular connection with the aorta, a border which most of the larvae do not cross. Larvae that spill over into the aorta may be considered as aberrant and lost to their species, in that they are unlikely to return to the cranial mesenteric artery and hence to the gut.

Tortuous intimal tracks consist of fibrin, necrotic debris, and a mixture of inflammatory cells, including eosinophils, in the intima (Fig. 1.85). The tracks become covered by endothelium, the fibrin is removed, and the tracks are converted to fibromusculoelastic thickenings. More extensive larval migration causes more extensive thromboarteritis. Small mural thrombi are formed about the larvae attached to the intima, and there is a reactive leukocytic infiltration, edema, and resultant degeneration of the elastic and muscle fibers of the underlying media. The initial acute inflammation persists as long as the parasite remains but is soon accompanied by a productive connective-tissue response, initiated by smooth muscle cells from the media, with attempted organization of the overlying thrombus and the accumulation of large numbers of mononuclear leukocytes. The proliferating connective tissues of the intima and adventitia may ultimately replace the normal structure of the arterial wall. The affected walls become solid and very thick and the affected artery may be up to 20 cm in its greatest diameter. The luminal surfaces of active arterial lesions are always rough and covered with layered thrombi in which the parasite is found partially embedded. It is usual to find some worms, both fourth-stage larvae and immature adults, in the thrombi, but the number of worms in any location in any one case varies from a few to several hundred. Following migration of the fifth stage larvae back to the intestine, or destruction of the larvae by anthelmintics, the intimal lesions resolve as fibrous intimal thickenings, and the luminal diameter will hence increase. The arterial wall thickness also decreases.

The lesions and accompanying worms are most common in the cranial mesenteric artery (Fig. 1.86) although they are also found elsewhere, including the aorta, the renal arteries, the celiac artery and its branches, and the spermatic vessels. They may be in any branch of the cranial mesenteric artery but are concentrated largely in the right division and the colic artery, which is its continuation, and, to a slightly lesser extent, in the cranial branch and its continuation, the right colic artery. The worms are rarely found in the aorta caudal to the origin of the renal vessels; they are relatively common about the origin of the cranial mesenteric and celiac arteries, and less common again in the thoracic aorta. Although this statement on the prevalence of lesions in the thoracic aorta applies to actively thrombotic lesions containing worms, it is probable that older, warty, mineralized lesions of the type often seen in the intima of the aortic arch have this origin (see Fig. 1.30A); they occur frequently in sites where active lesions occur. The lesions in the aortic bulb are located immediately proximal to the aortic valves on the cranial wall of the bulb and in the adjacent cranial aortic and caudal right aortic sinuses, but rarely in the caudal wall and the left sinus. This localization has been explained on the basis of the curve of the aortic arch and the axis of systolic ejection which should, theoretically, provide a zone of turbulence and relatively low velocity of blood flow in the cranial segment of the aortic bulb.

The *sequelae of verminous arteritis* due to *S. vulgaris* are varied and depend upon the location of the arteritis. Involvement of the cranial mesenteric artery is almost constant in horses, but untoward sequelae are much less common, no doubt due to the extensive collateral arterial circulation to the equine intestine, which may mitigate against the effects of frequent thromboembolic episodes. *Colic*, which is commonly caused in horses by *S. vulgaris* if parasite control is poor, may occur for a number of reasons: thromboembolism and intestinal

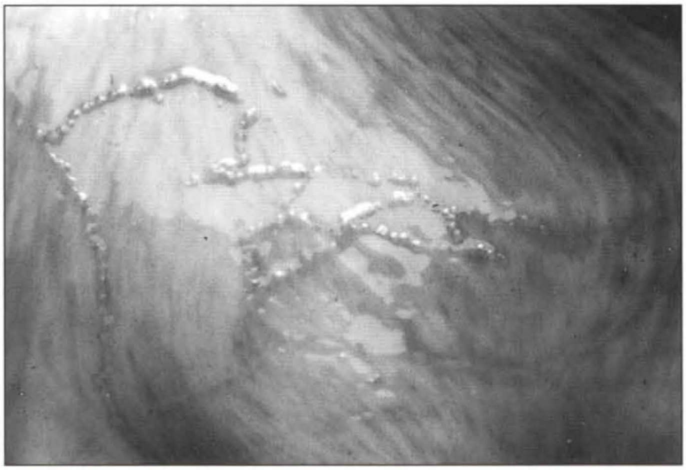

Figure 1.85 Tortuous intimal tracks due to *Strongylus vulgaris* migration in the aorta of a horse.

ischemia or infarction, interference with innervation of the gut due to pressure on abdominal autonomic plexuses, or release of toxic products from degenerating larvae. Fatal acute intestinal infarction occasionally ensues, with ischemia of large areas of the cecum or colon. Thromboembolism of the cecal and colic arteries may also lead to mucosal ulceration and diarrhea, and occasionally death. Hematochezia has been reported in a horse as a consequence of fistulous connections between a verminous cranial mesenteric arterial aneurysm and the cecum and ileum. As a result of successful suppression of *S. vulgaris* by anthelmintics, drug-resistant **cyathostomes** *(small strongyles)* have recently supplanted *S. vulgaris* as the most important cause of verminous colic. *Coronary arterial thrombosis and occlusion*, which occurs most commonly in the right coronary artery, can lead to myocardial infarction and death; similar consequences follow the development of verminous aortic valvular endocarditis (see Fig. 1.30A, B), a rare event in strongylosis. *Embolism of the brachiocephalic trunk* can occur and is especially significant when the emboli contain larvae that subsequently migrate in the brain causing encephalomalacia and either chronic incoordination or progressive fatal encephalitis. *Renal arterial verminous arteritis and thromboembolism* have resulted in renal infarction and, on rare occasions, passage of larvae in the urine. *Aortic-iliac thrombosis* may be a consequence of strongyle-related thromboembolism, but its pathogenesis remains uncertain. Thrombosis of the celiac artery and embolism of its branches is usually inconsequential.

Onchocerciasis (parasitic aortitis)

Onchocerca armillata *is a parasite of the wall of the aorta of cattle, water buffaloes, goats, and camels*, in south Asia and equatorial Africa. Several other *Onchocerca* spp. are described with tendons and aponeuroses under diseases of muscle in Vol. 1, Muscle and tendon. The life cycle and vectors involved in the transmission of *O. armillata* are unknown; however, black flies (*Simulium*) and midges (*Culicoides*) are the intermediate hosts of other *Onchocerca* spp.

Although virtually all older cattle may be infested in enzootic areas, the lesions produced are apparently not of clinical significance. *The preferential site is the arch of the aorta.* With chronicity, lesions extend cranially to include the brachiocephalic trunk, costocervical arteries, and brachial arteries, and caudally to include the abdominal aorta to the level of the iliac bifurcation. The intima is corrugated, and *numerous sinuous tunnelings end in small nodules in the intima and media*; the nodules protrude into the vascular lumen or through the adventitia. The males, which are about 7 cm long, inhabit the nodules along with the anterior end of the female, which bears the vaginal opening, and the microfilariae, which escape into the bloodstream. The body of the female lies in the sinuous tracts, from which the complete specimen cannot be readily dissected, but its length is estimated as >100 cm. Parasitic tunnels in the inner media have a thin fibrous tissue lining without cellular infiltration. There may be acute transmural aortitis with a predominance of eosinophils, but *subacute or chronic focal granulomatous inflammation is more frequent and occurs around tunnels containing dead, degenerate, or mineralized worms*. The granulomas in the media and adventitia become encapsulated by fibrous tissue to form nodules of 0.5–2.5 cm diameter containing caseous material and intact and/or dead worms, and eventually dry mineralized debris. The granulomatous reaction will resolve with time, and, in very old cattle, the aortic wall becomes thinner, has a corrugated lining with irregular mineralized ridges, and may develop aneurysms up to 3.5 cm in diameter. The suggested causes of the granulomatous aortitis include hypersensitivity to the parasite, foreign body reaction to degenerate and dead onchocercal worms, and the release of toxic factors from the parasites.

Microfilariae can be found in the blood of infected animals at all times, but there is a definite tendency to nocturnal periodicity; infection can be detected by examination of skin snips for microfilariae. In some bulls with large numbers of circulating microfilariae, repetitive episodes of collapse and tetanic convulsion have been observed and attributed to the microfilariae. Some of the bulls showing convulsions eventually developed acute or recurrent ophthalmitis with ophthalmoscopic evidence of retinal pigmentary degeneration and other changes similar to those seen in ocular onchocerciasis in humans.

Elaeophoriasis

The genus *Elaeophora* is another filarial parasite. Three species of interest are *E. poeli* and *E. schneideri*, which infect ruminants, and *E. bohmi*, a parasite of horses.

Elaeophora poeli occurs frequently in the *aorta of cattle and related species* in tropical areas of the Far East, but is of little clinical significance. Its life cycle is unknown. These are thread-like worms, the female of which may be up to 30 cm long. The lesions are found in the aorta and can be distinguished from those of *Onchocerca armillata* because the females of *E. poeli* are attached by the head with the body swinging free in the lumen of the vessel (Fig. 1.87). The males become encysted in intimal fibrous nodules that also contain the head of the female. In light infestations, the lesions are found chiefly on the dorsal wall of the aorta about the openings of the intercostal arteries. Heavy infestations are more diffuse and may provoke a prominent fibrous thickening of the vessel wall.

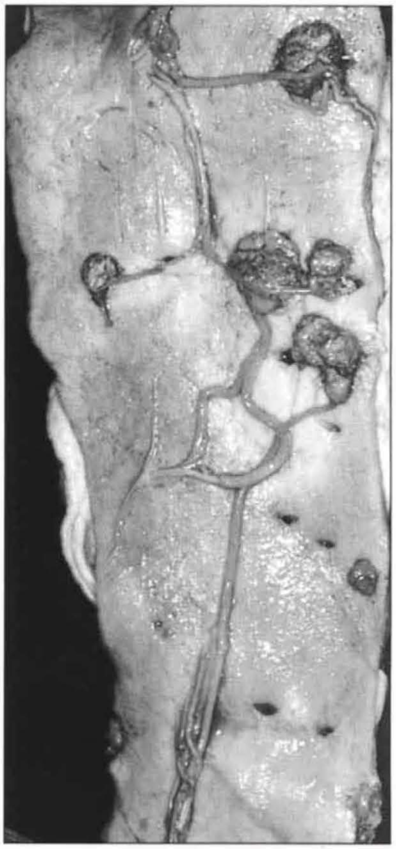

Figure 1.87 Intimal fibrous nodules in bovine aorta contain males and the heads of females of ***Elaeophora poeli***; the body of the female swings free in the aortic lumen. (Courtesy of PB Little and Can Vet J.)

Elaeophora schneideri is commonly found in the *arteries of mule deer and black-tailed deer*, as well as in white-tailed deer, domestic sheep and goats, elk (wapiti), moose, and bighorn sheep in mountainous areas of the western and southwestern USA and southwestern Canada, and in white-tailed deer in the southeastern USA. Mule deer and black-tailed deer are little affected by the parasite, and are considered the normal definitive hosts. Horseflies of the genera *Hybomitra* and *Tabanus* are the intermediate hosts. When the horsefly feeds, infective larvae invade the host and migrate to the leptomeningeal arteries, where they develop to immature adults that migrate against the blood flow to reside in the common carotid arteries. The parasites reach sexual maturity ~6 months later and begin producing microfilariae. Although adult worms normally inhabit the carotid arteries and their branches, they may be found in many other arteries through the body. Adult females are 6–12 cm long by 0.6–0.9 mm thick, and adult males are 5.5–8.5 cm long by 0.4–0.7 mm thick; adults live 3–4 years. Microfilariae are about 280 μm long by 18 μm thick, and are found in the capillaries of the forehead and face.

When larvae develop in the leptomeningeal arteries of elk, moose, domestic sheep and goats, sika deer, and possibly white-tailed deer, they can cause ischemic necrosis of brain tissue, resulting in "clear-eyed" blindness or sudden death. In elk, adult worms in the cephalic arteries cause mechanical irritation and hence endothelial damage, intimal proliferation and fibrosis, thrombosis, and embolism, which result in focal ischemia and infarction in the brain, eyes, optic nerves, ears, muzzle, nostrils, and other tissues of the head. Adult worms usually cause only mild intimal sclerosis in deer and sheep, and only rarely do they cause granulomatous verminous thrombosis. Microfilariae can cause multifocal myocardial infarction, myocarditis, and fibrosis in deer. Oral food impactions have been associated with *E. schneideri* in white-tailed deer, but a causal relationship has not been established.

Young domestic sheep and goats may develop nervous signs and die suddenly 3–5 weeks after infection as a result of thrombosis of cerebral and leptomeningeal arteries. In survivors, the most important consequence of elaeophorosis in sheep is *filarial dermatosis (sorehead)*, an often severe exudative dermatitis affecting the poll, face, abdomen, and lower parts of the legs, in up to 1% of sheep in enzootic areas. Stomatitis and rhinitis also occur. The lesions are due to microfilariae released by adult females located in arteries supplying the affected areas. Microfilariae can be demonstrated microscopically in the lesions and they are responsible for intense leukocytic infiltration, chiefly of eosinophils and mononuclear cells. There is hemorrhage, vesiculation, and ulceration of the epidermis with exudation of serum and leukocytes to form crusts. These lesions have the character of an allergic reaction and are presumably related to the alien nature of the sheep as a host, because they rarely occur in deer. The skin lesions are intensely pruritic and often lead to severe self-trauma. Lesions often persist for 3–4 years and will regress spontaneously following the death of adults and microfilariae.

Elaeophora bohmi was found in approximately 6% of a sample of Austrian horses, the vessels involved being arteries and veins of the metacarpus, metatarsus, and more distal extremities. The parasites rather selectively involve the media of the vessels avoiding the intima and adventitia, although the fibrous reaction that develops may cause stenosis of the lumen. The worms are coiled and entwined amongst the tissue layers, provoking *parasitic granulomas* with intense infiltration by eosinophils and macrophages. In cases of longer standing, diffuse or nodular fibrous thickenings are visible and palpable in the vessel walls. Microfilariae were found in the blood of 14 of 161 horses (9%) sampled in Iran. The infection appears to be of little clinical significance.

VEINS

Venous disorders may be of clinical significance by predisposing to thrombosis and subsequent embolism, or by obstructing venous return and hence causing passive congestion of the affected areas. Obstruction of venous outflow may be followed by the development of collateral venous drainage.

Anomalies of veins occur uncommonly. Arteriovenous fistulas have been discussed above with arterial anomalies. A variety of congenital **portosystemic anastomoses** occur in dogs and cats and allow portal blood, with its absorbed toxic substances, such as ammonia, to bypass the liver and cause hepatic encephalopathy. The most common of these defects is *persistent ductus venosus*. Other portosystemic anastomoses occur extrahepatically between the portal vein and various branches of the caudal vena cava or the azygous vein. As well, portosystemic anastomoses may be acquired due to portal hypertension, which in turn is caused by impedance of blood flow through a diseased liver, an obstructed portal vein, or a kinked intrathoracic caudal vena cava. *Hepatic microvascular dysplasia* can occur in dogs and cats in the absence of macroscopic portosystemic shunts, and result in similar clinical signs. Portosystemic anastomoses and hepatic encephalopathy are discussed in more detail with Diseases of the liver.

Dilation of a vein, variously termed *phlebectasia, varicosity, or aneurysm*, occurs but is of little or no importance. It is common as the so-called "*varicocele*" *of the pampiniform plexus*. Dilation may occur because of congenital defects such as venous diaphragms, agenesis, hypoplasia, or ectopia, or may occur secondary to trauma, neoplasia, or surgical intervention. The initial dilation causes insufficiency of the venous valves, and the veins may become dilated, elongated and tortuous. Thrombosis or sclerosis may be sequelae. The acquired portosystemic anastomoses noted above usually result from dilation of preexisting microscopic venous anastomoses to produce collateral venous drainage.

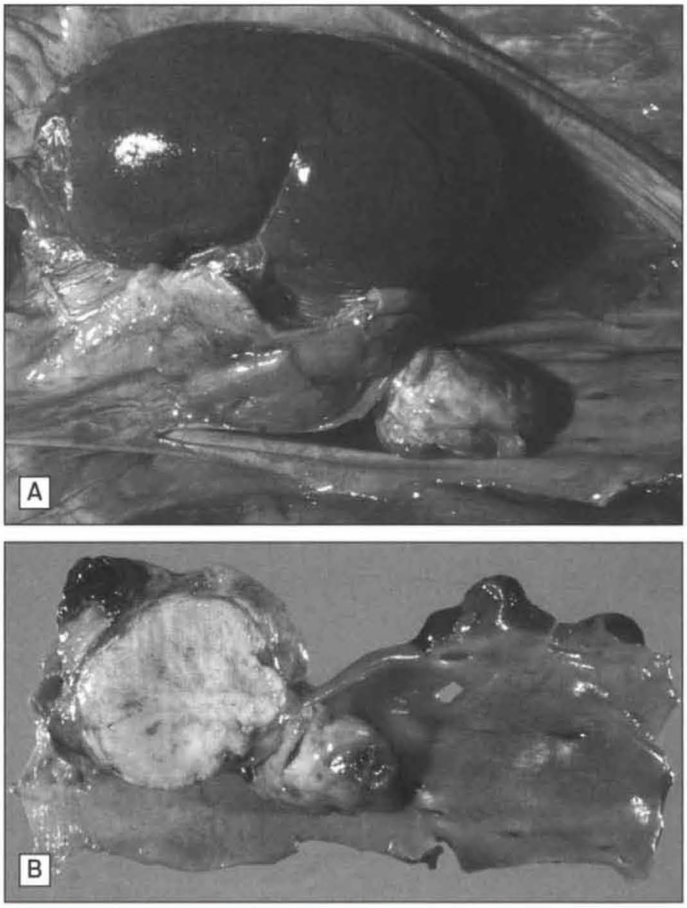

Figure 1.88 A. Pheochromocytoma of the right adrenal in an 8-year-old dog. **B.** Invasion of the caudal vena cava. The dog was found dead, but the pheochromocytoma was apparently functional as evidenced by acute catecholamine-induced myocardial necrosis.

Hepatic telangiectasis, peliosis hepatis, and hepatic "veno-occlusive disease" are described with diseases of the liver in Vol. 3, Liver and biliary system.

Rupture of a large vein, usually the result of physical trauma, may result in fatal hemorrhage. Spontaneous idiopathic rupture of the venae cavae or portal vein of horses occurs occasionally; rupture of the great coronary vein of the heart is a rare cause of unexpected death in horses.

Veins may be invaded by **neoplasms** (Fig. 1.88A, B), which may then metastasize, and may cause thrombosis or obstruction.

Phlebothrombosis and thrombophlebitis

Venous thrombosis (**phlebothrombosis**) results from the usual pathogenetic factors and often leads to inflammation of the vein wall, and hence becomes **thrombophlebitis**. Conversely, *phlebitis inevitably leads to thrombosis*. Spontaneous thrombosis affects the venae cavae and portal veins occasionally, and the inciting factors are usually unknown. *Neoplastic invasion*, e.g., by pheochromocytoma, is one cause of thrombosis of the caudal vena cava. Thrombosis of the renal vein and vena cava occasionally occurs in dogs with the *nephrotic syndrome* as a result of urinary loss of antithrombin and resulting hypercoagulability of the blood. Stasis of venous blood results in thrombosis of the femoral tributaries of cattle recumbent for more than 4–6 hours ("*downer cows*"). Venous infarction commonly ensues, and necrosis of the medial muscle masses and sciatic nerves causes permanent posterior paralysis. The thickened, congested, red-black mucosa of the gastric fundus in swine with acute septicemia is a *venous infarct* resulting from thrombosis of veins of the mucosa and submucosa, probably as a sequel to endothelial damage. *Gastrointestinal infarction and ulceration* can occur in phenylbutazone-intoxicated horses as a result of degeneration of veins and phlebothrombosis. Thrombosis of the *jugular veins* follows inept or repeated venipuncture, injection of irritant solutions, and the use of indwelling catheters, especially if contaminated with bacteria. Important sequelae to jugular thrombosis are pulmonary embolism, and, if the emboli are septic, valvular endocarditis and pulmonary abscessation.

Endophlebitis may result from the implantation of bacteria carried in the blood stream, as in salmonellosis, and from the injection of irritant solutions. An important form of acute suppurative endophlebitis is the *omphalophlebitis of the newborn* resulting from infection of the uncicatrized umbilical cord. The resultant bacteremia may result in acute death or give rise to widespread suppurative lesions, often polyarthritis. Hepatic thrombophlebitis is especially common in "navel-ill" (Fig. 1.89).

In *feline infectious peritonitis*, phlebitis occurs as a result of antigen–antibody complex deposition in the walls of small veins and venules, which is followed by complement fixation and neutrophil chemotaxis. Neutrophils cause tissue necrosis, and hence thrombophlebitis, which is followed by the focal pyogranulomatous reaction typical of this disease (Fig. 1.90).

Phlebitis very commonly occurs by extension from areas of inflammation, and importantly provides for the hematogenous dissemination of infection. The entire thickness of the wall of the vein is inflamed, and thrombosis occurs rapidly. If the thrombus is infected, it is likely to soften, disintegrate, and produce emboli. An important example of this pathogenetic sequence is *thrombosis of the caudal vena cava in cattle*, which occurs as a sequel to rumenitis and hepatic abscessation (Fig. 1.91). Perivascular hepatic abscesses often involve the vena cava causing thrombophlebitis and a variety of consequences: pulmonary thromboembolism and arteritis, pulmonary abscessation, or pulmonary arterial aneurysms that may rupture and cause massive pulmonary hemorrhage (Fig. 1.92). Valvular endocarditis is an occasional sequel. As well, the abscess may erode the wall of the vena cava wall and rupture into the vena cava, causing massive septic embolization and sudden death.

Parasitic thrombophlebitis

Schistosomes are important venous parasites in tropical Africa and Asia, and are discussed at length below. *Gurltia paralysans*, a metastrongyle, causes paralytic disease in domestic cats in South America. The adults lodge in the veins of the thigh and lumbar cord and cause thrombosis and ectasia.

Schistosomiasis (bilharziasis)

Schistosomiasis, a snail-borne fluke infection, is prevalent in domestic animals in Asia, Africa, and other tropical and subtropical areas, but does not usually occur as clinical disease; the importance of the disease may increase as irrigation projects enhance the habitat for the intermediate snail host. *Damage and clinical effects are the result of localization of permanently coupled adult male and female flukes in blood vessels of the liver, lungs, alimentary and urogenital tracts, and the nasal cavity.* Egg laying continues for many years, and schistosomiasis can be a disease of long chronicity.

Members of the family Schistosomatidae are the blood flukes of mammals and birds; species that parasitize mammals include those of the genera ***Schistosoma, Heterobilharzia***, and ***Orientobilharzia***. It is rather characteristic of the trematodes, including the blood flukes, that the intermediate stages are selective in their choice of hosts, mollusks, and that the infective and final phases do quite well in a variety of definitive hosts, although there is some host preference. The human schistosome, especially *S. japonicum*, may be discovered in domestic animals, and the mammalian schistosome may be discovered in man as patent or nonpatent infestations.

Based on egg morphology and intermediate snail hosts, the species that occur in domestic animals may be grouped as follows:

1. ***S. haematobium* group** – *S. bovis* in the portal and mesenteric veins of ruminants and occasionally horses, camels, and pigs, in southern Europe and tropical areas of Africa and Asia; *S. mattheei* in the portal and mesenteric veins, plus veins of the urogenital tract and stomach, of ruminants in central and southern Africa; *S. curassoni* in ruminants in west Africa; *S. margrebowiei* and *S. leiperi* in wild artiodactyls in central Africa.
2. ***S. mansoni* group** – *S. rodhaini* in dogs and other carnivores in central Africa.
3. ***S. indicum* group**, present in India and Southeast Asia – *S. spindale* in mesenteric veins of ruminants and, occasionally, of horses and dogs; *S. nasale* in nasal mucosal veins of cattle and, occasionally, of goats and horses; *S. indicum* in portal and mesenteric veins of herbivores; *S. incognitum* in swine and dogs.
4. ***S. japonicum* group** – *S. japonicum*, human by preference, in all domestic animals in the Far East; *S. mekongi* in dogs and humans in Southeast Asia.

Schistosoma bovis and *S. japonicum* are the most pathogenic of the schistosomes of cattle and sheep. Mixed infections with more than one species of schistosome occur; hybridization may occur in this circumstance.

Other members of the family Schistosomatidae of veterinary significance include: *Orientobilharzia turkestanicum* in mesenteric veins of herbivores and cats in the Near East, Russia, China, and Mongolia; *O. dattai* and *O. bomfordi* in artiodactyls in India; and *Heterobilharzia americana* in raccoons, bobcats, white-tailed deer, and occasionally dogs, in the southern USA.

The life cycles of the schistosomes are comparable to those of other flukes and follow the general pattern described elsewhere for the liver fluke, *Fasciola hepatica*. As a point of difference, the redia phase of *F. hepatica* in the intermediate host is replaced in the schistosome by a generation of daughter sporocysts.

The eggs of the schistosome are laid in the vessels that the adults inhabit. The eggs when laid are immature but contain a miracidium by the time they have worked their way through the overlying mucous membrane to escape to the exterior. The eggs hatch in water and the miracidia actively penetrate the soft tissues of aquatic snails to which they are physiologically adapted. The fork-tailed cercariae that emerge from the snail are the infective phase, and they enter the definitive host by burrowing through the skin; patent infestations can also develop if the cercariae are ingested with water. They will invade the skin of hosts that are quite alien to them, provoking allergic reactions and dermatitis (swimmer's itch, swamp itch).

Cutaneous lesions develop as a result of penetration of the skin by cercariae. They occur only on those portions of the skin that come in contact with infested water and are seldom observed in animals except under experimental conditions. The cutaneous lesions are tiny petechiated nodules in which there is a sharp leukocytic reaction to the parasite. Passage of a large number of parasites through the lungs will produce pneumonia. Ectopic localization in various organs, such as the kidney, produces small hemorrhages and inflammatory foci.

In the definitive host, the cercariae lose their tails and become *schistosomula*, which enter venules in the dermis and, thereafter, are conveyed passively in the blood, through the lungs, and into the systemic circulation. Once in the blood, there is probably no selective migration; those that are distributed to the vessels of their final habitat develop further and those that are distributed to other organs die. *Schistosoma nasale* develops in the veins of the nasal mucosa; all other species develop in veins of the abdominal cavity, principally in the portal vessels, until sexual maturity is attained, when they migrate out to the smaller veins of the mesentery (Fig. 1.93). In long-standing infections, *S. mattheei* may reside in veins of the urinary bladder as well as in portomesenteric veins. The prepatent period in the mammalian host ranges from 30 to 77 days.

In clinical cases of *schistosomiasis of portomesenteric distribution*, the animals are anemic, and may be severely emaciated in fatal cases. Diarrhea or dysentery occur at the time of patency, persist for a few weeks, and, in the absence of re-infection, may be followed by spontaneous recovery as the immune response of the host eliminates the parasites and suppresses the egg laying of survivors. The eggs can be found in the feces together with some mucus and blood. Blood loss leads to anemia and hypoalbuminemia, which may contribute to the presence of fluid in serous cavities. The wall of the intestine, chiefly the *large bowel*, is thickened by inflammatory and scar tissue, and may

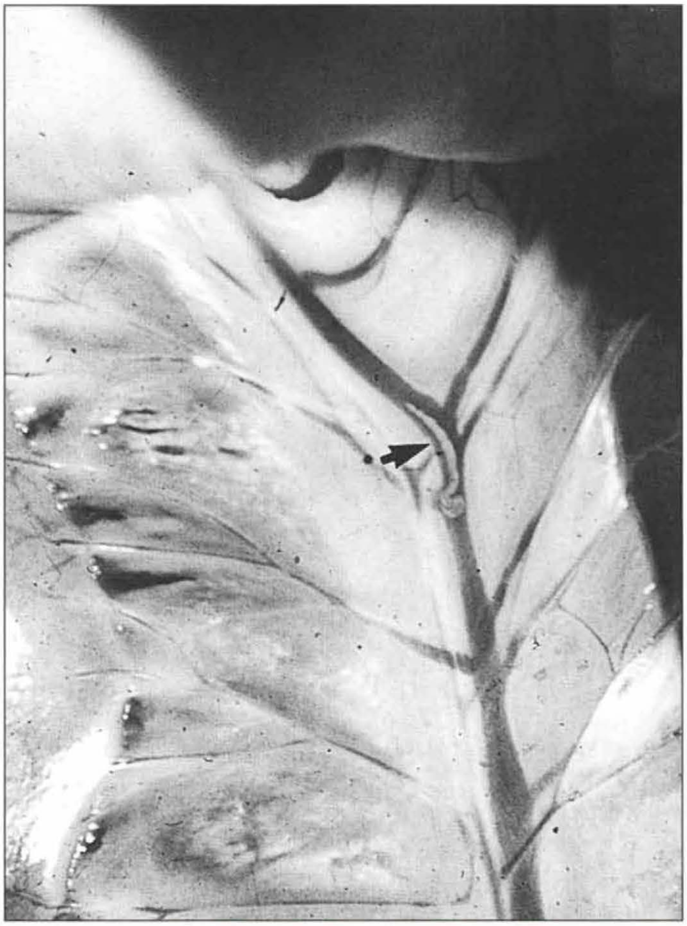

Figure 1.93 Adult **schistosome** (arrow) in a mesenteric vein in a lamb.

contain small granulomas and lymphoid nodules. Scarring begins in the mucosa and extends to involve all layers, including the serosa. The mucosa may bear polypoid and papillary proliferations. The mesentery is thickened and shortened by fibrous tissue, and the mesenteric nodes are enlarged and fibrotic. The adult parasites, which are about 1–3 cm long, can be found in the mesenteric and portal vessels. There is *fibrosis of the liver* of variable degree affecting particularly the portal vessels. The liver may be enlarged or small depending on the course and severity of the infestation. On cut surface, the periportal nature of the fibrosis is quite apparent but, with time and more severe infestations, the fibrosis becomes more diffuse and the surface of the liver may have a hobnailed appearance or be studded by numerous minute granulomas.

Proliferative granulomatous nasal lesions produced by *S. nasale* result in clinical signs of dyspnea and mouth breathing. Granulomatous lesions are frequently present in the *urinary bladder and ureters* of cattle with *S. mattheei* infection; lesions in the ureters, and occasionally renal pelvis, are linear, while those in the bladder become very extensive and polypoid.

The stage of oviposition and extrusion of eggs through the tissues and mucous membranes is the stage in which most damage is done. The mated schistosomes, in permanent copula, move out into the smallest venous radicles and the eggs are deposited first in the lumen of the vessel. They adhere to, and are eventually covered by, the endothelium. The eggs of some species are spinous and this probably facilitates passive migration into the tissue. The migration does appear, however, to be partly active by virtue of secretions elaborated by the developing miracidium, which diffuse through the shell of the egg into the tissues. These secretions may be also in part responsible for inciting the inflammatory reaction to the eggs. Initially most of the eggs are deposited in the lamina propria of the intestine, and break into the lumen with little more than mechanical injury. Rupture of congested mucosal venules accounts for the characteristic dysentery of schistosomiasis. Also contributing to diarrhea, loss of body condition, and failure to thrive are ganglionitis and degeneration of the enteric nervous system, which may result from a localized type I hypersensitivity reaction involving mast cell-derived chemical mediators.

As the disease progresses and the adults are excluded from smaller venules due to endophlebitis, eggs are laid in veins in deeper tissues where antigens released by the miracidium induce a delayed hypersensitivity response and formation of small granulomas ("*pseudotubercles*"). The granulomas are characterized initially by the infiltration of leukocytes, chiefly eosinophils, and later by the accumulation of mononuclear leukocytes, epithelioid and giant cells, and reactive fibrosis. Microabscesses occasionally form and rupture into the gut lumen. Eggs in submucosal granulomas degenerate and are removed, or may be mineralized and remain for a longer period of time. Some of the mature or disintegrating eggs may be coated with a bright eosinophilic deposit (*the Splendore–Hoeppli reaction*), the result of antigen–antibody complex formation. The granulomas gradually regress and are replaced by fibrous tissue. Host cell responses to eggs are primarily the result of host hypersensitivity to soluble egg antigens, and to a much lesser degree due to physical and chemical stimuli.

As would be expected, not all the eggs move in the proper direction. Some break into lymphatics and are conveyed to the regional nodes to produce granulomas but, more importantly, a great many of them pass to the liver producing portal phlebitis and granulomatous hepatitis, in concert with the adult flukes. In heavy infestations and possibly by means of venous shunts developed in the liver, many eggs may pass in venous blood to and beyond the lungs, producing granulomatous endoarteritis and adjacent granulomas wherever they lodge. The development of hepatic lesions follows the same course as for those that develop in the intestinal wall. In the liver, the eggs break out of the portal venules to become enclosed by granulomas. Sooner or later, they die and are mineralized, and by that time have provoked extensive surrounding fibrosis. The above course of events occurs similarly in urinary schistosomiasis caused by *S. mattheei*, wherein hematuria accompanies excretion of eggs in the urine, and *granulomatous cystitis and ureteritis* result from the host's immunological response to the schistosome eggs trapped in the tissues.

Adult schistosomes in mesenteric and portal veins elicit eosinophilic endophlebitis, often with irregular intimal proliferation, and may be found within thrombi. Adults may similarly cause reactions in veins of the pancreas and the mesenteric and portal lymph nodes, and in pulmonary arterioles. The dead parasites are removed by a granulomatous reaction that is often followed by the formation of a grossly visible lymphoid nodule. The lumen of the vein may be occluded, and the venous wall obliterated, by this lymphoid response. There may also be diffuse intimal proliferation and endophlebitis of intrahepatic portal veins, medial hypertrophy, and adventitial inflammation and fibrosis leading to prominent portal fibrosis, which may appear grossly as "clay pipe-stem" portal fibrosis. Irregular dilated vascular bypasses develop in the portal areas. The adults ingest erythrocytes and regurgitate hematin pigments, which are picked up by the monocyte-macrophage system, especially in the regional lymph nodes and liver; these black iron-porphyrin pigments may be responsible for the gray color of the liver and lungs in severe cases of schistosomiasis.

LYMPHATICS

The richness of the lymphatic plexuses in almost all tissues and their important role as drainage channels for interstitial fluid makes for almost inevitable involvement of lymphatics by any inflammation and by the many neoplasms that metastasize via lymph channels. In most instances, the lymphatic lesions are so small as to have no significance, but in some cases the consequence of lymphatic involvement may be the major presenting clinical sign or lesion. Such, for example, is the case when attention is drawn to papillary carcinoma of the canine ovary by severe ascites; disrupted portions of the neoplasm permeate and obstruct the ventral diaphragmatic lymphatics, which are the main efferent channels of the peritoneal cavity.

Lymphedema *is defined as swelling of a part of the body by an increased quantity of lymph due to a lymphatic system disorder.* The term should not be used to describe edematous swellings due to venostasis, hypoproteinemia, heart failure, or cellulitis. Lymphedema may be classified as primary or secondary:

- *Primary lymphedema,* which is usually congenital, and may be hereditary, is due to anomalous development of the lymphatic system.
- *Secondary lymphedema* occurs because of obstruction of previously normal lymphatics, due to inflammation, neoplasia, surgery or trauma.

Lymphedema is of significance because it may predispose the affected area, usually a limb, to secondary bacterial infection and poor wound healing. *Prolonged lymphedema leads to fibrosis.*

A **lymphocele** is a lymph-filled space that does not have a distinct endothelial lining, and may be the result of disruption of lymphatics by trauma or surgery.

Congenital anomalies

There are many degrees of variation of the standard disposition of the large lymphatic vessels but these are of no importance. *Epicardial lymphatics in horses* are occasionally dilated and tortuous, and may be anomalous; they are of no apparent significance (Fig. 1.94).

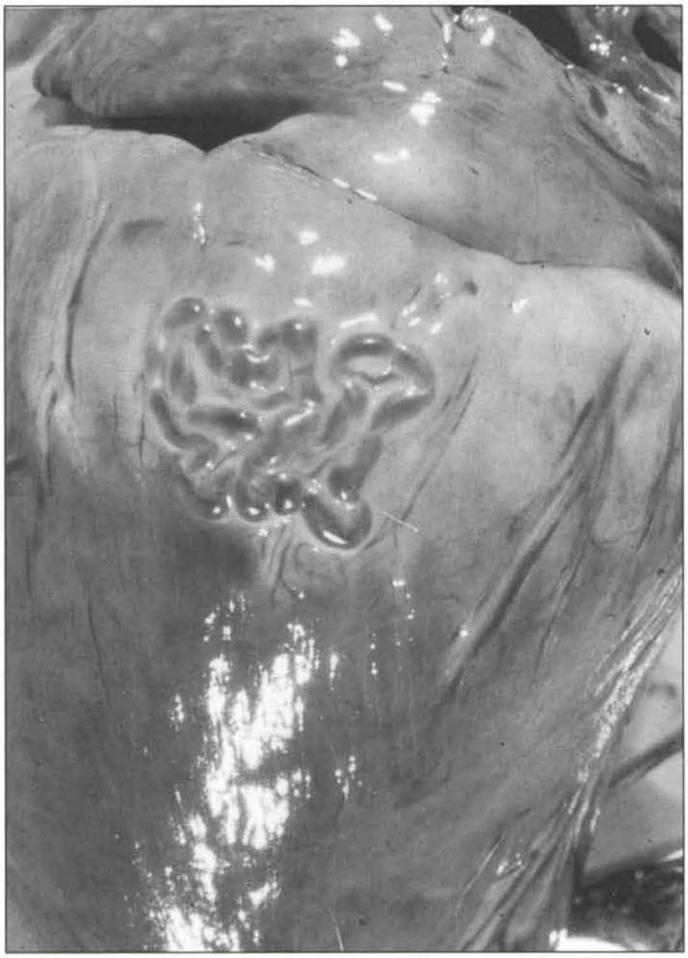

Figure 1.94 Dilated epicardial lymphatics in a foal.

Congenital hereditary lymphedema is a rare condition that has been reported in *calves, dogs, and pigs.* The lymphatic abnormality is inherited as an autosomal dominant trait in most cases examined. One of the regulators of lymphatic vasculature formation is T1α/podoplanin, a mucin-type transmembrane glycoprotein that is predominantly expressed by lymphatic endothelium and is regulated by the lymphatic-specific gene *Prox1.* T1α/podoplanin(–/–) mice die at birth and have defects in lymphatic vessel formation with consequent congenital lymphedema.

The central lymphatic system normally forms as outgrowths from the endothelium of primitive veins, and subsequent outgrowths form the peripheral lymphatic system. The primary lymph nodes develop from the primitive central lymphatic anlagen, the jugular and iliac lymph sacs. Secondary and tertiary lymph nodes later form along the peripheral lymphatic system and are the most severely affected nodes in congenital lymphedema. The earlier the stage at which lymphatic malformation occurs, that is, the more central the lesion, the more severe will be the clinical manifestations and the earlier will be their onset.

Grossly, the most severely affected individuals have generalized subcutaneous edema and fluid in serous cavities and are stillborn or must be delivered by cesarean section. The mortality rate of Ayrshire cows with lymphedematous fetuses has been high. Moderate degrees of lymphedema are seen as symmetrical swelling of the head, neck, limbs, and tail. The ears of lymphedematous calves often have edematous accessory lobes. Lesser degrees of lymphedema affect the distal parts of the limbs, especially the hindlimbs, and may not develop for several weeks postnatally. Mild regional lymphedema may be of little significance, although chronic subcutaneous edema will lead to fibrosis and may predispose to secondary bacterial infection. Mild lymphedema affecting only the hindlimbs will in some cases disappear, presumably due to postnatal development of the peripheral lymphatic system. The peripheral lymph nodes are usually smaller than normal or absent in affected animals. Although obstruction may be demonstrated by lymphangiography, nodal hypoplasia or absence does not necessarily lead to obstruction. Afferent and efferent nodal sinuses may be dilated and may be evident on gross examination. The thoracic duct may be dilated and tortuous in generalized lymphedema.

Histologically, a wide range of lymphatic abnormalities may be seen in the edematous, and possibly fibrotic, subcutis of affected areas. The lymphatics may be: *aplastic*, that is, no lymphatics are found; *hypoplastic*, in which case lymphatics are too few or too small; *or hyperplastic, or varicose*, in which case lymphatics are excessive in size and number, and dilation has resulted in valvular incompetence and lymphostasis. Ectatic lymph channels are commonly present around and within hypoplastic peripheral lymph nodes. Central nodes are similarly affected in animals with generalized lymphedema, and will be absent in cases of lymphvascular agenesis.

Dilation and rupture of lymphatics

Dilation of normally developed lymphatic vessels (**lymphangiectasis**) *almost invariably results from some form of obstruction and leads to the accumulation of excess interstitial fluid in the drainage area.* Causes of such lymphatic obstruction include infiltrating neoplasms that may obstruct the lymphatic vessel or the drainage node, inflammatory thrombosis and sclerosis of the channels or nodal sinuses, and postsurgical scarring. The vessels become irregularly dilated and tortuous distal to the obstruction and the accompanying increase in interstitial fluid, if persistent, will cause an increase in interstitial and subcutaneous fibrous tissue.

Intestinal lymphangiectasis is the most common cause of *protein-losing enteropathy in dogs*, and contributes to intestinal protein loss in *cattle with Johne's disease and other enteritides*. Dilated lacteals in intestinal villi rupture or leak their contents into the intestinal lumen and severe hypoproteinemia can result. Leakage of protein from capillaries in the villi may also be an important contributor to protein loss. Chyle may leak from dilated subserosal lymphatics and contribute to the hypoproteinemia-induced ascites.

Chylothorax, the result of *leakage or rupture of the thoracic duct*, occurs infrequently in dogs and cats. The cause of chylothorax is usually not apparent; rupture due to thoracic trauma is often postulated but rarely proven. An injured thoracic duct has limited capacity for spontaneous healing. Reported causes of chylothorax include neoplasia, right-sided heart failure, dirofilariasis, thrombosis of the cranial vena cava, congenital anomaly of the thoracic duct, and fungal infections; many cases appear to develop spontaneously. Obstruction of thoracic duct drainage may lead to lymphangiectasis of intrathoracic lymphatics and leakage of chyle. **Chylopericardium** is an unusual accompaniment of chylothorax. The *diagnosis of chylothorax* is confirmed by analysis of the pleural fluid, which is opalescent to opaque, milky-white to yellow, and on standing forms a top layer of cream (chylomicron fat) that is ether-soluble. Microscopically, the fluid contains large numbers of lymphocytes, a few neutrophils, red cells, plasma cells, and fat globules. The site of the rupture is often difficult to locate surgically or at autopsy. Ligation of the thoracic duct leads to the development of alternative lymphaticovenous anastomoses, and cessation of the chylothorax.

Chylous ascites results from rupture of the cisterna chyli, and is a rare event.

Lymphangitis

Lymphangitis with anatomic specificity is a prominent feature of a number of specific diseases. Most of the diseases are discussed elsewhere but warrant brief mention here also. Acute thrombotic lymphangitis, the thrombi containing large numbers of bacilli, with a marked tendency towards necrosis, is a feature of the restricted form of *anthrax* that is seen in pigs, dogs, and horses. Granulomatous lymphangitis occurs typically in *mycobacterial infections*; the mesenteric lymphatics stand out like threads beneath the serosa in Johne's disease, and are often beaded in intestinal tuberculosis; they bear the specific microscopic lesions of these infections (Fig. 1.95). The spread of *actinobacillosis* can often be discerned as long rows of small granulomas from the site of primary infection on the way to the regional nodes. The corded and nodular ulcerating lymphangitis of *cutaneous glanders* in horses must be distinguished from the specific forms of lymphangitis discussed below. Lymphangitis is often a prominent development in *cutaneous streptothricosis* in cattle, and can occur in various species with *cutaneous sporotrichosis*. Lipogranulomatous lymphangitis has been found in association with *intestinal lymphangiectasis* in dogs.

Bovine farcy is a chronic granulomatous disease of cattle in the tropics, and is characterized by nodular suppurative dermatitis, lymphangitis, and lymphadenitis. Most cases of bovine farcy are caused by *Mycobacterium farcinogenes* or *M. senegalense*.

Sporadic lymphangitis, *a nonspecific, nonulcerative lymphangitis affecting the hind legs of horses*, is relatively common. Synonyms include Monday morning disease, bigleg, and weed. The disease is ushered

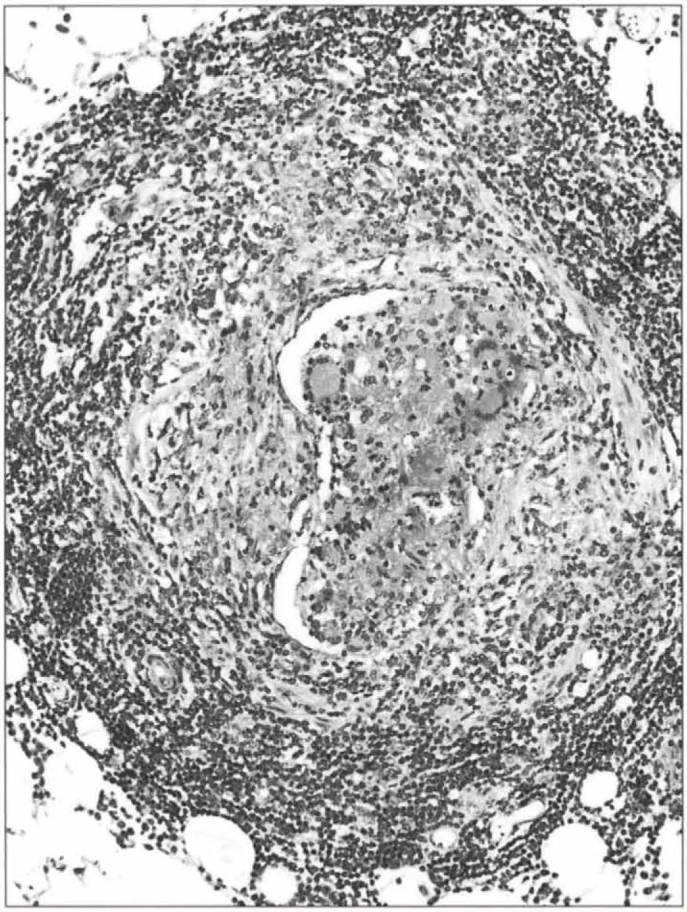

Figure 1.95 Lymphangitis in the ileal mesentery in Johne's disease. Note granulomatous inflammation with multinucleated giant cells.

in by acute lameness and severe cording of the lymphatics, although this is usually palpable only where the lymphatics lie near the saphenous vein on the inner aspect of the thigh. The limb swells rapidly, the swelling beginning about the pastern or metatarsus and reaching its zenith in 3 or 4 days, by which time it has usually extended beyond the stifle. There are transient general disturbances associated with fever. Recovery is usual although repeated attacks may occur and some cases are fatal, presumably as a result of septicemia. There is edema of the connective tissues of the distal portion of the limb with very rapid fibroplasia. Above the stifle, the edema is largely confined to the subcutis, this probably depending on the arrangement of fascia there. The lymphatics are dilated and the larger ones contain thick pus or a thinner mixture of pus and lymph. There is regional acute lymphadenitis.

The cause and pathogenesis of sporadic lymphangitis are unknown. Various pyogenic organisms have been recovered from the lesions, but it appears that, in the usual case, the initial acute infection is rapidly overcome. The occurrence of the disease after a period of inactivity, and the experimental production of a similar lesion by inoculation of bacteria into skin of the pasterns in undernourished horses, suggests that "stocking" of the hindlimbs (stagnant edema that is common in debilitated horses in periods of inactivity), predisposes to the progress of infection. However, most horses with stocking of the hindlimbs do not develop lymphangitis. The entry of infection is probably traumatic.

Ulcerative lymphangitis

This is a chronic progressive inflammation of the subcutaneous lymphatics of horses. ***Corynebacterium pseudotuberculosis*** *(ovis)* is the cause of the classical condition, but similar lesions may be caused by other pyogenic organisms, including streptococci, staphylococci, *Rhodococcus equi*, and *Pseudomonas aeruginosa*. Two biotypes of *C. pseudotuberculosis* are recognized: a nitrate-negative type isolated from sheep and goats, and a nitrate-positive type isolated from horses and cattle. *Corynebacterium pseudotuberculosis* produces a potent phospholipase exotoxin that attacks the sphingomyelin of vascular endothelial cells, and may be important in aiding the spread of the bacteria by acting as a permeability factor. Ulcerative lymphangitis was an important cause of debility in the horse era, but is *now sporadic and rather rare*.

Some features of the biology of *C. pseudotuberculosis* are discussed with caseous lymphadenitis. In that disease, as in ulcerative lymphangitis, the infection begins in cutaneous wounds. *Ulcerative lymphangitis typically begins about the fetlocks of the hindlimbs.* As a result of lymphangitis, there is diffuse swelling in the leg soon followed by development of dermal nodules. These are abscesses that ulcerate and discharge thick creamy pus that may be bloodstained. Only a small area of skin may be sloughed so that, usually, the margins of the ulcer are undermined. The ulcers heal and leave small areas of depilated, depigmented skin. As the primary ulcers heal, new nodules form in adjacent skin, suppurate, ulcerate, and cicatrize, and in this way the disease progresses slowly. As the new nodules develop, the lymphatics between them become corded and as much as 1–2 cm thick, and fresh abscesses develop along the inflamed vessels. In uncontrolled infections, over a course of many months much of the skin of the body and neck as well as the limbs may be affected, and this leads to death. Typically, the regional lymph nodes, although moderately enlarged, do not become suppurative or fibrotic. In rare instances, bacteremia results in internal dissemination, especially to the kidneys.

Ulcerative lymphangitis also occurs in **cattle**, but as well as affecting the distal portions of the limbs, as in horses, the initial lesions may also develop within the dermis or subcutis of the neck, shoulder or flank. The initial abscesses are large and may be >5 cm in diameter. Extending away from them are thickened lymphatics along which new abscesses develop. The abscesses ulcerate on the skin and the ulcers persist, oozing a serum-like exudate. There is early lymphadenitis with swelling of the node and its fixation to the surrounding tissue. The inflammation spreads slowly and there is progressive suppurative lymphadenitis.

The equine biotype of *Corynebacterium pseudotuberculosis* causes *deep pectoral and ventral abdominal wall abscesses in horses* in the southwestern USA. The transmission of *C. pseudotuberculosis* in these cases is obscure, but may be by arthropod vectors. Ulcerative lymphangitis does not occur; dissemination is by bacteremia. Untoward sequelae include prolonged resolution of the abscesses, multiple and internal abscessation, and abortion.

Epizootic lymphangitis

Epizootic lymphangitis, or *pseudofarcy*, is caused by ***Histoplasma capsulatum* var. *farciminosum*** (HCF) and clinically *resembles ulcerative lymphangitis and cutaneous glanders ("farcy")*. Epizootic lymphangitis occurs almost exclusively in *horses and mules*. "*Equine histoplasmosis*" is probably a more appropriate name, since HCF infection may be manifest as keratoconjunctivitis or pneumonia in the absence of past or concurrent lymphangitis.

Epizootic lymphangitis is enzootic in some Mediterranean countries, Africa, and the Near and Far East. The organism apparently exists as a soil saprophyte, and *enters the body through skin wounds of the lower limbs* to cause the classical epizootic lymphangitis, but may also invade castration wounds, ruptured abscessed lymph nodes after strangles, and gastric ulcers. *Histoplasma farciminosum* may cause sinusitis, and/or pneumonia via inhalation of contaminated dust, may cause rhinitis by contact with skin lesions, and may be transmitted by flies (*Musca* and *Stomoxys*) to cause keratoconjunctivitis.

The initial cutaneous lesion, or focus of infection in a wound, has a tendency to ulcerate, or it may undergo alternating periods of discharge and closure for some weeks before healing and scarifying. The infection may resolve, but often spreads centripetally in the adjacent tissues and along the lymphatics. In the adjacent tissues, which are swollen, small nodules develop (Fig. 1.96) which are about 1 cm in diameter and, in the course of a few days, these ulcerate to discharge at first a viscid gray exudate and, later, pus. The initial lesions are intradermal and are freely movable over the subcutaneous tissue. Spread of the infection is solely via the lymphatics and these convey the organisms into the subcutaneous and, occasionally, into the deeper tissues. The inflamed lymphatics are thickened and hard, and along their course new nodules form, ulcerate, discharge, and eventually heal with scarification, although there may be alternating periods of activity and quiescence with the growth of excessive granulation tissue. Sometimes the ulcers continue to enlarge and may coalesce. In this way, *the cutaneous infection spreads gradually but irregularly, but is always characterized by intradermal and subcutaneous nodules, ulcers, and irregularly swollen lymphatics*. In the early stages, the skin between the lesions remains normal and mobile, but in areas of extensive ulceration it becomes very thick, indurated, and firmly fused to the underlying tissues. When the thickened skin is incised, it presents the lardaceous appearance of granulation tissue in the horse and contains a number of small, yellow, purulent foci between which course the lymphatics, dilated and filled with pus and serous fluid. The regional lymph nodes are regularly involved and swollen. In the early stages, the swollen nodes contain many small foci of softening, but later the foci coalesce and are heavily encapsulated. The nodes may rupture. The condition is usually chronic, persisting for 3–12 months, and causes considerable debility, but low mortality.

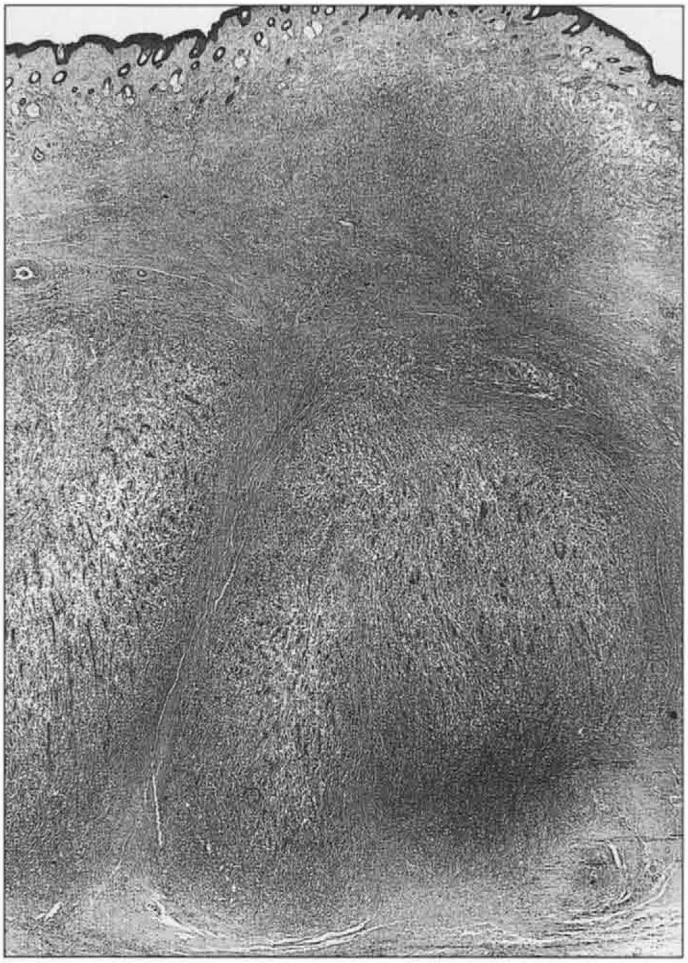

Figure 1.96 Intradermal nodes in **epizootic lymphangitis**. (Courtesy of DR Cordy.)

The disease may begin quite frequently on the *conjunctiva or nictitating membrane*, producing at first a small papule and a serous conjunctival discharge. The papules ulcerate to form flat, button-like growths of granulation tissue, the eyelids become severely swollen, and the inflammation extends to the tissues of the forehead.

Nasal infection is usually accompanied by a mucopurulent discharge containing large numbers of the fungus, and may be bloodstained. The lesions begin as yellow flat papules or nodules on the nasal mucosa and these soon break down to form craterous granulating ulcers that bleed easily. The nasal lesions are usually found near the external nares and they may extend from there on to the muzzle, or they may be found deep in the nasal cavity and in the pharynx. Similar lesions may occur in the nasal sinuses, the larynx, and the bronchi.

The *pulmonary lesions* may be solid granulomatous areas or they may be liquefied with pus-like contents. When ulcerative lesions are present on the nasal mucosa, there is suppurative regional lymphadenitis. The typical nodules of epizootic lymphangitis and the liquefied foci that form in deep tissues may also be found in the pleura, spleen, liver, testes, tunica vaginalis, and bone marrow.

The **diagnosis** of epizootic lymphangitis depends upon *demonstration of the fungus*, which is usually present in very large numbers in the contents of the nodules and fresh discharges from ulcers. The parasitic phase of the fungus is yeast-like, gram-positive, globose or oval in shape, and 2–3 μm in diameter. It occurs extracellularly and intracellularly in macrophages. The fluorescent antibody test is an effective means of diagnosis. In histologic sections, the organism is similar to *H. capsulatum*, consisting of a basophilic nuclear mass and thin capsule that can be demonstrated by stains for polysaccharides.

Parasitic lymphangitis

Filariid worms of the genus **Brugia** (syn. *Wuchereria*) parasitize the lymphatic system of dogs and cats in tropical areas. *Brugia malayi* occurs in cats and primates in India and Malaysia; cats may be reservoir hosts for human infection. *Brugia patei* occurs in dogs and cats in Africa, *B. pahangi* in dogs and cats in Africa and the East, and *B. ceylonensis* in dogs in Sri Lanka. *Brugia* spp. are transmitted by mosquitoes, and their life cycles are similar to those of other filarial worms. Infective larvae enter peripheral lymphatics, migrate to the nearest lymph node and develop for two weeks before migrating down afferent lymphatics where they mature and *produce granulomatous lymphangitis, lymphangiectasis, and lymphadenitis*, but do not usually cause lymphedema and elephantiasis as occur in humans due to infection with *B. malayi* or the closely related *Wuchereria bancrofti*. The main importance of *Brugia* spp. lies in the differentiation of their microfilariae from those of *Dirofilaria immitis*, and in their role in human infections.

VASCULAR NEOPLASMS

Tumors of endothelial origin are classified as benign or malignant, that is *angiomas* or *angiosarcomas*. Benign tumors consist of easily recognized vascular channels lined by a monolayer of relatively normal endothelial cells. Malignant tumors may not form well-organized vascular channels, are more cellular, and display cytologic anaplasia. Differentiation of vascular malformations or proliferations from hemangiomas may be difficult. Hemangiopericytoma is discussed with skin neoplasms.

There are rare reports of non-endothelial tumors, e.g., leiomyosarcoma, malignant melanoma, chondrosarcoma, arising from vessel walls, especially in the aorta or pulmonary artery.

The *nomenclature of benign vascular tumors or malformations* is confusing, and includes hemangioma, hemangioendothelioma, hamartoma, vascular malformation, telangiectasis, and angiokeratoma, and rare variants such as *angiolipoma, angiofibrolipoma*, and *angioleiomyoma*.

- **Hemangioma**, a benign tumor of endothelial cells, is supposedly a true neoplasm capable of independent growth. Some of the "growth" of a hemangioma may be due to congestion, hemorrhage, and thrombosis. Hemangiomas may be present at birth or soon after in children and foals, suggesting that they may in fact be vascular malformations.
- **Hemangioendothelioma** (HE) describes a benign vascular tumor with hypertrophic endothelial cells forming small hypercellular vascular channels, and is essentially a *very cellular capillary hemangioma*. In human pathology, HE is used to describe a vascular tumor that is histologically and clinically intermediate between hemangioma and angiosarcoma. Reports of rare variants of HE include *Kaposiform HE* in a dog, *epithelioid HE* in a dog, and *epithelioid/spindle cell HE* in a calf.
- **Hamartoma** is a general term that refers to *focal disordered overgrowth of mature tissue that is indigenous to the organ involved*. Since vascular tissue is ubiquitous, vascular hamartomas may occur in any site of the body; some authors refer to angiomas as vascular hamartomas. Most hamartomas are present at birth, and their growth is coordinated with that of the surrounding tissue.
- **Vascular malformation** is obviously a very broad term that may be included under the term hamartoma, and may include *arteriovenous fistula* in which thick-walled vessels occur in contrast to the thin-walled vessels of the other benign vascular proliferations.
- **Telangiectasis** refers to congenital or acquired *foci of abnormally dilated capillaries, sinusoids, arterioles, or venules*, usually seen as small masses in the skin and mucous membranes.
- **Angiokeratoma** is a rare benign tumor, usually of the nictitans and conjunctiva of dogs, in which *dilated vascular channels are associated with hyperplastic epithelium*.

Fortunately, these distinctions, though of pathogenetic interest, are of little practical importance since the lesions described are uniformly benign and excision, if possible, is curative.

Angioma

Hemangioma is a benign tumor of endothelial cells and may be classified as *capillary* or *cavernous* based on the size of the vascular channels formed. The tumor may be difficult to differentiate from vascular malformations and granulation tissue. Hemangiomas occur most commonly in older dogs, and are seen less frequently in other species. These tumors arise from vascular endothelium and hence may be found in any site in the body, but are *most common in the dermis and subcutis*, especially of the legs, flank, neck, face, and eyelid. Hemangiomas are usually single, ovoid, red-black masses of 0.5–3 cm in diameter, which ooze blood when cut. Histologically, blood-filled vascular spaces are lined by a single layer of well-differentiated endothelium, and may be thrombosed. The vascular spaces are separated by variable amounts of connective tissue stroma. Hemangiomas are not encapsulated, are not invasive, and do not recur after complete surgical excision. A rare form of cavernous hemangioma, analogous to the human **hemangioblastoma**, is reported in dogs, and is characterized by thin-walled capillaries separated by pleomorphic "stromal cells" of indeterminate origin.

Disseminated cavernous hemangioma is rare, but has been reported in calves, and a similar multifocal hemangioma has been reported in a pig. Multiple small tumors are present in skin, subcutis, gingiva, and internal organs. The condition has been termed *generalized congenital hemangiomatosis* and *juvenile bovine angiomatosis*, to include calves having either solitary, e.g., gingival or spinal canal, or multiple angiomatous lesions. Hemangiomas occur in the urinary bladder of cattle affected with enzootic hematuria, which is discussed in Vol. 2, Urinary system.

A number of hemangioma-like lesions occur in domestic animals. **Bovine cutaneous angiomatosis** of adult dairy cows is reported from Britain, France, and the USA. Nodular dermal vascular proliferations occur anywhere in the skin, but especially along the back, may have a considerable inflammatory component, and resemble "pyogenic granuloma" of humans. **Varicose tumor of the scrotum** of dogs is a benign vascular proliferation that resembles cavernous hemangioma when fully developed. Lesions resembling hemangioma occasionally develop in the skin of the scrotum or perineum of boars, or the vulva, mammary glands, or ovaries of sows. **Meningioangiomatosis**, a rare condition reported in dog, horse, and cow, is characterized by benign focal proliferation of blood vessels and meningothelial cells in the leptomeninges and underlying brain parenchyma.

Formerly thought to be due to neoplastic proliferation of endothelial cells and hence termed *malignant angioendotheliomatosis*, **intravascular lymphoma** is a rare large-cell lymphoma, seen in humans, dogs, and a cat, in which neoplastic lymphocytes proliferate within the lumens of blood vessels. **Lymphomatoid granulomatosis** is a rare pulmonary disorder of middle-aged dogs characterized by infiltration of lung and various other organs by neoplastic mononuclear cells admixed with eosinophils, lymphocytes, and plasma cells; originally thought to be angiocentric, this pulmonary neoplasm is now thought to be an atypical T-cell lymphoma that is angioinvasive.

Lymphangioma is a rare, benign tumor that consists of lymph channels forming capillary, cavernous, or cystic tumors. Lymphangiomas may occur as congenital malformations (hamartomas) or may develop spontaneously in adults. Cavernous and cystic lymphangiomas may progressively enlarge, dissect along fascial planes, and be difficult or impossible to remove surgically.

Glomangiomas (*glomus tumors*) of nonhuman primates, dogs, and cats, are rare benign neoplasms of the neuromyoarterial temperature receptors, primarily in the digits, characterized by branching vascular channels in a fibrous stroma that contains nests of specialized glomus cells, a type of smooth muscle cell. **Glomus jugulare and glomus pulmonale tumors** have been reported in dogs. The glomus jugulare and pulmonale are chemoreceptors, and tumors of these bodies resemble other chemodectomas, namely nests of monomorphic rounded cells with scant cytoplasm separated by thin septa. The tumor is encapsulated and grows expansively.

Angiosarcoma

Hemangiosarcoma (malignant hemangioendothelioma), a malignant tumor of endothelial cells, occurs most frequently in old dogs, but is less common than hemangioma. German Shepherd Dogs (Alsatians) are most commonly affected. Hemangiosarcoma occurs infrequently in cats, horses, cows, and sheep. The tumor may arise in any site of the body. *The most common primary sites in dogs are spleen, skin/subcutis, right atrium, and liver*; in cats, spleen, intestines, and subcutaneous tissue; in horses, ocular, cutaneous, and multicentric. *Hemangiosarcoma is the most common primary cardiac tumor of dogs*, and the tumor usually occurs subepicardially in the wall of the right atrium at the entrance to the auricle near the coronary groove (Fig. 1.97A) or in the auricular appendage. Hemangiosarcoma probably arises *de novo* and not from preexisting hemangiomas. The tumors have a gray to red-black hemorrhagic appearance, and may reach a diameter of 30 cm in the spleen as a result of hemorrhage within the tumor. Large hemorrhagic masses can often be found in the spleens of dogs; some are hematomas rather than either hemangiomas or hemangiosarcomas. The distinction is important because splenic hemangiosarcomas carry a very poor prognosis. However, the distinction can often be difficult because *splenic hemangiosarcomas often hemorrhage and if the resultant hematoma is not sampled carefully its neoplastic origin will be missed*. Following rupture, implants of splenic tissue or tumor may be found on the peritoneum. Hemangiosarcomas typically metastasize widely, especially to the lungs ("cannonball" metastases) (Fig. 1.97B). Histologically, these tumors consist of vascular spaces lined by elongated, plump, anaplastic endothelial cells. Vascular spaces must be identified in tumors with a highly cellular stroma to differentiate hemangiosarcoma from fibrosarcoma. Hemorrhage and necrosis commonly occur within these tumors, and death may occur due to hemorrhage into the peritoneal cavity, pericardial sac, or brain. When metastases are widespread, the primary tumor site may be difficult to determine, and multicentric origin is a possibility. Poorly differentiated hemangiosarcomas may usually be differentiated from spindle cell sarcomas or other nonendothelial neoplasms by immunohistochemical staining for factor VIII-related antigen, a marker of endothelial cells. *Ulex europaeus* lectin, a marker of neoplastic human endothelial cells, is unreliable as a marker of canine vascular tumors. Ultrastructurally, Weibel-Palade bodies are present in at least some of the typical neoplastic endothelial cells.

Lymphangiosarcoma (malignant lymphangioendothelioma) is an extremely rare tumor in domestic animals. The tumor is histologically similar to hemangiosarcoma, but the irregular vascular channels contain few red cells; it may be diffusely invasive and metastasize widely. Ultrastructurally, lymphangiosarcoma is distinguished from hemangiosarcoma, at least in cats and humans, by the general lack of a basal lamina, few micropinocytotic vesicles, few intercellular junctions, lack of pericytes, and a discontinuous endothelial cell layer in lymphangiosarcoma. Immunohistochemistry (factor VIII, vimentin, laminin) and lectinhistochemistry (RCA-I, PHA-E) may be other useful adjuncts in differentiating the two tumors.

NORMAL HEMATOPOIESIS

The **hematopoietic system**, as used herein, refers to the system as a whole and *acknowledges the ultimate derivation of all fixed and circulating blood cells from a common pluripotential precursor that resides in the bone marrow of normal adults.*

The close relationship between bone and hematopoiesis is a constant finding in mammals and birds. While fetal and splenic hematopoiesis is largely erythroid, the full expression of all cell lines is largely confined to bone marrow. This intimate relationship appears to be dependent on the pattern of blood flow in bone and on a bone–bone marrow portal capillary system. The blood vessels of cortical bone that are derived from periosteal vessels arborize on the endosteal surface where they form a secondary capillary system that traverses the marrow cavity and drains into the central venous sinus. The radicles from the nutrient artery travel directly to the endosteum and penetrate the cortical bone to return via capillaries to the endosteal network. There is thus *anatomic evidence for a preferential microenvironment for hematopoiesis adjacent to endosteal bone* (Fig. 2.1), which may be generalized to explain the distribution of blood-forming activity in marrow and in ectopic or metaplastic bone.

Marrow capillaries form the conduit for delivery of blood cells to the systemic circulation via the vein which parallels the nutrient artery. All venous flow appears to be centripetal, with periosteal, osteal and marrow drainage all emptying into the central venous sinus. The marrow capillary endothelium is thin and the cells are without tight junctions. They are incompletely covered on the abluminal surface by a fenestrated basal lamina which is in turn covered to about 60% of area by cytoplasmic processes of adventitial reticular cells. These reticular cells are believed to be weakly phagocytic but are stromal in origin and distinct from the monocyte–macrophage system. They have no capability for hematopoietic differentiation but are **stromal stem cells** capable of forming adipocytes, osteoblasts, chondroblasts, and likely myoblasts. They form reticulin fibers that crosslink between vessels and form the structural support for bone marrow. These marrow stromal cells are hormonally active and essential for the maintenance, growth and differentiation of the hematopoietic stem cells by both cell–cell interactions and release of cytokines. Stromal cells secrete extracellular matrix proteins as well as producing cell surface transmembrane proteins that result in adhesion between the stromal cells and the developing hematopoietic cell lineages. A wide range of signaling molecules are produced, including M-CSF, G-CSF and IL-6,

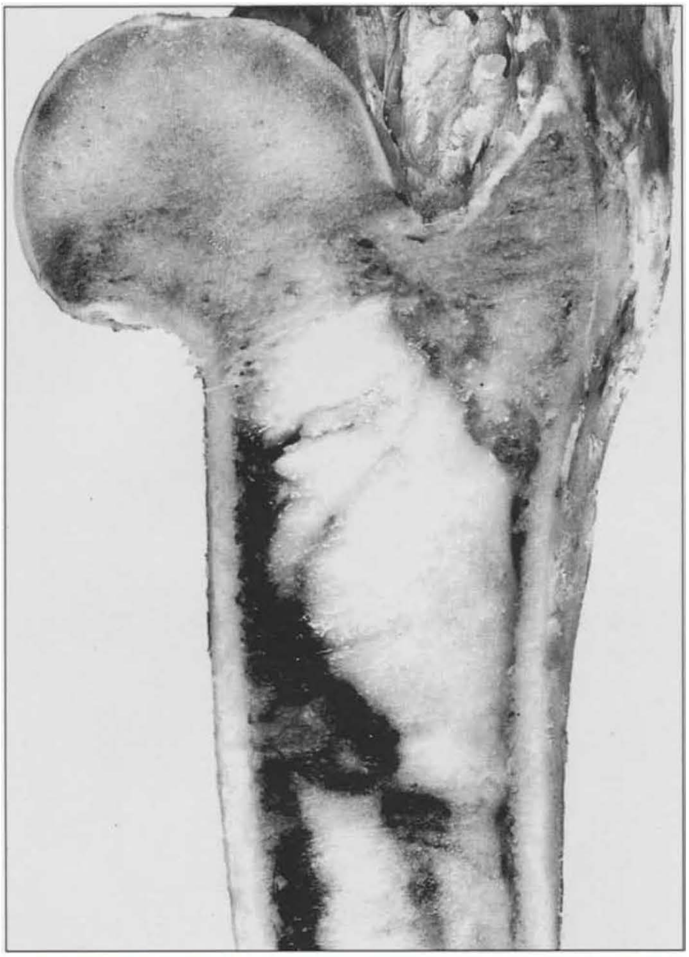

Figure 2.1 Expansion of erythropoietic marrow adjacent to **endosteum** in response to hemorrhagic anemia in a pig.

both in a constitutive and inducible manner, suggesting that the marrow stroma is able to adapt to body signals by altering the proportions of myeloid or lymphoid cell production.

The nonhematopoietic marrow includes nerves and fat cells. The adipocytes have a fatty acid content that differs from that in other sites. Marrow fat is more resistant to lipolysis in response to starvation. The nerves of bone marrow are both myelinated and unmyelinated and may innervate blood vessels.

In adults of all species, the hematopoietic marrow is concentrated in the spine, pelvis, sternum, ribs, calvarium, and proximal ends of the limb bones. When increased hematopoiesis is required, there is first lipolysis and myeloid expansion in those areas with residual red marrow. If requirements are further increased, there is hematopoietic conversion of fat in more distal areas. This expansion of activity, while focally irregular, follows a general preference for sites of higher blood flow which are found in close proximity to endosteal surfaces. Thus, *regenerative hematopoiesis is most prominent in areas of cancellous bone and in endosteal margins of metaphyses* (Fig. 2.1).

Coincident with the remodeling of fetal bone which provides a marrow cavity, there is colonization by hematopoietic stem cells which arise from the blood islands of the yolk sac. The cellular migration from the blood islands occurs in embryogenesis with seeding into the thymic anlage, the primordial lymph nodes, the liver and spleen. At birth, hematopoiesis is largely medullary with some persisting in liver and spleen and to a lesser extent in adrenals and kidney. In the adult, extramedullary hematopoiesis is largely limited to splenic erythropoiesis, as exemplified by the mouse.

The hematopoietic stem cell system *consists of a hierarchical lineage with the most primitive cells being capable of differentiation into all blood cell lines and almost unlimited self renewal* (Fig. 2.2). Growth and differentiation depends on the provision of a suitable inductive microenvironment dependent on an array of *growth factors* and *interleukins* (Figs 2.3, 2.4). Commitment to differentiation represents an interplay between inherent genetic capability and the selective hormonal pressure of the marrow microenvironment. More differentiated or committed stem cells can produce only one or two cell types and have limited proliferative capacity. The differentiation pathways result from the interaction of specific receptors for the various growth factors and the proportionate levels of the factors themselves. Thus, high levels of a particular factor may upregulate the production of its specific receptor and thereby recruit additional precursors to the production of a single cell lineage. Growth, differentiation, and maturation are forced by a higher proportion of receptors for the factors acting early in the proliferative cascade on primitive cells and vice versa (Fig. 2.2). These principles apply in leukemic as well as normal states and manipulation of this interplay is both a direct and supportive feature of antineoplastic chemotherapy. The cloning of growth factors and identification of their genetic origin to loci that are characteristically translocated in leukemias provides a molecular basis for understanding leukemogenesis. The process is most apparent when genes for growth factors translocate adjacent to potent promoters (oncogenes) thus providing the leukemic cells with the constitutive capability for stimulating their own proliferation.

Under normal circumstances, only a few of the primitive cells will be replicating at any time, the remainder being in resting phase and therefore relatively protected against insult. In the event of stem cell depletion by therapy or disease, the small number of active primitive cells is a limiting factor in the rate of recovery; and competition for the progeny most in demand (usually neutrophils) will decrease production of other cell lines (usually erythroid). *Primitive stem cells resemble medium lymphocytes and cannot be defined on a morphologic basis.* Maintenance of the stem-cell pool represents a significant proportion of the total marrow output.

Knowledge of relationships between precursor cells is provided by observations on stem cells in in vitro cultures. The precursors for the platelet and red cell series are related by genetic capability or by receptor status as are precursors for the neutrophil and monocyte series. These relationships provide an explanation for the clinical observation of concurrent increased production of red cells and platelets or of neutrophils and monocytes (Figs 2.3, 2.4). Hormonal factors influence the final defensive capability of leukocytes as well as their release from the marrow. Inflammation causes the release of a family of short- and long-acting mediators of which *tumor necrosis factor* stimulates growth factor production which increases marrow cell release. Failure of this final step in blood cell production results in *ineffective hematopoiesis* and death of the cells in the marrow. This syndrome is seen most frequently in the myelodysplasias of the cat and dog where there is the paradoxical concurrence of pancytopenia and hyperplastic marrow.

Knowledge of the cell kinetics and production times of blood cells and the proportions of their progenitors in normal marrow is essential to the

interpretation of this tissue in disease. This information is summarized in Fig. 2.5.

The recognizable *blast cells* of the four lines (erythroid, neutrophilic, megakaryocytic, and monocytic) make up only about 1% of all marrow cells. Six morphological stages of myeloid and erythroid differentiation are recognized of which the first three are dividing cells and the last three are undergoing nuclear and cytoplasmic maturation. Very consistently in steady-state conditions, 25% of marrow cells are in the proliferative phase and 75% are in the maturation phase. An *increased proportion of proliferative phase* cells indicates active regeneration, leukemia, or ineffective hematopoiesis associated with nuclear maturation defects such as occurs in folate and vitamin B_{12}-related disorders. *Increased proportions of the maturation phase* cells with pancytopenia indicate ineffective hematopoiesis and myelodysplasia. Late asynchrony limited to the erythroid system concurrent with hypochromic anemia results from the *cytoplasmic maturation defect* of iron deficiency.

The proportions of proliferative phase cells indicate that *promyelocytes* and *prorubricytes* result from a simple doubling of the numbers of precursor blast cells. The proportions of myelocytes and basophilic rubricytes suggest that there is some proliferative activity in these stages, and nuclear labeling shows that metamyelocytes and polychromatic rubricytes can divide to a limited extent in conditions of increased demand. *Monocytes* have three morphological stages of differentiation of which the first two are dividing cells and the last is a maturation phase. The total production time of the monocyte appears to be only one quarter of that required to produce a neutrophil.

The *megakaryoblast* is about the size of a prorubricyte and can be identified by binucleation with interphase nuclei and intense cytoplasmic basophilia. Thrombopoietic cells can be divided into two broad groups. The proliferative phase cells are multinucleated and have minimal, very basophilic cytoplasm. Maturation phase cells have a multilobulated nucleus and abundant cytoplasm in which the

basophilia decreases as the granulation increases over the 4-day production period. Normal or increased nuclear ploidy with inadequate cytoplasmic volume is indicative of *ineffective thrombopoiesis*.

Lymphocytes are present in normal marrow at 3–5% of marrow cells. In inflammatory states, their number apparently increases by several percent and lymphocyte identification is complicated by an increased proportion of morphologically similar stem cells. Normally, *plasma cells* are present at very low levels in young animals and increase to 1–2% of marrow cells in adults. In chronic inflammatory disease, their numbers may rise to 25% or more of marrow cells. A large increase in plasma cells without cytologic atypia does not support a diagnosis of immunoblastic tumor. Germinal centers are not found in the marrow of normal animals at any age.

Cellularity of marrow *is used herein to indicate the proportions of hematopoietic to fatty marrow*, and **cell density** *to indicate the spatial relationship of hematopoietic cells to each other.* It is generally accepted that, excepting focal lesions such as tuberculosis, myeloma, or metastatic carcinoma, *red marrow obtained from any site will have the same cellularity and cell differential.* In other words, the marrow functions as an organ with proliferative and control mechanisms providing local and whole-body homogeneity. *Normal marrow functions at about 50% cellularity.* Persistently increased demands for cells may raise this proportion to 100%, in which event the marrow organ will be greatly expanded with conversion of fatty to red marrow in the endosteal marrow of the distal extremities. In normal animals, the hematopoietic cells are densely packed with their boundaries in close apposition. This close apposition is a function of cell–cell interaction in control mechanisms. In chronic disease with failing marrow, such as occurs in equine infectious anemia or bovine trypanosomiasis, the cell density is reduced, and in these circumstances the loss of marrow volume is partially compensated for by sinusoidal dilation. This latter change results in a marrow which appears "red" grossly but is cytologically hypofunctional.

Marrow iron is an important feature of myeloid evaluation. Stainable iron is rare in normal animals under a year of age and gradually increases with maturity. *Hemosiderin is intracellular in macrophages and in this state is only slowly mobilized for erythropoiesis.* Thus an animal with substantial marrow iron reserves will respond faster to acute hemorrhage if supplemental iron is provided. A coarse pattern of iron deposition in marrow indicates poor iron utilization, and is the characteristic pattern in the anemia of chronic disease. In hemolytic anemias, there is usually an increase in total marrow iron with abundant coarse and fine hemosiderin indicative of rapid turnover. A hypochromic microcytic anemia with late erythroid asynchrony and scant iron is found in iron deficiency anemia, while the same peripheral and marrow picture with increased hemosiderin strongly suggests copper deficiency.

In normal marrow, the **fat** is firm and opaque on gross examination. There is little change in volume on drying. The fat is completely removed in histologic processing leaving empty adipocytes. In contrast, in **serous atrophy** the marrow becomes grossly translucent and pink rather than clearly red or white, and the marrow shrinks rapidly on exposure of the medullary cavity to air indicating a higher than normal water content. Histologically, the fat cells in serous atrophy contain a thin, pink proteinaceous background. Serous atrophy of marrow fat is a late change in cachexia or starvation and is a significant lesion.

DISORDERS OF STEM CELLS

Disorders of stem cell function include errors in the number and/or quality of cells produced. *Numerical disorders* consist of congenital cytopenias, acquired leukemias, toxic-induced neutropenia, idiopathic aplastic anemia, and pancytopenia. *Qualitative disorders* include congenital errors in cytoplasmic and nuclear development which result in defective protection against infection, oxygen transport, or clot formation.

Congenital abnormalities in blood cell numbers: cyclic hematopoiesis

Deficient cell production is seen in cyclic hematopoiesis of *humans* and *gray Collie dogs* and in the genetically anemic *W/W^v mouse* in which the error is in the restriction of the pluripotential stem cell pool. In contrast in the genetically anemic *Sl/Sl^d* mouse, the stem cell pool is adequate but marrow stroma is deficient resulting in an inadequate hematopoietic microenvironment. While not of clinical or diagnostic concern, these latter two diseases have contributed greatly to the understanding of hemopoietic dependence on a functional pluripotent stem cell in an appropriately fertile microenvironment. The diseases described in the next two sections are remarkable in that they combine a genetic origin with a dilution of melanin in pigmented hair and hematologic abnormalities.

Cyclic hematopoiesis *is a rare abnormality of pluripotent stem cells in gray Collies*, transmitted in an autosomal recessive manner. Affected puppies can be identified by their light silvery gray hair and by microphthalmia. The defect is lethal and death occurs before maturity. There is a trilineage cycling of blood cells with the deficits most apparent in neutrophils, which have the shortest peripheral lifespan estimated at 6–8 hours under steady-state conditions. In affected dogs, cycling occurs with a 12–14 day periodicity with severe neutropenia at each period of marrow hypoplasia followed by marked neutrophilia in rebound. The disease appears due to cycling levels of suppressor T lymphocytes which are in the ascendancy when hematopoiesis is failing and are reduced during recovery. The total leukocyte count of 2–20 × 10^9/L is treated by increasing the size of the stem cell pool by the administration of lithium carbonate, endotoxin, or prednisone. The latter acts presumably by reducing the level of the suppressive managerial T cells. The precursors for megakaryocytes and rubricytes go through similar cycles but, because of their longer peripheral lifespan, the deficits in these cells are less apparent. The dogs are immunologically competent, and lymphoid hyperplasia is an early compensatory mechanism for recurrent neutropenia. Amyloidosis is a common sequel in animals that survive 3 months or longer.

Dogs with cyclic hematopoiesis are difficult to maintain. *Disease is recurrent and related to sepsis.* Characteristically there are about 3 days of neutropenia followed by normal or increased neutrophil counts for 6–7 days. At periods of neutropenia, there is marked left shift with myelocytes present which have toxic vacuolation and granulation (Fig. 2.6) and Doehle bodies. Apparently cell supply is not the only error, and neutrophils have deficits in killing for a variety of bacteria. Animals may be mildly icteric and there is increased blood urea especially in those dogs which develop amyloidosis.

The disease tends to vary somewhat with the age of the animal, but *the same organ systems are affected at all ages*. The animal is usually in poor condition and there are often focal skin lesions with abscessation or cellulitis. Young dogs tend to have bronchopneumonia with purulent exudates, whereas older animals tend to have interstitial pneumonia with focal areas of scarring. There is frequently valvular endocarditis and catarrhal enteritis and frequently bleeding into the lower intestinal tract. The liver is usually pale and fatty and the spleen is uniformly enlarged. Lymph nodes are generally enlarged and may be focally abscessed. The bone marrow is uniformly reddened in mid-femoral shaft. Focal areas of sepsis, which may occur virtually anywhere in the monocyte/macrophage system, appear to impair bone remodeling. Dogs which die in the first few weeks of life tend to succumb to infections of the respiratory and enteric tract, whereas dogs which survive for several months frequently die of renal failure.

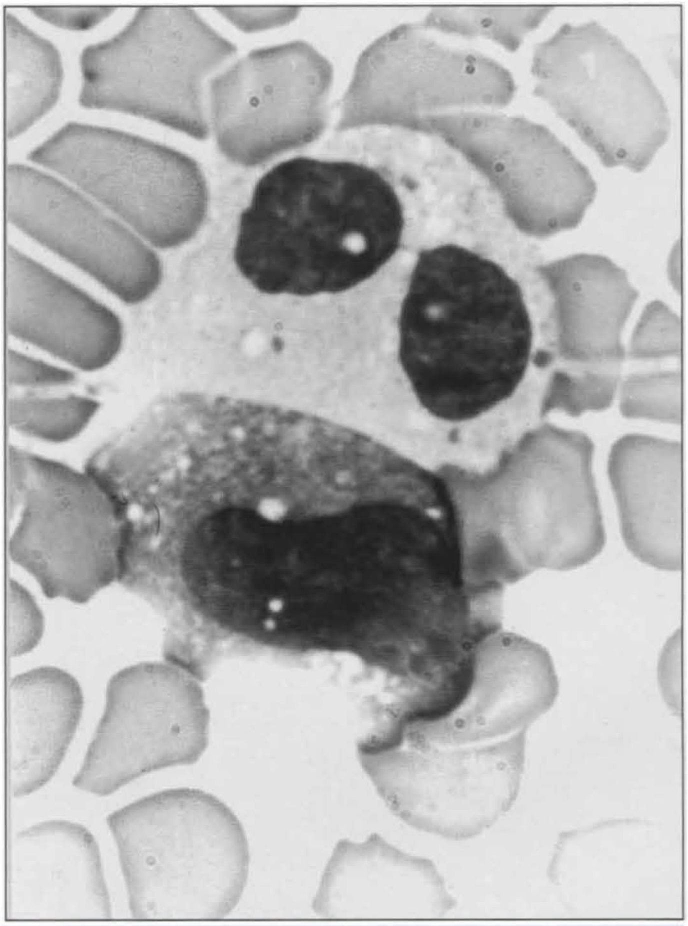

Figure 2.6 Cyclic hematopoiesis in a dog; blood smear. Immature monocyte, center. Bilobed neutrophil indicative of premature release from marrow contains toxic granules and vacuoles.

The lesions in the lung, kidney and gastrointestinal tract are those of chronic and recurrent inflammation usually due to common bacterial invaders. The principal changes occur in the hemic lymphatic system and consist of *widespread lymphoid atrophy* with reduced density of splenic periarteriolar sheaths (Fig. 2.7) and of germinal centers. In some dogs, the germinal centers may be markedly enlarged by both perifollicular and interfollicular deposition of amyloid which may appear as early as 3 months of age. The lymph nodes have normal numbers of germinal centers with poor cell density, and the paracortical areas have reduced area and cell density and there is characteristic sinus histiocytosis without medullary cord hyperplasia (Fig. 2.8). *The bone marrow varies widely depending on the stage of the cycle at the time of death.* Characteristic changes include a progressive increase in sinus and hemopoietic area with loss of fat and a generalized increase in connective tissue that becomes more prominent with survival. There is a characteristic

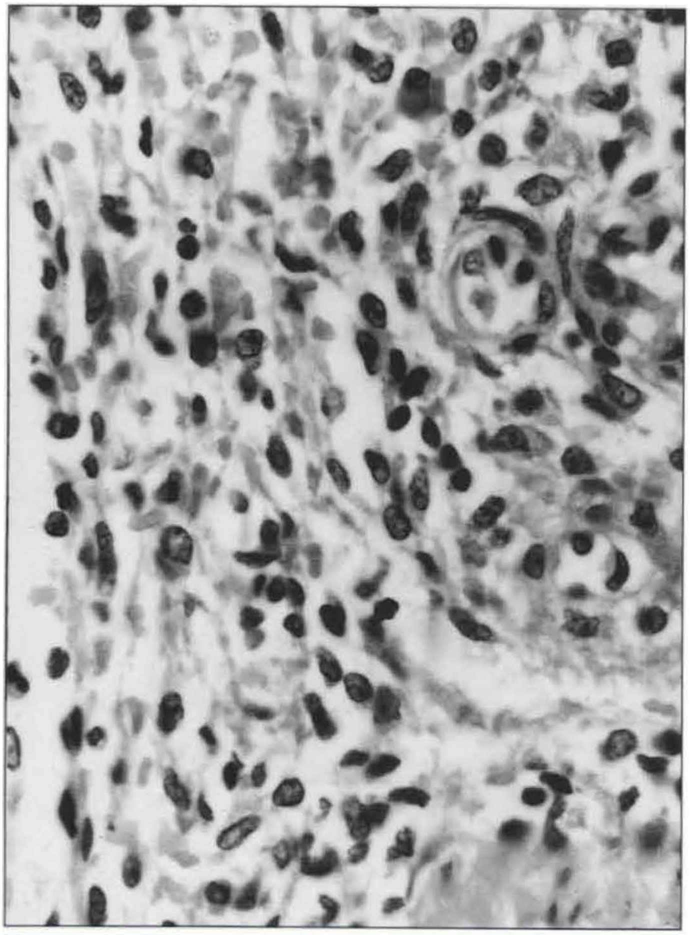

Figure 2.7 **Cyclic hematopoiesis** in a dog: spleen. Depletion of small lymphocytes in periarteriolar sheath.

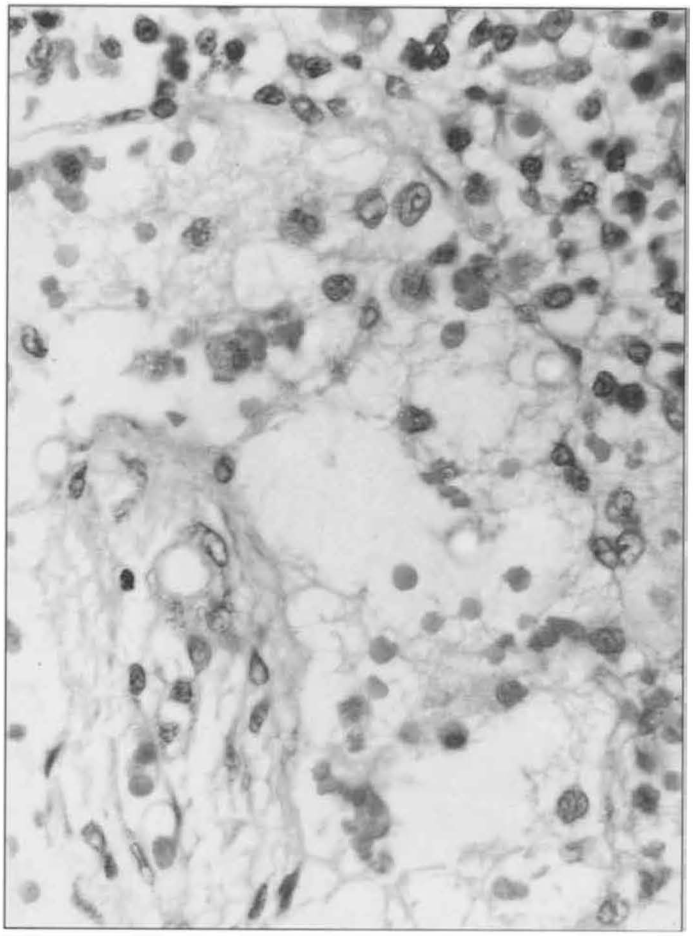

Figure 2.8 **Cyclic hematopoiesis** in a dog: lymph node. Cellular depletion of medullary cords and sinuses.

increase in marrow plasma cells and at the time of rebound, the marrow granulocyte reserves are increased, while at the time of aplasia there are few young cells present and the marrow is hypocellular. At the stage of rebound, there are many large, round cells with deeply stained cytoplasm which are likely myeloblasts and promyelocytes with a lesser number of erythroid precursors. There is thymic cortical atrophy.

Congenital abnormalities in blood cell function

Chediak-Higashi syndrome

The Chediak-Higashi syndrome is a composite disorder of granule formation in cells and is of a simple recessive character in cattle of the Hereford, Brangus, and Japanese black breeds, cats, mink (Aleutian disease), mice, and humans. The condition may also occur in bison, killer whales, foxes, and white tigers. The disease is manifested clinically by *partial albinism or color dilution, high susceptibility to infections, and a hemorrhagic tendency.* It is a rare syndrome except in mink, in which all of the favored blue Aleutian strains are affected.

Enlarged cytoplasmic granules, which are the result of fusion of preexisting granules of normal size, are found in most types of cells which normally contain granules. The partial albinism is ascribed to *clumping of melanin granules* in such tissues as eye and skin and their fusion with lysosomes. There are fewer, larger granules than normal also in hepatocytes, renal epithelium, neurons, endothelial cells, and the blood leukocytes.

The prolonged bleeding time and hemorrhagic tendency is, at least in part, due to defects in platelets. The clumping response of platelets on exposure to collagen is deficient and is associated with reduced levels of platelet adenosine diphosphate.

Giant lysosomes are present in circulating granulocytes, lymphocytes, and monocytes. Phagocytosis appears to be normal but bacteriocidal activity is impaired. The impaired capacity of phagocytes to deal with ingested macromolecules or microorganisms appears to be due to *impaired fusion of lysosomes with phagosomes* and provides an explanation for the high incidence of recurrent infections.

Bovine leukocyte adhesion deficiency

Bovine leukocyte adhesion deficiency (BLAD) occurs in Holstein cattle as a heritable syndrome of chronic febrile disease characterized by poor growth and early death. *The disease is due to a congenital deficiency of leukocyte integrins essential for normal adhesion to endothelium and subsequent emigration to sites of inflammation.* These integrins have been classified as CD11/CD18 according to their alpha and beta subunits. Clinically, there is emaciation, dermatitis, persistent oral ulcers, enlarged lymph nodes, and slow healing of wounds and infections. There is anemia with marked persistent neutrophilic leukocytosis of up to 100×10^9/L and mild left shift. Bone marrow has marked myeloid shift with synchronous maturation of all cell lines, which appear normal by light and electron microscopy. There is polyclonal gammopathy with decreased albumin/globulin ratio. Morphologically, there is fibrosis of lymph nodes and wide spread infection of body surfaces but, significantly, neutrophils are present in large numbers in vessels but not in infected tissues. Neutrophils from these animals have reduced motility, phagocytosis, and intracellular killing. Since motility and phagocytosis are abnormal, this disease is distinct from "chronic granulomatous disease" of humans. The cases described all derived from a single sire, apparently as an autosomal recessive trait.

Canine leukocyte adhesion deficiency

Canine leukocyte adhesion deficiency (CLAD) occurs as the result of an *inherited autosomal recessive trait in young Irish Setter dogs* expressed as a syndrome of *recurrent severe bacterial infections*. The cause is a missense mutation in the beta-2 integrin subunit gene (ITGB2) that results in a defective beta-2 subunit of heterodimeric leukocyte adhesion proteins. The lack of the Cd11a,b,c and CD18 leukocyte adhesion proteins is similar to the granulocytopathy syndromes described in humans and in Holstein calves. Functionally the neutrophils from these dogs have severely diminished capacity for adherence, aggregation, chemotaxis, and reduced capability for phagocytosis. The neutrophils have normal oxidative burst activity and the animals have normal levels of complement and immunoglobulin. Morphologically the disease in dogs appears to be similar to BLAD described in affected Holstein calves with abundant neutrophils in small blood vessels in affected sites but not in the adjacent tissues and sites of bacterial colonization. Since the error lies in the mobilization and chemotaxis of the neutrophils but not the capacity for intracellular killing, CLAD is distinct from the pathogenesis of the chronic granulomatous disease syndrome of children wherein the defect is in the oxidative burst activity and intracellular killing of bacteria.

Pelger-Huet anomaly

The Pelger-Huet anomaly is a *benign dominant hereditary condition* characterized by *hyposegmentation of neutrophil nuclei* which have mature aggregation of chromatin despite their immature shape. The condition occurs in humans, dogs, and rabbits. The neutrophils respond normally in functional tests and heterozygotes survive normally. A homozygous form in rabbits is lethal. The main importance of the trait is to distinguish it from inflammatory states. Affected animals have a normal total leukocyte count; band neutrophils may be 30–70% of total cells. Metamyelocytes are present at much lower frequency, and myelocytes are not found in the blood of healthy dogs. An ephemeral form resembling this condition has been described in the dog possibly resulting from drug idiosyncracy.

Feline mucopolysaccharidosis

The type I or Hurler/Scheie and type VI or Maroteaux-Lamy forms of this disease occur in cats and are associated with *metachromatic, 0.5–1.0 μm diameter granules in the neutrophils*, which are not prominent with routine stains. Typical facial dysmorphia consisting of frontal bossing and depressed nasal bridge is most obvious in the type IV syndrome seen in the Siamese breed. Affected animals survive to reproductive age with normal mentation, small stature and cloudy corneas. They are not noted to be unusually susceptible to infection.

Sphingomyelinosis

A lysosomal storage disease due to an autosomal recessive trait resulting in a loss of sphingomyelinase occurs in humans and also in the cat, dog, and mouse. Storage in the hematopoietic system results in splenomegaly with psychomotor retardation as a result of accumulation in neurons. The enzyme is usually absent from leukocytes in the form seen in animals, and *lymphocytes and monocytes are characteristically vacuolated*. Nervous signs predominate.

The leukon

LEUKOCYTE RESPONSES TO PERIPHERAL DISEASE

This section describes changes which occur in the different types of leukocytes. The following section deals with characteristic changes in leukocyte numbers in various species of domestic animals.

Neutrophils

Studies of granulokinetics using nuclear labels (tritiated thymidine) show remarkably similar results for humans and those domestic species studied. In the steady state, a total production time of 6 days is followed by a ripening period of 1 day prior to release from marrow. The peripheral circulation time is probably 6–8 hours. Neutrophils do not re-enter the circulation after tissue migration. Band neutrophils are released into the circulation in a bolus or discontinuous fashion.

The fine structure of neutrophils is quite similar for all domestic species. The **primary or azurophil granules,** most prominent in promyelocytes, contain myeloperoxidase, neutral and cationic proteases, are peroxidase-positive, and have microbicidal properties. The **secondary or specific granules** synthesized later in granulocytopoiesis contain lysozyme, collagenase and in most species, alkaline phosphatase, except in the dog, cat, mouse, rhesus monkey, and birds. The secondary granules are peroxidase-negative and form the background cytoplasmic density of the mature cells. The functional properties of neutrophils appear in a distinct order in granulopoiesis with Fc receptors first, followed by immune phagocytosis, complement receptors, oxygen-independent microbial killing, oxygen-dependent microbial killing, and finally chemotaxis. Phagocytosis is followed by activation of the NADPH-oxidase enzyme burst secretory system which is bactericidal for a wide variety of pathogens.

In *toxemic states*, the primary granules are visible in the cytoplasm of mature neutrophils as fine azurophilic or pink granules with Romanovsky stains. These primary granules are normally present in mature cells and can be demonstrated as artifactual change in aged or overstained neutrophils. Other indications of systemic toxemia include cytoplasmic vacuoles and Doehle body formation. In general, *toxic granulation represents the mildest change, followed by vacuolation and Doehle body formation.* In severe toxemias, such as those that occur in canine pyometra, bovine mastitis, and equine salmonellosis, all three changes occur together. Doehle bodies are composed of lamellae of rough endoplasmic reticulum persisting from the normal basophilia of immaturity. Since rough endoplasmic reticulum is part of the synthetic mechanism of the precursor cells, it is expected that as toxic changes increase, the specific or secondary granules are decreased. In contrast, animals with well-controlled or mild inflammatory disease usually have increased secondary granulation with minimal toxic changes. Presumably the functional capability of these cells varies directly with the level of granule-bound enzyme, as evidenced by cytoplasmic density in stained blood films.

There is considerable variation in enzyme content of granules in various species, with the dog and cat neutrophil lacking alkaline phosphatase. *Neutrophils function as secretory cells in the inflammatory reaction,* with granule exocytosis being mediated by a number of stimuli. The secreted material modulates and enhances the acute inflammatory reaction and appears to stimulate myelopoiesis. Such stimulation may partially explain why in diseases such as enteritis, mastitis, and dermatitis, in which neutrophils are lost from the body, blood neutrophils tend to be fewer than in tissue reactions where secretory granules are retained. The spilling of enzyme into tissues during phagocytosis may cause tissue injury in acute inflammation. The phagocytic vacuoles of neutrophils have a pH as low as 4.5, and adherence of activated cells to endothelium may cause vascular injury.

Leukocytes are usually quantitated on a numerical basis, however numbers and functional capability are not synonymous. Neutrophils may be hypofunctional and cytologically appear less dense in the same manner as red cells may be hypochromic and carry less oxygen. Neutrophils produced under conditions of severe toxemia have less specific granulation and are vacuolated; presumably their function is decreased in concert with their cytologic deterioration. In general, *the cytologic quality of neutrophil cytoplasm varies directly with leukocyte count and the clinical progress of the animal.* Thus animals in extremis tend to have very low leukocyte counts with severe toxic changes, whereas those that are responding well to their infection have high cell counts and the density of neutrophil cytoplasm is increased. Many factors may influence the quantitative and qualitative responses of the bone marrow in infectious disease.

Neutrophils complete their maturation under the influence of a number of factors including granulocyte-monocyte colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), and interleukins-3, -4, -11 (Fig. 2.3). In *neonates*, free radical production in neutrophils and microbicidal capability but not phagocytosis is below adult levels, which may be a factor in their early susceptibility to infectious disease. In addition, severe *protein-calorie malnutrition* impairs neutrophil adherence and motility. Motility in neutrophils is accomplished by membrane flow in the direction of chemotaxis in a "tank-tread" manner. *Blood cells do not necessarily function independently,* for example, neutrophils and platelets act synergistically in both coagulation and inflammation. Thus selective cytopenias, such as neutropenia or thrombocytopenia, will impair the function of cells that are not numerically deficient. *Bacterial toxins* acting locally induce an inflammatory response, and result systemically in release of mature neutrophils and toxic changes in those in the process of maturation. Chronic infection with *Bovine viral diarrhea virus* decreases the functional reactivity of both neutrophils and lymphocytes. Phagocytosis is depressed in *hypercoagulable states*, likely due to the release of fibronectin products lysed by plasmin. Leukocyte function is impaired by *endogenous toxins* as occurs in uremia, and neutrophil enzyme is reduced in iron-deficient states. Leukocyte function may be significantly altered by *dietary factors*. For example, selenium deficiency causes reduced intracellular killing, and omega-3 fatty acids reduce leukotriene B4 and thus have anti-inflammatory effects. *Dexamethasone* depresses the functions of both neutrophils and lymphocytes, and this effect on neutrophils may be blocked by administration of ascorbic acid.

Antibiotics vary in their ability to enter neutrophils, but those that do, such as tetracycline and chloramphenicol, decrease chemotaxis;

tetracyclines and polymyxin B decrease both phagocytic activity and oxidative metabolism. Finally, the systemic effects of *cancer* include impairment of phagocyte function.

Eosinophils

The production kinetics of eosinophils are similar to those of neutrophils, but unlike the latter, they may survive many days in tissues. Eosinophils respond to different stimuli and their granulation is cell specific and, to some extent, species specific. They are capable of killing bacteria but are less efficient than neutrophils. Their armamentarium includes the major basic protein of their **specific granules**, a potent H_2O_2–peroxidase–halide system, and inactivators of the leukotrienes of anaphylaxis. They have *receptors* for complement 3b as well as for IgA, particularly secretory IgA, which may be why eosinophils tend to localize in mucosal surfaces as well as provide the means by which they bind to tissue parasites. Eosinophils express *leukocyte adhesion molecules*, but like lymphocytes are able to emigrate to sites of inflammation in animals with the leukocyte adhesion deficiency syndrome. In comparison to neutrophils, *eosinophils are primarily residents of tissues* and appear to be targeted to tissues on release from marrow such that while their level in the blood may not be elevated there may be heavy tissue accumulation. The association between parasitism and eosinophilia is less than is usually accepted. Eosinophils are late arrivals in the immune response to parasites, and their chemotaxis can be explained on the basis of specific lymphokines from prior sensitized T lymphocytes. The increase in mature eosinophils seen in mature sheep with hemonchosis is probably part of the syndrome of iron deficiency and not directly related to parasitism.

In blood films, eosinophils have more cytoplasmic basophilia than neutrophils. This is reflected in their wide spectral separation from other cells in fluorescent activated cell counters. In diseased animals, eosinophils frequently have more marked **toxic changes** than neutrophils. These changes consist of *reduced granulation, increased diffuse cytoplasmic basophilia, and large vacuoles.* The toxic changes are seen most often in diseases involving the gut, lung, and skin, and are not species specific. Eosinophils are most prominent in these three tissues, and this may provide an anatomic basis for the preference. Eosinophils can be considered to be concentrated on body surfaces, with greatest frequency in intestine and lesser numbers in dermis and hemiclymphatic tissue, lung, and uterus. Significantly, many tissues normally contain none at all. Cows in estrus usually have an eosinophilia of $0.5–1.5 \times 10^9/L$. Toxic changes are absent.

The **functions** of eosinophils are incompletely understood. They are known to interact with homocytotropic antibodies (IgE and IgG) and with mast cells and basophils. The antibody and T lymphocytes provide specificity to the reaction, and the IgE on mast cells attracts eosinophils which modulate the inflammatory reaction. The relative quantities of tissue IgE, extractable histamine, and eosinophils suggest that these components form a system which is most prominent on body surfaces, immunologically mediated, often parasite related, and frequently associated with eosinophilia. While eosinophils are able to phagocytose and kill bacteria, *their main role seems to be to react against large non-phagocytosable organisms, such as parasites, fungi and foreign bodies.*

When benign **eosinophilia** is marked and persistent, it can be assumed to be due to immune phenomena. Less clear is the distinction between benign hypereosinophilic syndrome and chronic myelogenous leukemia of the eosinophil type. While both conditions will cause tissue damage, the immaturity and atypia are more prominent in the malignant disease and are usually accompanied by some degree of basophilia. **Eosinopenia** is characteristic of acute infection. It appears that corticosteroid modulates the level of blood eosinophils, but their production and release may persist despite high levels of steroid if the peripheral stimulus is of sufficient intensity. Eosinophils appear to have a short circulation time in disease states, which may explain the apparent increased eosinopoiesis in marrow with focal tissue accumulation, without eosinophilia, such as occurs in eosinophilic myositis. The level of serum cationic protein derived from eosinophils may markedly increase in acute inflammation despite eosinopenia, suggesting that these cells are being produced and are degranulating rapidly but are not obvious in the blood because of rapid transit.

Basophils

Basophils arise from bone marrow precursors which can first be recognized at the promyelocyte stage. A number of cytokines are active in stimulation of basophil production including interleukins 11, 4, and 3, of which the last seems to be most important. Their maturation sequence and kinetics are similar to neutrophils with peak peripheral blood arrival of labeled cells 7 days after injection of tritiated thymidine. The circulation time is unknown but is probably short. Newly released cells are specifically directed; they do not have a random and age-dependent removal as do neutrophils. Basophils do not segment as fully as neutrophils, and in this respect resemble eosinophils. Basophils are about a third greater in diameter in blood films than neutrophils, and retain smooth nuclear boundaries unlike the irregular constrictions of mature neutrophils. These characteristics are of interest because *basophils are easily degranulated in slide preparation and may be mistaken for neutrophils.*

The relationship between basophils and mast cells appears to be functional, with a reciprocal variation in their relative proportions. *Basophils have segmented nuclei with moderate granulation, whereas mast cells are mononuclear and heavily granulated.* The granules of both cells contain *histamine and heparin*, but the histamine concentration in mast cells is some 20 times greater than in basophils. Basophil granules are like eosinophils, ultrastructurally distinct, contain major basic protein, and are peroxidase-positive. Mast cells contain hydrolytic enzymes and 5-hydroxytryptamine, which are not present in basophils.

It appears that basophils have a committed precursor at about the same level as neutrophils, and which is probably more primitive than the myeloblast. *Mast cells* are believed to be derived from an undifferentiated precursor in perivascular connective tissue that may in turn derive from monocytes. In this respect, mast cells differ from basophils and eosinophils which have their progenitors in marrow, whereas mast cells may arise in peripheral tissues as well. In cytologic preparations of mast cell tumors, it is common to find stromal type cells with bipolar and incomplete cytoplasmic boundaries which contain only one or two basophilic granules. These may be the stem cells for the bulk of the tumor mass.

Basophils are capable of phagocytosis and are weakly motile. Unlike mast cells, which degranulate by exocytosis and can then regenerate, *basophils largely degranulate by diffuse internal lysis and have less synthetic capability.* It is likely that basophils of most species have receptors for IgE and degranulate when attached antibody binds with specific antigen. There is, however, marked heterogeneity of response by basophils in different sites, as in mast cells, and activation and secretion is not an all-or-nothing phenomenon. The secretory activity of both basophils and mast cells is dependent upon the presence of calcium and magnesium ions. In addition to their specific involvement in hypersensitivity reactions, basophils release heparin during postprandial lipemia, which activates the enzyme lipoprotein lipase. Steroid hormones appear to cause a reduction in blood basophils, as well as eosinophils, and basophil counts are reduced in acute infections. Since basophils are rarely found in the blood of normal cats and dogs and are usually $<0.1 \times 10^9/L$ in the blood of other species, a reduction in basophils is seldom detected. **Basophilia** is seen in hypothyroidism, after protein injection (vaccination), estrogen injection, and accompanying eosinophilia. Basophilia may be seen in immune hemolytic anemia, after insect bites, severe cold, exposure to endotoxin, and in canine hyperadrenocorticism. Inhibition of basophil activation is induced by cyclosporine A and corticosteroids. Basophilia that accompanies a leukemoid reaction increases the likelihood of chronic myelogenous leukemia.

Monocytes

Blood monocytes derive from a marrow precursor in common with that for neutrophils and under cytokine pressure from GM-CSF, M-CSF, and interleukins 4, 11, and, most importantly, interleukin-3. There is some "switching" probably determined as late as the myeloblast stage. The peak of labeled blood monocytes occurs 2 days after injection of tritiated thymidine and, in contrast to neutrophils where the marrow and circulating pools of cells appear equal, *the monocyte pool is composed almost entirely of circulating elements*. Monocytes leave the peripheral blood with a half time of ~20 hours and are not believed to reenter the circulation.

Monocytes can be distinguished from lymphocytes on routine staining by their more irregular nuclear outline and uniform cytoplasmic density. Lymphocytes usually have a perinuclear halo of reduced cytoplasmic basophilia. Monocyte chromatin is consistently fine with or without a few large chromocenters, whereas lymphocyte chromatin varies widely with cellular activity. Cytochemically, monocytes have diffuse cytoplasmic staining for nonspecific esterase (α-naphthyl acetate esterase) activity which is absent in neutrophils of most domestic animals. Monocytic esterase is inhibited by sodium fluoride, which permits differentiation from early granulocytic precursors and from T lymphocytes. The specific granules of monocyte cytoplasm are not always resolvable by light microscopy. When present, they are similar in size and tinctorial properties to toxic granules of neutrophils. Newly released monocytes tend to have more cytoplasmic basophilia and lack vacuoles, while the opposite is true of older monocytes; vacuolation of monocytes is common in animals with inflammatory disease.

Monocytes leave the blood to replenish the entire spectrum of tissue macrophages, known specifically by location as macrophages of lung, spleen, marrow, peritoneum, and the lymph node sinuses as well as Kupffer, Langerhans, and giant cells. It is still undetermined whether the interdigitating reticular cells of germinal centers are derived from the monocyte–macrophage population. The terms reticulo- and reticulum should not be used with reference to the monocyte–macrophage system (formerly called the "reticuloendothelial system"). The metallophilic reticular cells of interstitial tissues produce reticulin or collagen and are weakly phagocytic. They are fibroblast-derived and distinct from macrophages, which do not produce fibers. Most of the tissue depots for macrophages are at the termination of the marrow–blood–tissue pipeline; however, in some sites, particularly lung and liver, there is local proliferation which may be accelerated in marrow failure.

The activities of the monocyte–macrophage system are almost as diverse as their tissue distribution and include phagocytosis, myeloproliferative control, antigen processing with expression of both MHC I and II antigens, and production of endogenous pyrogen. The ability of these cells to bind to antigens and lymphocytes is central to these functions. Macrophages have membrane receptors for the Fc portion of immunoglobulin, for C3b and C5a of the complement system, and for CD14 that binds to the LPS of gram-negative bacteria.

Phagocytosis is considered in three functional steps consisting of *particle attachment, internalization, and ingestion*. Attachment is a function of binding capabilities while the signal for ingestion may be either immunologically or nonspecifically activated. Ingestion is the energy-dependent step in phagocytosis. The energy is provided by anaerobic glycolysis, and macrophages characteristically function well in anoxic milieu such as occurs in abscesses and granulomas. In contrast, alveolar macrophages are critically dependent on a pO_2 of greater than 25 mmHg for phagocytosis. Once ingested, a foreign particle is subjected to an array of lysosomal enzymes after fusion of the primary vesicle with the membrane-bound enzyme to form the phagosomal digestion chamber.

Macrophages produce specific stimulatory molecules, called *colony-stimulating factor*, which are important in inducing myelopoietic differentiation. It is likely that other cells also produce this factor; however, the critical microenvironment in marrow probably requires a cell–cell interaction in which local macrophages are most effective. Marrow macrophages serve as nurse cells to erythropoietic islands and remove the nuclei (hematogones) from maturing rubricytes, recycling the digested nuclei at the nucleotide level into others at an earlier stage of development.

Monocytes and macrophages are involved in the immune system during *antigen recognition* and later as *effector cells during the cell mediated response*. Administered antigen first becomes associated with medullary macrophages and cortical dendritic cells of lymph nodes. This process, known as *antigen focusing*, appears to involve the phagocyte in antigenic degradation and adjuvanting with RNA, followed by transfer to competent B lymphocytes in intimate contact with the phagocyte membrane.

Temperature elevation is part of the host response to inflammation. *Leukocyte pyrogen* is produced de novo by all granulocytes but primarily by macrophages. Most inducers are themselves pyrogens, of which endotoxin is one of the most potent. Release of pyrogen, such as TNFα, accompanies phagocytosis, and like that process is energy dependent. The monocyte system also produces *interferon* and appropriately armed macrophages are able to kill tumor cells by mechanisms that are immunologically nonspecific.

In the dog, steroid injection causes prompt **monocytosis** which reaches $2–3 \times 10^9/L$ and persists for 8 hours. In the cat, horse, and cow, monocytes decrease in acute stress and return with marrow rebound. Monocytosis of $3–5 \times 10^9/L$ is characteristic of the dog with pyometra and, to a lesser degree, with immune hemolytic anemia. Monocytosis may accompany lymphoma, especially if there are large areas of tumor necrosis. Monocytosis may be seen in muscle bruising and with sterile hematomas.

Lymphocytes

Lymphoid precursors arise in the blood islands of the yolk sac and colonize *the primary lymphoid organs, the bone marrow and thymus,* in early embryonic life. Both of these sites remain active in lymphopoiesis with their progeny circulating to the *secondary lymphoid organs constituted by the lymph nodes, spleen, and gut- and lung-associated lymphoid tissue.* In general, the primary lymphoid tissues of marrow and thymus remain isolated from the activities which arise during cellular differentiation in the secondary or peripheral lymphoid tissues. Kinetically, the very great bulk of circulating lymphocytes are thymus-derived and long-lived (years), while a small number of cells with rapid turnover have a shorter lifespan (days). Lymphocytes more often terminate their sojourn in a particular compartment by division rather than death, and in this sense the concept of lifespan differs from that of granulocytes which are end-stage cells with a finite life.

Both B- and T-cell precursors are derived from the bone marrow from resident pluripotent stem cells. T-cell differentiation occurs primarily in the thymus but likely also to some extent in all body surfaces including the gut and lung. Naive T cells from the bone marrow (CD7+) mature in the thymus where, by contact with the epithelial cells of the thymic cortex, they are selected for histocompatibility (MHC) self-recognition and tolerance and undergo rearrangement of T-cell antigen receptor (TCR) genes. These 4 genes A, B, G, and D undergo recombination of their 3 major segments, comprising the variable, diversity, and joining sequences, which are themselves interwoven with nontemplate nucleotides by the enzyme TdT. This process produces T cells with a very large range of specificities within the two $\alpha\beta$ and $\gamma\delta$ lineages. Lymphocytes that do not pass the process of self-recognition undergo apoptosis with evidence of their passing seen as tingible body debris in the cytoplasm of thymic cortical macrophages. The pathway of naive lymphocytes through the thymus is thought to be by entry into the cortex and progression to exit near the corticomedullary junction.

The exiting TCRαβ+ T cells form two lineages. The TCRαβ+CD4+ become *helper/inducer cells* that are able and restricted to interact with antigen presented on the surface of MHC II positive antigen presenting cell (APC) macrophages. The other lineage comprising the TCRαβ+CD8+ cells *interact with antigen* presented on the surface of MHC I by any other nonhematopoietic cell in the body. Thus, *these two lineages become the managerial cells for adaptive immune responses by the combined B–T cell system.* Further combinations of T cells include the double positive CD4+CD8+αβ T cells and the double negative CD4-CD8-γδ T cells which make up the major circulating populations. The proportions of these 4 lineages vary both with age and species.

Naive B cells from the marrow migrate to the lymphoid areas of peripheral tissues and undergo a V, J, D Ig gene rearrangement process similar to that of T cells. Initial arrangements include the heavy Ig gene (V_H DJ) and later either the kappa or lambda light chain (V_L J). The initial maturation of B cells is antigen-independent and may occur in marrow with surface Ig of M or D types while the subsequent differentiation in the presence of antigen results in a class switch to Ig of G, A, or E types. The process of B-cell maturation is not associated with morphologic specificity. However, in the process of clonal proliferation of antigen-specific lineages, there is increase in nuclear size and cytoplasmic volume that usually includes the presence of nucleoli and variable nuclear indentations that may terminate in small mature lymphocytes or plasma cells. In this process, the B cells undergo an orderly succession of membrane markers that proceeds from CD79α and β in naive B cells to CD45, CD45R, CD19, CD20, CD21, and finally CD22. There are two major populations of B cells, with B-1 cells most prominent in the fetal/neonatal stages and expressing sIgM and CD5. The B-1 population is sparse in the adult but is the population of cells expanded in human B-CLL and in the benign lymphocytosis induced in cattle by BLV. Some lymphomas of humans and dogs may express CD5 but never CD3. The B-2 population of lymphocytes is continuously produced by the marrow throughout life and is the dominant B cell in the blood of most species.

In a kinetic sense, *the number of lymphocytes in the peripheral blood is the net result of recirculation from lymph to blood via the thoracic duct and from blood to tissue via the postcapillary venules of lymph node cortex.* Lymphopenia results in low transmural traffic across these venules while in lymphoid leukemia they may be dilated and tightly packed with tumor cells. Steroid therapy causes **lymphopenia**; this change is due partially to lympholysis and partially to redistribution of lymphocytes into tissues. Lymphopenia occurs in chronic renal disease, lymphangiectasia, chylothorax due to rupture of the thoracic duct, in canine parvoviral infection, distemper and viral hepatitis, in hyperadrenocorticism, and in chronic classical swine fever. In all species, persistent lymphopenia indicates a poor prognosis. **Lymphocytosis** occurs in ruminants responding well to chronic disease. Examples of the latter are found in tuberculosis, brucellosis, trypanosomiasis, and *Bovine leukemia virus* infection. Lymphocytosis occurs in cats as a fear reaction, and in dogs and cats with hypoadrenocorticism.

Platelets

Blood platelets are produced by **megakaryocytes** that arise from committed hematopoietic stem cells. There is a *common precursor for the erythroid and megakaryocytic systems* that differentiates at the same hierarchical level as the precursor for the neutrophil–monocyte system. Evidence for this relationship is found in in vitro culture systems where both megakaryocytes and rubricytes may develop under the inductive pressure of erythropoietin. In the fetus, megakaryocytes are found successively in the liver, spleen, and marrow and in adult mammals they are found in the marrow, lung, and spleen. Megakaryocytes develop from CD34+ stem cells, as do other hematopoietic lineages, but gain the thrombopoietin (TPO) receptor c-MPL. Their proliferation and maturation are induced by interleukins 3, 6, 11 and stem cell factor (SCF) Flt-3 ligand and TPO. As megakaryocytes mature, they gain specific markers including glycoprotein (GP)IIb-IIIa and GPIb.

The volume of marrow occupied by megakaryocytes bears a constant relationship to peripheral platelet consumption. Thus, with increased platelet utilization, there is an increase in megakaryocyte number and volume, giving rise to the concept of *megakaryocyte mass.* Normally there is also a *direct relationship between megakaryocytic ploidy and cytoplasmic volume.* Thus, increased output from the system is accomplished by both increased input from the stem cell pool and by increased output per cell as a result of increased nuclear reduplication. This duplication from 2 N to 16 to 32 N occurs by both endomitosis and mitosis, although the latter tends to be seen only in a stressed system. It has been estimated that about 50 platelets are produced per nuclear lobe or 1600 platelets from a 32 N cell. In most species, platelets can be produced in 4 days. They have a circulation time of 9 days, which is determined largely by age-dependent utilization and to a lesser extent by random removal at sites of endothelial injury. The cellular production from a hematopoietic system can be said to be effective when the peripheral arrival of new cells is consistent with the volume of marrow precursors. In immune thrombocytopenias, there is usually increased peripheral destruction with an appropriate increase in marrow production. Occasionally there is depression of the precursors, and the disease is then greatly complicated by decreased marrow production. A less obvious problem of ineffective thrombopoiesis occurs in humans in pernicious anemia and in calves with trypanosomiasis and probably in other conditions as well. *Ineffective thrombopoiesis* is characterized by increased megakaryocytic mass with increased nuclear volume and normal or decreased cytoplasmic volume in the face of a peripheral thrombocytopenia that is due primarily to decreased production. The rate of thrombopoiesis is probably controlled by regulatory T lymphocytes at the stem cell level and by the $\alpha 2$-globulin, thrombopoietin, at the level of differentiation and maturation.

Blood platelets are discoid cells generally one-third to one-half the diameter of homologous red cells. Platelets have mitochondria and are capable of glycolysis with pathways remarkably similar to those in skeletal muscle. The cell is sponge-like and perforated by a microtubular array that probably aids rapid release of granular contents during the secretory phenomenon known as the *platelet release reaction*. In stained blood films, platelet granules are pink and may be centralized into a granulomere leaving a basophilic agranular peripheral hyalomere. Platelets can be quantitated like red cells on the basis of hematocrit and mean volume. Platelets contain *fibrinogen* and the contractile protein, *thrombosthenin*, which provides the force for clot retraction. A variety of plasma proteins adhere to the platelet membrane and may function in establishing the electrical properties of platelets. Platelets undergo metabolic aging in the circulation undergoing progressive lipid peroxidation. This may be the mechanism of senescent removal. Young platelets tend to be larger with greater basophilia, whereas older platelets are less granular and may lack basophilia. Platelets larger than red cells and usually basophilic, are called *"shift" platelets*; they indicate increased production. Their detection in thrombocytopenias is thus prognostically significant in differentiating increased destruction from decreased production. Normally the blood platelets present a spectrum of size, basophilia and granulation which corresponds to cell age and indicates age-dependent removal. In thrombocytopenias with increased turnover, they may all appear young, or all appear old if utilization is normal and production has ceased.

The role of the platelet in **hemostasis** is discussed in a later section. Briefly, *the normal contractility of injured vessels is assisted by platelet adhesion, aggregation, release reaction, and contraction which is associated with a laminar layering of fibrin.* While blood will clot in the absence of platelets, the hemostatic plugs so formed are unstable due to deficient adhesion and contraction. *Platelets can be said to support endothelial integrity*, and thrombocytopenia results in red cell diapedesis through apparently intact endothelium. Clinically, endothelium appears to remain intact for some hours after thrombocytopenia develops, and similarly petechiation may persist for some hours after platelet production increases.

Platelets are not equal in their functional capability and may be deficient because of congenital or acquired defects. *Congenital thrombopathies* are recognized in dogs and cattle, and *acquired dysfunction* occurs in acute leukemias and with aspirin therapy. In routine hematopathology, the *clot retraction test* is a useful measure of the functional capability of the circulating platelets. This variability in function accounts for the variations in the platelet counts at which purpuric hemorrhage occurs. Thus, petechiae may not be seen at a level of 10×10^9/L if platelets are large and very functional, while purpura may be seen at 50×10^9/L or higher if function is poor or impaired.

Acquired thrombocytopenia was formerly termed idiopathic but is *now accepted to be immune in origin* unless shown to be otherwise. The spongy nature of platelets makes them susceptible to immune sensitization because of adsorbed drugs, toxins and virus. *Immune-mediated thrombocytopenia of unknown cause occurs in dogs, cats, cattle, and horses and probably in other species.* Thrombocytopenia is a constant finding in acute equine infectious anemia and in bovine trypanosomiasis. Low platelet counts due to decreased production occur in cyclic hematopoiesis, pancytopenia, and following estrogen toxicity or marrow irradiation. Concurrent hemolytic anemia and consumptive thrombocytopenia is seen in dogs, and a large spleen in any species may cause deficits in circulating cells. Thrombocytosis of small platelets is characteristic of iron and copper deficiency. Thrombocytosis is transient after splenic removal and occurs in polycythemia vera (of humans but not of dogs) and in megakaryocytic myelosis both of which are rare, but are seen most commonly in dogs.

LEUKOPENIA-LEUKOCYTOSIS IN BENIGN DISEASE

The **hematologic profile** is a powerful tool in the assessment of response to disease. Serial blood profiles allow an assessment of an animal's response to a disease process and are of prognostic value. In general, *the three factors most important in predicting the magnitude of (neutrophilic) leukocytosis are* **animal species**, *and* **cause** *and* **localization** *of disease.* There is marked variation in hematologic reactivity among species of domestic animals, which is related to the normal ratio of neutrophils to lymphocytes in peripheral blood. Thus the dog, with a **neutrophil:lymphocyte ratio** of 2.4, is most reactive, whereas the cow, with a ratio of 0.5, is least reactive. The maximum leukocytosis likely to be encountered in each species can be predicted by multiplying the normal neutrophil:lymphocyte ratio times 50 as shown in Table 2.1.

In general, carnivores are more responsive than herbivores, and ruminants are the least reactive of the herbivores. Acute viral infections tend to involve large volumes of tissue and to injure body surfaces (gut, lung, skin) so that not only is the area of chemotaxis large but also leukocytes and their leukopoietic products may be lost from the body. Localized inflammatory processes are likely to be associated with leukocytosis regardless of species and type of agent. The differences between the cow and dog are largely in the rate of acceleration of cell production rather than in their potential for maximal response. The cow is able to mount a sustained neutrophilic leukocytosis like that of the dog with pyometra if given proper conditions of time and containment. These conditions are usually produced by abscessation of lung or liver which may be either miliary or single and massive. While sustained leukocyte counts in the cow greater than 50 × 10^9/L are rare, they do occur. The cow with a neutrophilic leukocytosis of 20–25 × 10^9/L that is sustained for more than a week can confidently be assumed to have abscessation.

Table 2.1 Leukocyte responses in benign disease

Species	Normal neutrophil: lymphocyte (N:L) ratio	Maximum expected leukocytosis (×10^9/L)
Dog	2.4	120
Cat	1.5	75
Foal	1.4	70
Horse	1.2	60
Pig	0.7	35
Goat	0.6	30
Sheep	0.5	25
Calf	1.0	50
Cow	0.5	25

In animals, *infection frequently causes leukopenia,* particularly in ruminants with mastitis and metritis and in carnivores with systemic viral infection such as infectious canine hepatitis and distemper in the dog and parvoviral infections in the dog and cat. Guidelines for leukocytic interpretation that are valid for all species, are that *the* **absolute increase** *in leukocytes indicates individual or species reactivity, whereas the* **proportional increase** *in mature and immature neutrophils and the level of toxic changes indicates the "effort of the response."* In all species, a low total leukocyte count with persistent neutrophil immaturity and toxemia is a *poor prognostic finding.* The return of the leukocyte count to normal from levels which were either increased or decreased, with reduction in immaturity and cytologic toxicity, is indicative of *recovery.* The return of eosinophils to the blood is usually prognostically favorable if accompanied by other signs of recovery.

MYELOID REACTIONS

Leukemoid reactions

Leukemoid reactions are abnormalities of peripheral blood which resemble leukemia but are due to other causes. They occur in all species but are most often seen in the *cat and dog.* The leukemoid reactions occur in a variety of hematologic perturbations including *infections, intoxications, severe hemorrhage or hemolysis, and in some malignant diseases.* In terms of cellular kinetics, a marked increase in blood leukocytes with immaturity is due to a combination of increased cell production and release and may be exacerbated by deficient cell removal and destruction. In the dog, leukemoid reactions are most often seen in association with *pyometra, peritonitis and hemolysis.* The cat is similar. The administration of tuberculin to previously sensitized rabbits can produce a leukemoid reaction with leukocyte counts in excess of 100 × 10^9/L that is primarily neutrophilic and with left shift.

Hematologically, there is *neutrophilic leukocytosis* which is usually in the range of 50–100 × 10^9/L. Mature neutrophils predominate in the peripheral blood, but there is immaturity to at least the promyelocyte stage. Blast cells are seen occasionally, but these are usually lymphoid and misinterpreted because of the myeloid immaturity. There is usually diffuse cytoplasmic basophilia of mature cells with reduced secondary granulation and variable cytoplasmic vacuolation. Toxic azurophilic granulation and Doehle bodies may be present. There is usually *anemia* of at least mild degree that is nonresponsive due to the intensity of the myeloid reaction. Mild rubricytosis of maturing cells is irregularly present. There is usually *monocytosis* of 2–4 × 10^9/L with mild immaturity and variable cytoplasmic vacuolation. Eosinophils are generally mature and less than 1 × 10^9/L and may have decreased secondary granulation with vacuolation and increased cytoplasmic basophilia. Basophils are absent.

Aspirated bone marrow is hypercellular, generally above 70% with synchronous myelopoiesis, a marked increase in mature reserves and less than 10% blast cells. There is erythroid atrophy, but not phthisis, and hemosiderin is usually coarse and increased.

Animals showing a leukemoid reaction often recover. Those that die show various lesions depending on the primary cause. Morphologically there is an increased volume of hematopoietic marrow. By definition, the leukemoid reaction must resemble leukemia. *The diagnosis of leukemoid reaction tends to be a working clinical designation used until biopsy, autopsy or recovery resolves the problem.*

Leukoerythroblastic reaction

The leukoerythroblastic reaction is characterized by leukemoid reaction with the presence in the peripheral blood of rubricytes as young as basophilic rubricytes. The leukoerythroblastic reaction is seen in all species and is *most common in the cat and dog*, and least common in the horse. Since this reaction is always part of other processes, there are no characteristic clinical signs. It is most apparent in *immune hemolytic anemia* of animals other than the horse. Immature cells of both systems are likely to appear in the peripheral blood when there is heightened marrow activity. The degree of immaturity is important and is less with reactive marrow than with malignant infiltration.

It is uncommon to have benign erythroid hyperplasia without concurrent myeloid hyperplasia. Thus, *responsive immune hemolytic anemia is usually accompanied by a sustained neutrophilia with mild left shift.* In contrast, myeloid hyperplasia is regularly accompanied by some degree of erythroid atrophy. Myeloid immaturity is thus expected in increased erythropoiesis, but rubricytes are not expected in myeloid hyperplasia unless there is a considerable level of stress. *The leukoerythroblastic reaction is therefore present at some point in all leukemias and is most common in the acute leukemias.*

Recognition of the leukoerythroblastic reaction does not constitute a diagnosis but rather a *condition of concurrent release of benign immature myeloid and erythroid cells.* It needs to be differentiated from malignancy in both the erythroid and myeloid systems and interpreted in the light of relative immaturity and the nature of the concurrent process.

MYELOID NEOPLASMS

Myeloproliferative disease *is a general term for diseases characterized by medullary and extramedullary proliferation of one or more marrow myeloid cell lines, with specific exclusion of the lymphomas and lymphoid leukemias.*

The **acute myeloid leukemias (AMLs)** are a biologically aggressive and morphologically diverse group of hematologic neoplasms characterized by *proliferation of poorly differentiated cells arising from the marrow myeloid progenitor cells.* On a morphologic basis, the acute myeloid leukemias are divided into four groups comprising the *granulocytic (neutrophil, eosinophil, basophil), monocytic, erythroid, and megakaryocytic lineages.* The presentation of AML is usually with proliferation of only one of these four cell lines, or less often with multiple lines involved in a panmyelopathy. The proliferation of the neoplastic clone causes phthisis of normal marrow elements with the result that animals with AML usually have some degree of marrow failure at the time of diagnosis including anemia and thrombocytopenia. The indications of AML in the blood may vary widely with very high leukocyte counts or severe leukopenia, but blast cells are always present. *The AMLs are classified here according to the revised WHO system and essentially on a morphologic basis* (Table 2.2). One of the major changes from the FAB (French–American–British) system of classification of the acute leukemias is that the WHO format reduces the level of blast cells required for a diagnosis of AML from 30 to 20% of nucleated cells in marrow or blood. A further proposal of the WHO classification is recognition that AMLs that arise in individuals that have had a prior diagnosis of myelodysplasia have a poorer prognosis than in the recognition of de novo acute leukemia, and therefore these cases should be given a separate category of classification. Further, if on the diagnosis of AML it is apparent that there are dysplastic changes in benign cell lines (multilineage dysplasia), then this finding should also require a separate category based on a poorer prognosis. In human pathology, lymphoid tumors can be classified largely on the basis of immunohistochemistry for routine diagnosis, whereas the AMLs require a battery of cytogenetic and molecular techniques for adequate characterization. With the sequencing of animal genomes now a reality, these more sophisticated techniques for the diagnosis of AML will be added to the morphologic identification of AML in animals. In the interim, there is every reason to rely on proven and available techniques such as the myeloperoxidase reaction and Sudan black B stain to differentiate the blast cells of the AMLs from those of the lymphoid system (Table 2.2).

Table 2.2 Cytochemistry for acute myeloid leukemias

Reaction	Normal cells manifesting reaction	Diagnostic utility
Myeloperoxidase	Neutrophil series Eosinophils (cyanide resistant) Basophils ± Monocytes ±	Myeloblastic leukemia without maturation – M1 Myeloblastic leukemia with maturation – M2
Sudan black B	Neutrophil series Monocytes ±	M1, M2
Chloroacetate esterase	Neutrophil series Monocytes ±	M1, M2
Nonspecific esterase (α-naphthyl acetate substrate, or α-naphthyl butyrate)	Monocytes (inhibited by sodium fluoride)	Monocytic leukemias Monocytic leukemia, differentiated – M5 Monocytic leukemia, poorly differentiated – M5 (acute monoblastic) Myelomonocytic leukemia – ??
Periodic acid-Schiff (PAS)		Erythroleukemia – M6 Acute lymphatic leukemias

With permission of R. D. Brunning, MD, Department of Pathology, University of Minnesota.

Leukemias result from the accumulation of chromosomal abnormalities that both permit and sustain neoplastic proliferation. Cytogenetic studies on human leukemias have established correlations between cytogenetic changes and clinical phenotypes for specific subtypes of leukemia. Because many of these chromosomal changes represent recurring types of leukemia, they have been molecularly cloned thus providing powerful tools for detection of specific types of genetic injury of both diagnostic and prognostic value. In addition, the presence or absence of these genetic changes provides clear and definitive distinction between benign and malignant disease. The structural basis for genetic change resulting in malignancy lies in the translocation of parts of chromosomes that both inactivates tumor suppressor genes and the normal caspase system of programmed cell death and permits the production of aberrant growth factors. Chromosomal translocations may alter gene function by *dysregulating gene expression*, as occurs in the lymphoid tumors due to breakages involving the immunoglobulin gene of B-cell tumors and the T-cell receptor genes of the T-cell tumors. These rearrangements cause inappropriate activation of an oncogene with the production or overproduction of a normal protein in a tissue where it is not normally found. The second mechanism by which translocations cause cancer is by the *joining of two genes normally on different chromosomes so that abnormal fusion proteins are produced.* Since the newly formed gene and its product are not found in normal tissues, the chimeric protein becomes tumor-specific and constitutes a tumor marker. These markers can be the basis for tumor diagnosis and for the detection of residual disease after therapy. In addition to activation of new proteins, chromosomal translocations or deletions may result in the loss of gene function such as occurs with tumor suppressor genes whose normal function is to limit cellular proliferation. Since there are two copies of each gene, both copies of the suppressor genes must be inactivated (loss of heterozygosity) in order for the implications of other translocations capable of causing cancer to become apparent.

In terms of pathogenetic mechanisms, the chronic leukemias have contributed greatly to understanding of the leukemic process since the description of the 9;22 (Philadelphia) chromosomal translocation characteristic of human chronic myelogenous leukemia.

Those acquired chromosomal alterations with high sensitivity and specificity for lineage specific malignancies are termed **primary changes**, as in the Philadelphia chromosome. Nonrandom acquired chromosomal changes which occur in the course of the accelerated phase of chronic myelogenous leukemia are termed **secondary changes** since they occur in other conditions and are not useful as tumor markers but are useful for staging and prognosis. Typically in late-stage human chronic myelogenous leukemia, there are further random changes in chromosomes which result from the basic instability of the malignant clone and lack lineage specificity but are associated with the level of tumor aggression and these are termed **tertiary chromosomal changes**. Tertiary changes are common in solid tumors and for years obscured the specificity of the less common primary and secondary changes. Clonal chromosomal abnormalities are found in the great majority of human leukemia-lymphoma and myelodysplasia suggesting that these changes have been inadequately looked for in spontaneous tumors of animals.

The major determination in the diagnosis of acute poorly differentiated or undifferentiated leukemia is the distinction between myeloid and lymphoid lineage. This distinction has traditionally been based on histochemistry (Table 2.2). However, the recognition and characterization of lineage-specific cell surface antigens has produced a large family of reagent antibodies directed against these antigens particularly for human and mouse cells. By international concordance these antigens are grouped by *cluster designation (CD)* in which CD4 defines T helper and CD8 defines T suppressor subsets, and CD13 defines poorly differentiated lymphoid clones whereas TdT defines poorly differentiated lymphoid clones.

The most useful reagents are those that are active in formalin-fixed, paraffin-embedded tissues. Many of the CD reagents are active only in flow cytometry, which limits their use to cases where the diagnosis has been largely determined by routine cytology and live cells can be prospectively prepared for in vitro staining and subsequent counting. Currently, *the most helpful CD antibodies for general use in histopathology are CD3 which is a pan-T-cell marker and CD79α as a pan-B-cell marker.* The CD3 antibody binds to the rearranged T-cell receptor and is thus able to mark all differentiated T cells. The CD79α peptide is Igα, and Cd79β is Igβ. They are both IgSF (superfamily) members and together form a heterodimer associated with surface IgM on B cells to form the B-cell receptor (BCR). These proteins appear on the surface of all differentiated B cells and the BCR is expressed prior to the appearance of the cytoplasmic μ chain. The anti-CD79α antibodies cross-react with endothelium in most domestic species, and with the cytoplasm of mature megakaryocytes and variably with hepatocytes. These are minor reactions and serve as an internal positive control. A less valuable feature of CD79α is that it may frequently mark the nuclei of T cells in a nonspecific reaction with only cytoplasmic marking indicating B-cell differentiation. *Both CD3 and CD79α mark the lymphocytes of most domestic species and rodents. These two reagents plus the histochemical reaction of Sudan black B are the major means of differentiating myeloid and lymphoid blasts.* Where time and additional unstained cytological preparations are available, the use of *myeloperoxidase* to identify granulocytic and monocytic precursors is an efficient means to prove that these are nonlymphoid lineages. Within the myeloid tumors, the *chloroacetate esterase stain* specifically identifies the granulocytic precursors whereas the *nonspecific or α-naphthyl acetate or α-naphthyl butyrate esterase stains* specifically mark the cytoplasm of monocytic precursors and macrophages.

As might be expected, the simplest techniques suffice in more differentiated malignancies, and in primitive tumors all modalities may be required to fully define cell lineage and thus management strategies. Collectively, these diagnostic techniques have added greatly to the understanding of leukemias particularly in the areas of apparent conflict. For example, in myeloid leukemia in blast crisis, in 25% of human cases the tumor cells carry lymphoid markers recapitulating the evolution of the clone from a totipotential stem cell capable of producing both myeloid and lymphoid progeny. Some 30% of human acute lymphoid leukemia in adults have the Philadelphia chromosome, and in some cases the response to treatment varies with the presence of specific cytogenetic alterations although the tumors may appear morphologically similar.

The myeloproliferative diseases occur mostly in dogs and cats; their recognition in other domestic and wild animals is relatively rare. In dogs, myeloproliferative disease constitutes about 5% of hematopoietic neoplasia. Cats have the greatest proportion and range of myeloproliferative diseases, which constitute 10–15% of hematopoietic neoplasms with a similar proportion of lymphoid leukemias and the rest lymphomas. Characteristically, the acute leukemias have a course of 1–2 months from diagnosis to termination, whereas the chronic leukemias have a natural course of 1–3 years. Acute leukemias of humans and animals, because of their high rate of proliferation, are most responsive to chemotherapy. In contrast, animals with chronic leukemia may derive little benefit from intensive cytoreductive chemotherapy based on cells in active proliferation because the mitotic rate of the tumor cells is similar to or less than that of residual normal marrow.

The descriptions provided are of the diseases unaltered by chemotherapy. Treatment of the acute leukemias causes lymphoid atrophy and reduced cellularity of bone marrow. Treatment of the chronic leukemias causes similar changes but with more generalized sclerosis.

Chemotherapy tends to reduce the size of the residual tumor cells and to reduce their lineage-specific differentiation. It is therefore highly desirable to base histologic and cytologic diagnoses on tissues derived prior to onset of therapy.

Acute leukemias

M1, Myeloblastic leukemia without maturation (acute myeloblastic leukemia, AML)

M1 is defined as having *a predominance of blasts in blood and marrow with less than 10% having cytoplasmic granulation.* At least 5% of malignant blasts stain positively for Sudan black and myeloperoxidase. AML of the M1 and M2 type is largely a disease of young mature dogs and cats with a tendency for increased frequency in males. Swine are occasionally affected and other domestic animals very rarely. The M1 variant of AML is likely under-diagnosed since lymphoid tumors are much more common and, if the few cells with cytoplasmic granules are not recognized and cytochemistry is not carried out or is inconclusive, the tumor cells most resemble large malignant lymphocytes (Fig. 2.9A).

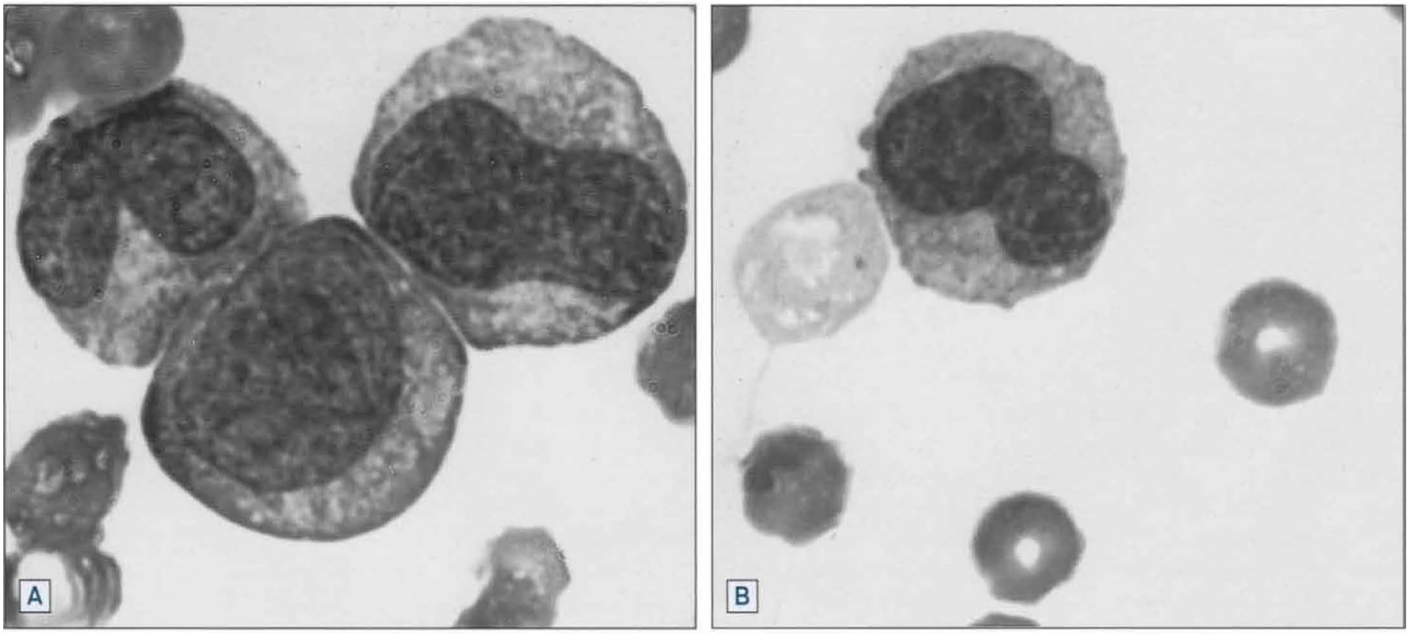

Figure 2.9 M2, Acute myeloblastic leukemia in a dog; blood smear. **A.** Poorly granulated myeloblasts. Myeloid origin can be deduced from the pattern of maturation that ends at the metamyelocyte stage. **B.** Bilobed progeny of malignant myeloid precursors. Cytoplasmic fragment from injured tumor cell that contains granules may be confused with a large platelet.

Histologically, M1 is indistinguishable cytologically from acute lymphocytic leukemia (ALL) or large cell lymphoma, thus *blood and marrow cytology is essential for the diagnosis of this disease.* Architectural differences between M1 and lymphoma are usually sufficient to identify the disorder as a primary leukemia but will not differentiate M1 from ALL.

M2, Myeloblastic leukemia with maturation (AML)

M2 is similar to M1 except that maturation proceeds to or past the promyelocyte stage in at least 10% of tumor cells (Fig. 2.9). Approximately half of the tumor cells stain positively with Sudan black and myeloperoxidase. Most animals are presented in good body condition because of epistaxis or melena of acute onset and have mucosal pallor often with thrombocytopenic petechiation. The liver and spleen are usually not palpably enlarged and the lymph nodes are characteristically of normal size. Acute myeloblastic leukemia usually has a course of 2–3 weeks from the time of diagnosis. Death is due to hemorrhage and sepsis, if not complicated by chemotherapeutic myelosuppression.

Anemia is moderate (80 g/L) and due to *myelophthisis*, or marked (20 g/L) when complicated by thrombocytopenic hemorrhage. Anisocytosis is mild and there are a few poikilocytes which are more numerous if platelets are deficient. Howell-Jolly bodies are usually present and indicative of reduced splenic function. Hypochromia will be present if the animal survives hemorrhage by a week or more. The erythroid response is mild or absent and usually less than the normal level of 60×10^9 reticulocytes per liter. Rubricytosis is often present to a mild degree, usually less than 1.0×10^9/L, and with cells as immature as prorubricytes and occasionally a rubriblast in the peripheral blood. These cells are benign and their release independent of age is indicative of leukemic myelophthisis (leukoerythroblastic reaction).

Thrombocytopenia is generally marked and in the $5–50 \times 10^9$/L range with immature platelets rare or absent. The platelets present tend to have uniform basophilia but reduced granulation and functional deficits accompany low numbers. Cytoplasm shed from the fragile tumor cells rounds up and with its sparse pink granulation may be mistaken for platelet material, especially large immature platelets.

The total leukocyte count is highly variable but may be in the normal range and is usually less than 25×10^9/L, but may rise to 50×10^9/L near termination. There is an absolute neutropenia and usually lymphopenia with myelocytes predominating followed by promyelocytes, metamyelocytes, and myeloblasts. *The tumor may be of the neutrophil, eosinophil, or basophil type, but the neutrophil type is most common.* Peripheral blood differentiation does not proceed past the metamyelocyte stage and if more mature cells are present they are likely to be the progeny of residual normal marrow. Hypersegmentation may be present in benign neutrophils due to hyposplenism and probably to folate deficiency. If neutropenia has persisted for a week or more, bacteremia is often present and the benign cells have toxic changes.

Cytologically (Fig. 2.9A), the leukemic cells in blood have round centrally placed nuclei 2.5 red cells in diameter with a fine uniform or cribriform chromatin pattern. One to three nucleoli which are round and from one-third to two-thirds the size of a red cell are visible in the leukemic myeloblasts and promyelocytes. The cytoplasm is moderate in volume and basophilia and has a smooth outline that is not usually indented by adjacent cells. There is usually sufficient fine azurophilic granulation, most visible in the Golgi clearing, to identify the cells as being of myeloid origin. In addition, the process of recognition by "the company they keep" is important; the mild reniform nuclear indentation in the most mature tumor cells suggests metamyelocyte differentiation (Fig. 2.9B). This indentation is much more shallow than the sharp folding characteristic of lymphocytes. Rarely in blood, benign promyelocytes and myelocytes will be recognized by their lower nuclear/cytoplasmic ratio, small nucleoli and increased granulation. They are part of the process of myelophthisis and the leukoerythroblastic reaction.

Aspirated bone marrow (Fig. 2.10A) has very high cellularity and cell density, with few fat vacuoles. There is *virtually complete phthisis of the normal elements* (Fig. 2.10B), resulting in loss of rubricytes, megakaryocytes, and mature granulocytes, and a coarse hemosiderin pattern. Characteristically the marrow cells are about one morphologic stage less mature than those in the peripheral blood. Early metamyelocytes are rare and myeloblasts and promyelocytes predominate. Mitoses are very frequent and granulation is usually recognized in metaphase cells when the obscuring basophilia is minimal. The animals are usually presented for examination when 50% or more of the marrow is occupied by tumor and marrow failure is imminent.

At *autopsy*, there is pallor of membranes and tissues and mild-to-moderate loss of condition. The lymph nodes are of normal size and often edematous. The liver is of normal size and pale. The spleen is usually mildly and uniformly enlarged and may be focally infarcted. Femoral marrow is uniformly vascular and a glistening pale tan rather than the hard white of normal fat. There are usually foci of hemorrhagic infarction if thrombocytopenia has been severe. The thymus is atrophic. Solid foci of the tumor in parenchymal organs are not found. Secondary lesions of marrow failure include hemorrhage, pneumonia and cellulitis. Because of the absence of neutrophils, even septic lesions may have minimal cell reaction.

Histologically the neoplastic cells are round with peripheralized chromatin, prominent pink nucleoli, and a moderate amount of amphophilic cytoplasm. There are frequent mitoses and some cells of metamyelocyte type are present. Mature cells of the normal series are rare and if the tumor is of the neutrophil type, most segmented cells will be residual, normal eosinophils. Megakaryocytes and rubricytes are rare or absent.

The spleen has lymphoid atrophy that is most prominent in thymic-dependent areas. The sinus areas contain few erythrocytes, are hypercellular due to tumor infiltration and have increased, coarse hemosiderin. Benign hematopoiesis, if present, is characteristically paratrabecular and largely limited to thrombopoiesis. There is usually some subendothelial colonization of the large muscular sinuses by tumor cells. The liver usually has periacinar ischemic degeneration. The tumor has a sinusoidal distribution and if the leukocyte count was low, tumor cells may not be obvious. Periportal colonization is minimal and absent from many triads; this is an important distinction from the lymphomas. Benign hematopoiesis is similarly inconspicuous, which suggests that there is exhaustion of benign stem cells. Lymph node histology is highly variable and may vary from minimal involvement occurring first in medullary cords (Fig. 2.11A) with moderate lymphoid atrophy to diffuse involvement with capsular colonization (Fig. 2.11B), usually without an increase in overall size. If transfusions have been given, there will be erythrophagocytosis in the medullary sinuses of the lymph nodes and sinuses of the spleen.

M2 myeloblastic leukemia is distinguished from acute lymphoblastic leukemia on the basis of cytoplasmic granulation and a positive

M3, Promyelocytic leukemia

Promyelocytic leukemia (Fig. 2.12) is a *rare disease of young mature animals*, most commonly recognized in *dogs and cats* but also in swine and likely occurs in species where it is looked for. Clinical signs are similar to M1/M2 myeloblastic leukemia but with a greater tendency for bleeding. The course of the disease is usually only 1–2 days from time of diagnosis. In humans, there are two forms of M3 with 80% of cases having very prominent cytoplasmic granulation in the malignant promyelocytes and less tendency for bleeding. The second type of human M3 has hypogranular promyelocytes with very fine azurophilic granulation and is associated with DIC.

Promyelocytic leukemia differs from myeloblastic leukemia by a predominance of promyelocytes in both blood and bone marrow. Most cases in animals are seen at necropsy and live presentation is rare. The M3 in animals associated with bleeding may resemble warfarin poisoning or other coagulopathy. The disease, while rarely occurring, may be even more rarely recognized because of the difficulty of making a specific diagnosis of acute myeloid leukemia solely on histologic examination. There is pancytopenia on presentation, and often severe and widespread hemorrhage and apparent bruising. The proportions of the heavy and lightly granulated forms of the disease in animals is unknown and, likely because of the association with coagulopathy and early death due to bleeding, the level of blast cells in the poorly granulated type never reaches the 20% level required for the diagnosis of other types of AML. Atypical promyelocytes are the predominant cell in both blood and marrow and further differentiation to myelocytes is minimal, and metamyelocytes arising from the malignant clone are rare. The malignant promyelocytes have nuclei the same size or larger than in AML of M0/M1 types but cytoplasm is much more abundant. The promyelocyte nuclei have shallow indentations but do not form typical myelocytes or metamyelocytes. The cytoplasmic granulation in both variants of this disease is intensely positive with Sudan black and myeloperoxidase stains. In M3 in humans, the cytoplasmic granules are procoagulant, and rapid cytoreductive therapy may result in disseminated coagulation. The disease in humans is associated with a specific primary 15;17 chromosomal translocation which results in fusion of the retinoic acid receptor-α gene on chromosome 17 with the zinc finger binding transcription factor (known as the promyelocytic leukemia or PML gene) on chromosome 15. This pathogenesis provides the basis for a very highly effective treatment of this disease with transretinoic acid.

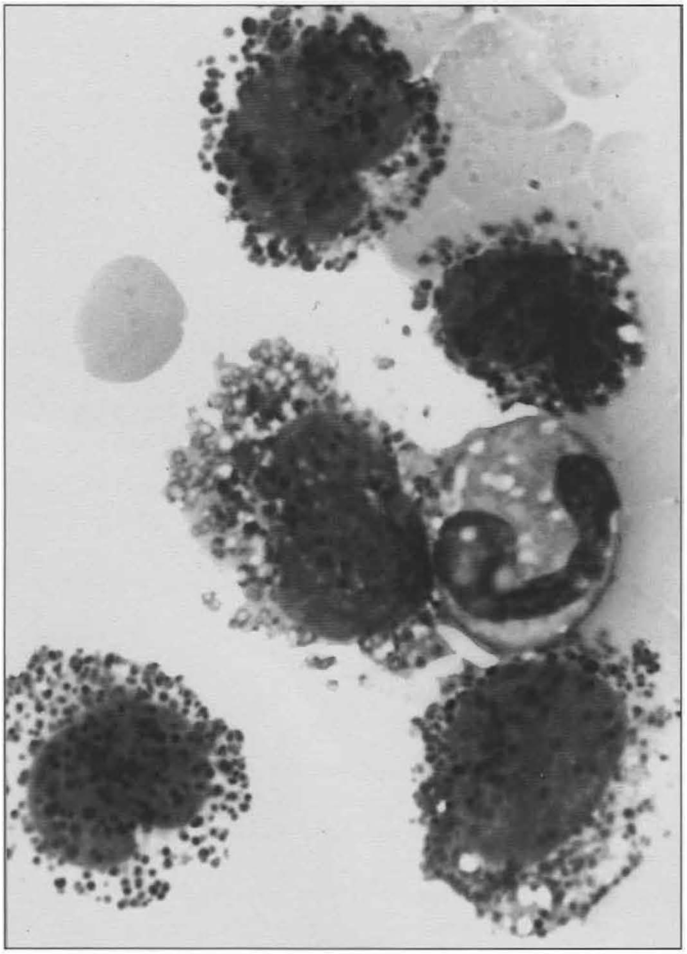

Figure 2.12 Promyelocytic leukemia, canine blood. Nuclear indentation indicates that this tumor is of basophil type rather than a mast cell leukemia.

M4, Acute myelomonocytic leukemia

Myelomonocytic leukemia is a rare disease recognized in dog, cat, horse, and humans in which there is concurrent neoplasia of the neutrophil and monocytic cell systems. Most commonly the disease consists of concurrent clones of tumor derived from both the monocytic and neutrophil systems and as such the tumor cells mimic their normal counterparts in both morphology and histochemical reactions. As much as a third of human cases of M4 have a single tumor clone which combines the cytochemical characteristics of both cell lines and therefore represents an entity for which there is no normal counterpart. *AML of the M4 type have at least 20% of blast cells in blood or marrow and at least 20% of the marrow cells must be of monocytic lineage to distinguish M4 from M2.* In AML of M4 type in humans, there is often an increase in marrow eosinophils rather than neutrophils and these are atypical and have a mixture of eosinophil and basophilic granules. In older classifications, M4 is defined as having at least 20% of both tumor cell lines staining for the neutrophil series (chloroacetate esterase, Sudan black or myeloperoxidase activity) or for the monocytic series (fluoride-sensitive esterase). The requirement for at least 20% involvement by both tumor lines rules out confusion with hyperplasia. *The critical point in the diagnosis of this disease is that both types of lineage-specific staining must be found in cells which are independently determined to be malignant.*

Animals are presented in good body condition but with a history of weight loss of recent onset accompanied by malaise and anorexia. Clinically, there is pallor of mucous membranes, irregular enlargement of cervical nodes, mild splenomegaly and moderate fever. Anemia is moderate to marked and nonresponsive, with some fragmented cells, increased pallor and Howell-Jolly bodies. Thrombocytopenia is marked and poorly responsive. The leukocyte count is generally between 25 and 50 $\times 10^9$/L. Morphologically, the leukocytes resemble those of myeloblastic leukemia with some maturation, and acute monocytic leukemia, occurring in the same animal. Malignancy, as determined by nuclear atypia and immaturity in the peripheral blood is present in both systems. In general, the degree of esterase staining varies with the degree of cytoplasmic granulation, and both cell lines may be positive for peroxidase activity. The course is 4–6 weeks with termination due to sepsis and thrombocytopenic bleeding. Grossly there are widespread petechial hemorrhages, focal infarctions of liver, kidney, spleen and marrow and usually oral ulcerations.

Histologically there is widespread tumor infiltration in marrow, splenic sinuses, nodes, portal areas of the liver, and irregularly in other organs including lung. In untreated cases, benign extramedullary hematopoiesis may be found in adrenal glands and nodes. There is prominent phthisis of normal lines in marrow, particularly of megakaryocytes, and the diagnosis is dependent on cytology and cytochemistry. *M4 must be differentiated from monocytic leukemia (M5) and from myeloblastic leukemia M2, from which it is indistinguishable histologically.*

M5, Acute monocytic leukemia

Acute leukemia of the monocytic lineage occurs as a *poorly differentiated* **acute monoblastic type M5a** *and in a more mature cell type* **acute monocytic M5b**. *The predominant cell in M5 is a monocytic precursor as defined by nonspecific (α-naphthyl-butyrate) esterase activity.* In the monoblastic M5a type, there are at least 20% of blast cells in marrow or blood and at least 80% of the cells are of monoblastic and promonocytic types. In the more mature M5b type, the same level of blast cells are present but promonocytes predominate in both marrow and blood with the total of both blastic and promonocytic forms equaling 80% of nucleated cells. In contrast to M4, less than 20% of cells mark with Sudan black or myeloperoxidase indicating granulocytic origin. The leukocyte count tends to be low or normal in the more acute form and elevated in the differentiated variant.

Monocytic leukemia occurs in young dogs and cats and in mature horses and cattle. The disease in the young tends to be of the M5a type whereas that in adults is M5b. This description is typical of the disease as occurs in the dog. M5a is an acute disease with clinical presentation similar to that of myeloblastic leukemia. Animals are presented because of general signs of lethargy, weight loss, vomition, diarrhea, and anorexia and more specifically recurrent epistaxis. Clinically there is pallor that appears worse than the PCV would dictate and is characteristic of this disease where there is sludging of tumor cells in the microvasculature. The course of the disease is generally 2–4 weeks.

Anemia is usually marked (<50 g/L) and nonresponsive with pallor in larger red cells. Thrombocytopenia is severe and nonresponsive. The leukocyte count is usually $<25 \times 10^9$/L at diagnosis but increases to between 50 and 100 $\times 10^9$/L terminally. There is often mild neutrophilia and left shift, which is likely due to growth factors produced by the tumor and a field effect of the autocrine pathogenesis driving the tumor cells themselves. *Cytologically, the tumor is relatively monomorphic, but both monoblasts and promonocytes are present, with the latter predominating in the blood* (Fig. 2.13). The monoblasts are large, 2.5 to 3 red cells in diameter with an irregularly indented nucleus whose boundaries are obscured by intense cytoplasmic basophilia. The promonocytes have slightly smaller nuclei, less than 3 red cells in diameter, with convoluted or cerebriform outline, a fine retiform chromatin pattern, and 1–2 nucleoli of moderate size. The cytoplasm is more basophilic than in young benign monocytes, and characteristically of uniform density from the nucleus to the cytoplasmic boundary. This is a useful distinction from the perinuclear clearing seen in lymphocytes. Very fine azurophilic granulation is apparent in the Golgi clearing, and clear vacuoles are frequent and often penetrate the nucleus. Rubricytes may be present, but the anemia is nonresponsive.

Aspirated marrow is highly cellular with relatively complete phthisis of erythroid and megakaryocytic cells. Myelopoiesis is synchronous to the neutrophil stage but relatively reduced in amount. Marrow cells are 80% undifferentiated blasts, monoblasts and promonocytes with nuclear hyperchromicity and prominent nucleoli and a moderate mitotic rate.

Lesions are similar to those of myeloblastic leukemia, often with focal hemorrhages, but less often with secondary infection. The tumor distribution (Fig. 2.14A, B) is like M2 with greater dissemination to the urinary system and adrenals. Histologically, the nuclear convolutions are less apparent than on cytologic examination and the tumor cells resemble cleaved lymphocytes with deeply amphophilic

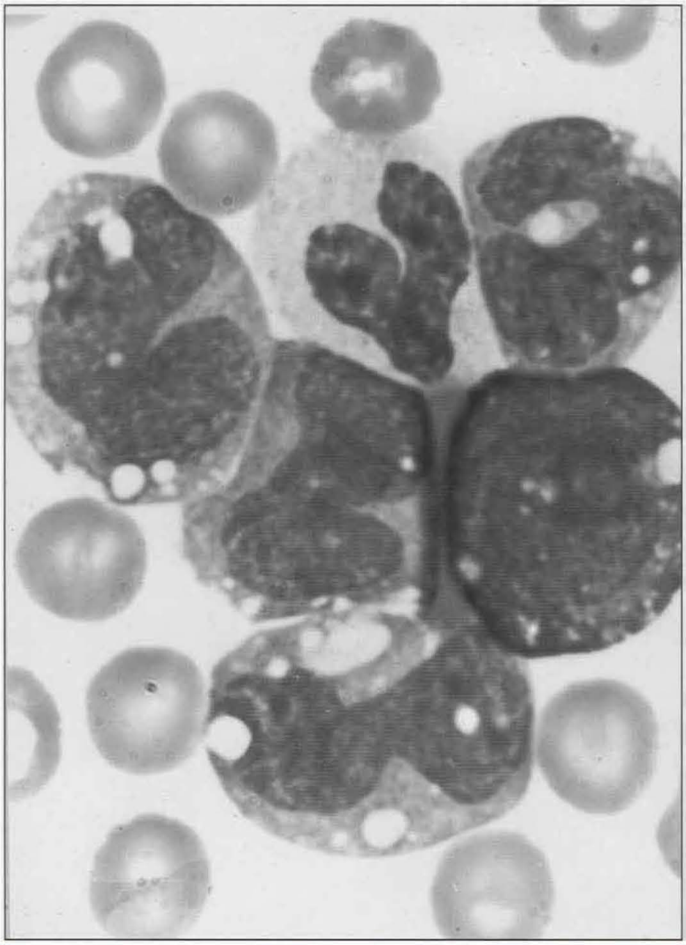

Figure 2.13 Monocytic leukemia, blood, dog. Irregularly convoluted and segmented nuclei with prominent cytoplasmic vacuoles indicate monocytic differentiation. Vacuolation characteristic of monocytes is present in the blastic cell at center right.

cytoplasm. The tumor cells are not regularly phagocytic and this criterion is not helpful in distinguishing this disease from acute lymphocytic leukemia (ALL) of the L2 type. *Definitive diagnosis requires cytochemical staining on blood and marrow aspirates or imprints.*

M6, Acute erythroid leukemia

M6 occurs in two forms, of which **M6a (erythroleukemia)** (Fig. 2.15) *is a combined acute leukemia of both the erythroid and myeloid systems. In M6a leukemia, the erythroblasts are usually more than 50% of all marrow cells.* If this condition is present and erythroleukemia is suspected, then a second count of blast cells is made with the erythroid cells excluded. If in that count the level of myeloblasts equals or exceeds 20% of other marrow nucleated cells, then M6a or erythroleukemia is confirmed. In **M6b leukemia (erythremic myelosis)** (Figs 2.16–2.18), *the malignant erythroblasts are even more prominent and erythroblasts and prorubricytes constitute as much as 80% of all nucleated marrow cells.* Myeloblasts make up much less than 20% of the remaining marrow cells and some myeloid cells may have dysplastic changes. Erythroleukemia, or M6a, while rare in animals, is relatively less so in humans. On the other hand, erythremic myelosis or M6b, a disease associated with *Feline leukemia virus* infection in the cat, is much more common in animals than in humans where it is exceedingly rare. Hematopoietic proliferation in benign cells has *two loci of genetic control* to which the feedback system of growth factors provides the fine tuning. In malignancies, the system may become deregulated at either level resulting in either a poor- or well-differentiated tumor. In the erythroid system, autonomy at the early loci results in erythremic myelosis, whereas at the late loci the disease is polycythemia vera with an overproduction of normal appearing red cells. Within erythremic myelosis, there are variations in the general maturity of the tumor cells such that the more mature variant may initially be mistaken for a benign response to severe anemia while the immature variant resembles the hairy cell leukemia or "reticulotheliosis" described in cats. These variations are apparent histologically in the accumulation in the spleen and liver of rubricytes that are either relatively mature and well-saturated with hemoglobin or are primitive and resemble lymphocytes with round nuclei and an unusual level of anisokaryosis. The malignant erythroid cells mimic their normal counterparts in containing sufficient glycogen to stain positively with the periodic acid-Schiff (PAS) reaction in both cytologic and histologic preparations.

Erythremic myelosis is largely a disease of cats but we have seen it in a mature Holstein cow. It may appear from 1 year to old age and has a 2:1 predominance in males. The disease occurs rarely in other domestic animals.

Animals are presented with a history of depression lasting from a few days to 2 months. Anorexia develops and is occasionally accompanied by vomition and diarrhea. With recent onset, the animals are in good condition and later are thin with mild abdominal distension due to splenomegaly and mild hepatomegaly. The lymph nodes are of normal size or small and there is marked mucosal pallor, occasionally with mild icterus. The course of the disease is 1–3 months.

Anemia is severe with hemoglobin levels varying from 20–50 g/L. Hemotrophic mycoplasma infection (*Haemobartonella*) is often suspected and may occasionally be present but should be recognized as incidental because there is lack of polychromasia and blast cells are present in the blood. Anisocytosis is mild to moderate and in the cat the mean corpuscular volume is characteristically increased from a normal of 45 fL to the range of 60 fL. Changes in shape are slight and hemoglobin saturation is normal. Howell-Jolly bodies and spherocytes, and occasionally Heinz bodies, are present, but immature or polychromatic red cells average less than 1 per oil immersion field. The total nucleated cell count varies from 20 to 200 × 10^9/L and is

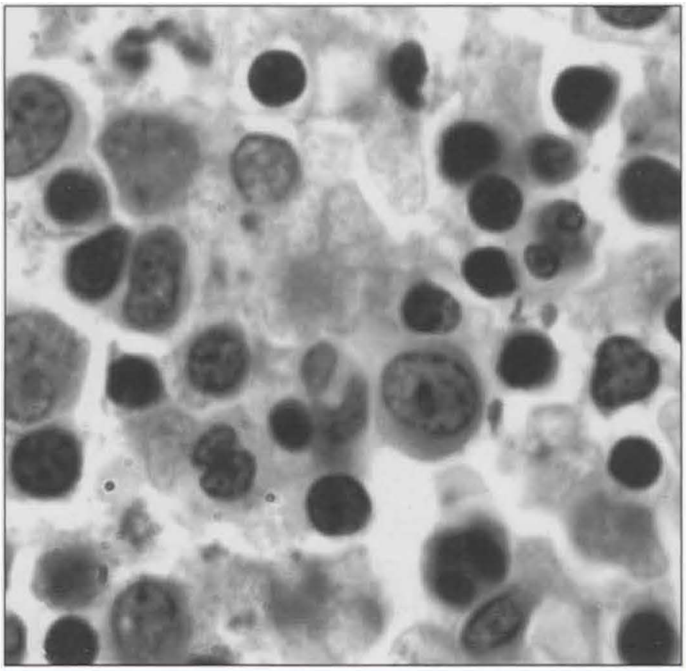

Figure 2.17 Erythremic myelosis in a cat. Histology of marrow. There is a predominance of maturation phase rubricytes.

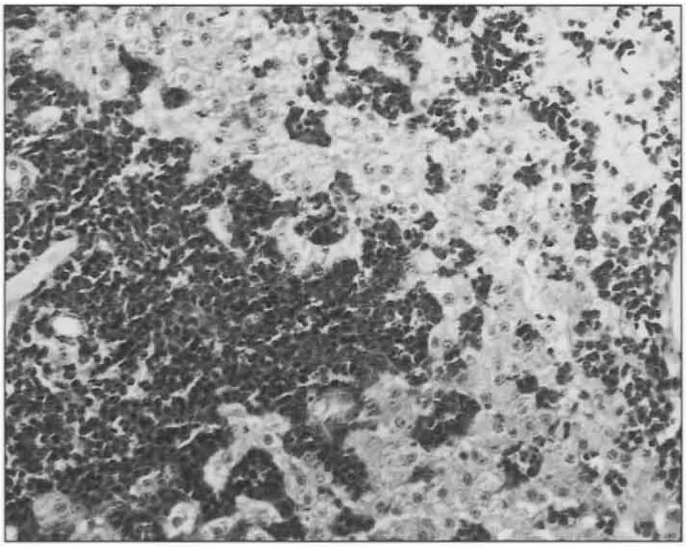

Figure 2.18 Erythremic myelosis in a cat. Liver with heavy periportal colonization (left) and multiple foci of tumor colonization in sinusoids and around central vein (right).

usually $>50 \times 10^9$/L. Neutrophils are at low normal or deficient levels and there may be a mild left shift. Lymphocytes may be $>10 \times 10^9$/L with higher counts probably reflecting the integrity of extramedullary lymphopoiesis. Rubricytes occupy 90% of the differential count and two-thirds of these are readily recognized polychromatic, normochromic and metarubricytes which have normal hemoglobin saturation but are larger than normal and have nuclei which appear inappropriately young for the degree of cytoplasmic maturation (early asynchrony). Presumably this larger size accounts for the persistent rise in MCV despite the lack of polychromasia, indicating that many red cells are the progeny of leukemic precursors. By association, the maturing rubricytes can be related to basophilic and prorubricytic precursors, but their significance may be missed if lymphocytosis is present and the numerous leukemic blasts are thought to be part of lymphoproliferation with benign rubricytosis. *Rubricytosis in the absence of polychromasia does not indicate a marrow response and this asynchronous production suggests neoplasia in the erythroid system itself.* The blasts (Figs 2.15–2.18) typically have round nuclei with dense cribriform chromatin and a single nucleolus which may be as large as a normal red cell and one third the nuclear diameter. The cytoplasm is moderate in volume, markedly eccentric, and basophilic. The malignant cells mimic benign rubriblasts in having a few fine azurophilic granules similar to those seen in myeloblasts. The granules differentiate these blasts from the lymphoid series, including the reticuloendotheliosis variant which these cells otherwise closely resemble. Platelets are generally $<75 \times 10^9$/L but immature platelets may be numerous. Many of the malignant rubricytes are injured in preparation of blood films and up to 25% of the differential count may be bare nuclei which in interpretation need to be included with their cohort.

Aspirated marrow is hypercellular and usually without fat or the usual coarse hemosiderin pattern of malignancy. There is an absence of mature granulocytes, and megakaryocytes are dysplastic but at near normal numbers, which may suggest that the leukemogenesis has occurred near the common precursor for the erythroid and platelet systems. There is marked early erythroid asynchrony with 70% of cells having large primitive nuclei which are described as "megaloblastic." Mild dyserythropoiesis is present with some bi- and trinucleation and small satellite nuclei. Mature rubricytes are rare considering their frequency in the peripheral blood.

On *gross examination*, all tissues are pale and there may be slight icterus. There is usually loss of condition and occasionally emaciation. The lymph nodes are of normal size or slightly enlarged. Lesions are largely limited to pallor, diffusely reddened femoral marrow, and moderate splenomegaly. The spleen is uniformly enlarged, and fleshy and dry on cut surface, without obvious lymphoid follicles.

Microscopically, the bone marrow has high cellularity with dense cellular packing (Fig. 2.16). Granulocyte reserves are absent. About 90% of the cells appear blastic with the rest much smaller and with apparent cytoplasmic hemoglobin. Megakaryocytes are present, usually in small clusters. The primitive cells have a fine granular chromatin pattern with thickened membranes and a single prominent central nucleolus. Nuclei are round or mildly irregular and the cytoplasm is moderate in volume, faceted against adjacent cells and deeply stained. The spleen has atrophy of thymic-dependent areas and increased sinus stroma with loosely packed, diffusely distributed tumor cells. Benign hematopoiesis is usually inapparent and hemosiderin is reduced. There is some subendothelial colonization of large muscular sinuses. Lymph nodes generally have cortical atrophy with sinus histiocytosis and occasionally contain focal neoplastic invasion. The liver usually has accentuation of zonation due to periacinar ischemia, and increased hemosiderin in Kupffer cells which suggests increased destruction of red cells. Tumor involvement is usually sinusoidal with dilation of periacinar sinusoids and mild focal investment of triads (Fig. 2.18).

Erythremic myelosis must be distinguished from hemolytic anemia. Cats with immune hemolysis may occasionally have marked rubricytosis of $50–90 \times 10^9$/L but these precursors are accompanied by $300–600 \times 10^9$ reticulocytes/L. Spherocytosis and rafting of red cells are present in immune hemolysis, the erythroid immaturity is less severe than in erythremic myelosis, and nuclear atypia is absent.

M7, Acute megakaryoblastic leukemia

Acute megakaryoblastic leukemia is a rare disease mainly seen in dogs. This disease *may be underdiagnosed clinically* because of confusion with myeloblastic leukemia (M1), and acute lymphocytic leukemia (ALL) of the L2 type and morphologically with myeloid metaplasia or by new terminology acute panmyelosis with myelofibrosis. *M7 is characterized by 20% or more of blasts in the blood or marrow and at least 50% of the marrow cells must be of megakaryocytic lineage of some level of maturation.* The disease affects a wide age range in both humans and animals. Pathogenetically, the aberrant cytoplasm of the tumor cells is procoagulant resulting in fibrin deposition and repair by largely reticulin fibrosis. Platelet-derived growth factor (PDGF) is felt to be up-regulated and drives the *proliferation of benign stroma. The result is myelophthisis and very rapid marrow failure.* Clinical signs are typical of acute leukemia, often with fever, subcutaneous hematomas and gastrointestinal hemorrhage. The animals are usually in good condition indicative of rapid onset and typically are presented with hepatosplenomegaly. The course is usually 2–4 weeks.

There is pancytopenia with moderate to severe nonresponsive anemia and thrombocytopenia, and a total leukocyte count around $5 \times 10^9/L$ with neutropenia and peripheral blast cells. In blood, the megakaryoblastic nuclei are typically 1.5 to 3 red cells in diameter and round (Fig. 2.19), but irregular constrictions and binucleation may be seen. Chromatin is dense and cribriform and nucleoli are not prominent. Clear vacuoles may penetrate the tumor nuclei and cytoplasm and appear in platelets. Unlike malignant myeloblasts, the cytoplasm is not round and entire but scanty and may have one or two blunt pseudopodia. Basophilia is marked and obscures azurophilic granulation, which is variably present and is most easily seen in the cytoplasmic protrusions. Platelets vary widely in size and are basophilic but poorly granulated. If bleeding is prominent, there will be fragmented red cells.

Aspirated marrow may be highly cellular but the irregular sclerosis rapidly makes a core biopsy essential to evaluate marrow. There is early loss of erythropoiesis and granulopoiesis and loss of granulocyte reserves. Usually 70–90% of marrow cells are hyperchromatic blasts with irregularities in nuclear size, shape and number per cell. *The presence of nuclear fusion in some cells is highly significant and is characteristic of megakaryoblastic leukemia.* The tumor cells mimic their normal counterparts and about a third stain positively with the PAS reaction both cytologically and histologically depending on their content of cytoplasmic glycogen. Because cytoplasm is scanty in the mononuclear blasts, the PAS reaction is most prominent in the larger cells with lobulated nuclei and in these the reaction is highly variable in the same cell. Tumor cells stain negatively with Sudan black and myeloperoxidase and positive with α-naphthyl acetate esterase and for factor VIII antigen. Monocytic leukemia or malignant histiocytosis is ruled out by the absence of erythrophagocytosis and by lack of reaction to the α-naphthyl-butyrate esterase. *L2 is ruled out on the recognition of the multinucleated and lobulated nuclei on routine stains of aspirates and sections.*

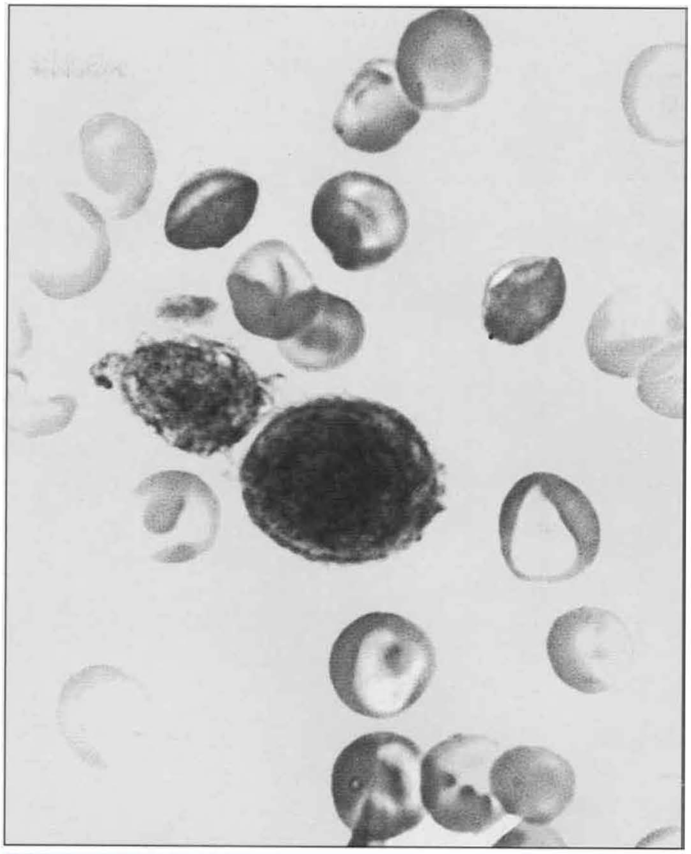

Figure 2.19 Acute megakaryoblastic leukemia, canine blood. Malignant megakaryoblasts with filiform and blunt cytoplasmic pseudopodia.

Grossly, there is pallor and irregularly hemorrhage that is more typical of factor deficiency than thrombocytopenia. The spleen is large and firm, and histologically there is lymphoid atrophy and marked sinus expansion with both blasts and irregular nests of megakaryocytic-like cells with marked atypia and occasionally very large nucleoli. Splenic stroma is increased and extramedullary hematopoiesis is absent or minimal. Tumor is present in the hepatic sinusoids and irregularly in nodes. There are remarkable tumor emboli in pulmonary arterioles with tumor cells apparently growing in syncytia (Fig. 2.20A). There is focal positivity for fibrin in these emboli indicating the propensity of this tumor to cause disseminated coagulation. In marrow, there is loss of fat and irregular phthisis of normal elements (Fig. 2.20B). The tumor cells proliferate in large foci that meld to diffuse areas that become fibrotic. In these foci, *the single and multilobular nucleated tumor cells greatly predominate and their apparent atypia rule out benign disease.* On specific staining, there is a marked and variable increase in reticulin but not of collagen.

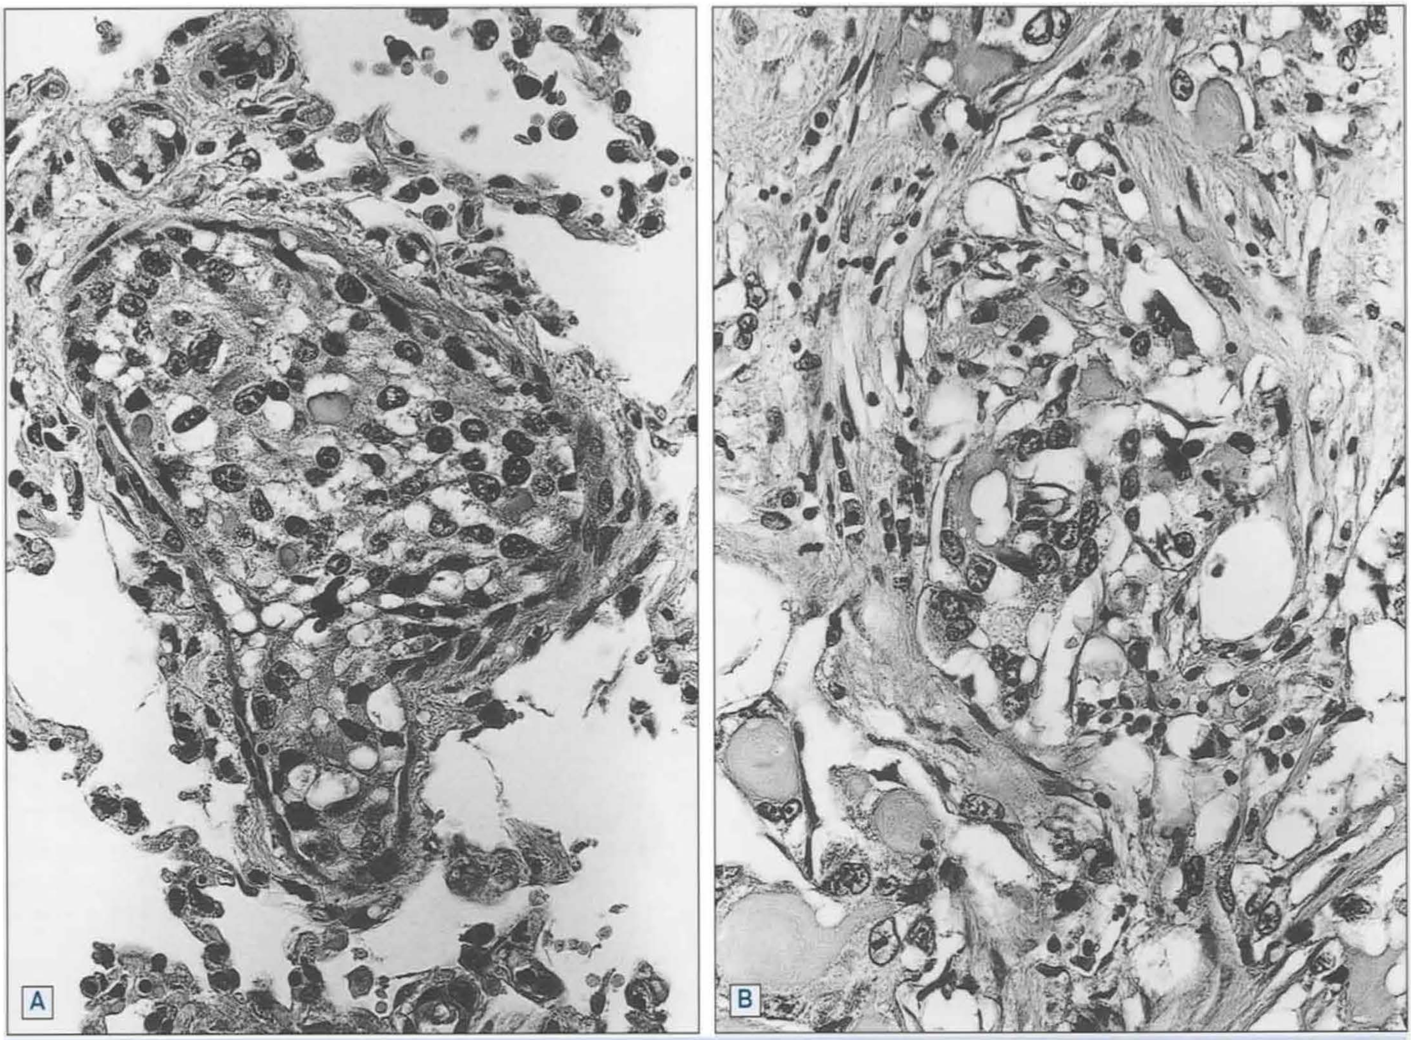

Figure 2.20 Acute megakaryoblastic leukemia in a dog. **A.** Lung, tumor emboli in arteriole. Small homogeneous areas are fibrin. **B.** Marrow with myelophthisis, myelofibrosis of benign stroma, and colonization by malignant megakaryoblasts.

Chronic leukemias/myeloproliferative diseases

Fifty years ago, William Dameshek pointed out the similarities between the different types of chronic myeloid leukemia and noted that in many cases all lines of marrow production were involved as if the marrow was being driven to over-production by some abnormal stimulation. While one or more marrow lineages might be predominant in any particular case, the common presentation of slow insidious onset, indolent progression, with gradual development of hepatosplenomegaly, leukocytosis, thrombocytosis, and gradual onset of myelofibrosis and termination in acute leukemia suggested a single disease with a variety of early manifestations that were collectively termed the *chronic myeloproliferative diseases* (CMPDs). The individual disease entities in this grouping *included chronic myelogenous leukemia (CML), polycythemia vera (PV), chronic idiopathic myelofibrosis with myeloid metaplasia (CIMF), and essential thrombocythemia (ET) also known as megakaryocytic myelosis*. Subsequent work has shown that *a major feature linking the CMPDs is their clonal origin in a single marrow stem cell.* Thus even though a single cell lineage may have a proliferative advantage in a given case, multiple abnormal cell lines may be derived from the same abnormal stem cell.

The evidence for this relationship followed Dameshek's proposal by 10 years when the cytogenetic abnormality subsequently called the *Philadelphia chromosome* was found to be associated with most cases of CML, and not only in the neutrophil line but also in erythroid and megakaryocytic precursors and later in monocytes and some lymphocytes as well. This information *firmly established the CMPDs as clonal diseases with a variety of blood manifestations*. Each of the CMPDs is characterized by *early effective hematopoiesis with increased numbers of a neoplastic clone that reaches normal maturation with few morphologic or functional abnormalities.* Early signs of the CMPDs are related to the increased numbers of cells in the blood and to the accompanying increase in size of the spleen and liver. Finally, with progression of the disease, *each CMPD tends to progress to a point where hematopoiesis is ineffective and abnormalities develop in both maturation and function of the neoplastic clone with increasing immaturity to terminate in acute leukemia often with some features of myelofibrosis.* The proliferation of reticulin fibers and even collagen in the CMPDs was initially felt to occur because the marrow stroma itself was also part of the neoplastic clone. The advent of cytogenetic and molecular analyses has shown that the marrow stroma is not itself involved in the clonal abnormality but is responding appropriately to abnormal stimuli. Fibrosis is a common or constant finding in lesions characterized by megakaryocytic proliferation whether of the acute myeloid leukemia AML M7 type or CMPD of ET type or in the myelodysplastic diseases. Since there is some aspect of megakaryocytic proliferation in the CMPDs of other than the ET type, it has been assumed that platelet-derived growth factor, which stimulates proliferation of fibroblasts, and transforming growth factor-β (TGF-β), which regulates synthesis of extracellular matrix, are the operative stimuli. Subsequently it has been apparent that other myeloproliferative diseases like chronic myelomonocytic leukemia (CMML) and chronic monocytic leukemia also belong in the CMPD grouping. Newly recognized entities in human disease, including atypical CML (aCML) and juvenile myelomonocytic leukemia (jMML), are added to the CMPDs in the revised WHO classification of hematopoietic and lymphoid neoplasms.

CML has been the bellwether of things to come in our understanding of hematopoietic neoplasms. After the recognition of the micro-chromosome in CML, a great deal of work followed in the development of cytogenetics as a diagnostic tool. The advent of staining metaphase spreads of cells to identify specific areas in each chromosome or "banding" permitted each of the chromosomes to be specifically identified and numbered. Subsequently, Janet Rowley in 1973 recognized that the chromosomal abnormality in CML was not a deletion but rather a reciprocal translocation involving chromosomes 9 and 22. A decade later, work showed that the breakpoint cluster region (BCR) on chromosome 22 became linked to the ABL proto-oncogene from chromosome 9. The resulting fusion produced a new gene (BCR-ABL) that was not only capable of being transcribed to mRNA but was translated into a chimeric or fusion protein endowed with tyrosine kinase activity that is potentially oncogenic. There is current interest in work showing that the t[9;22] translocation and the formation of the BCR-ABL gene, while part of the process of clonal proliferation in CML, may not be the initial event but a secondary injury in a clone of stem cells that have already undergone a primary injury.

The ABL proteins have been shown to have a number of domains that allows for multimerization and also domains for DNA binding and for retention of the resulting protein in the nucleus. Variations in the resulting proteins permits elimination of the nuclear retention, and the subsequent cytoplasmic localization allows the hybrid protein with the tyrosine kinase activity to act on the RAS and RAF pathways which control cell proliferation. In human CML, the *BCR* breakpoint in chromosome 22 typically occurs in a region that spans the exons e12 to 16 and commonly known as b1 through b5 with the breakpoint usually at the b2 or b3 areas. In chromosome 9, the break in the ABL gene is usually at the beginning of the gene in an area known as b2 so that most of the gene is transferred to chromosome 22. Thus, the typical fusions are termed *b2a2* or *b3a2*. These two fusions are seen in virtually all cases of CML and in 20–50% of adult and 10% of pediatric cases of Ph+ acute lymphoblastic leukemia (ALL). Other breakpoint combinations occur and produce the fusion genes associated with the Ph+ ALL seen in the rest of the Ph + adult and pediatric cases. An *e19a2* fusion (also called *c3a2*) is felt to be the basis for a rare type of human CML in which there is very primarily neutrophil proliferation and known as chronic neutrophilic leukemia (CNL).

Typically, human CML progresses in 4–5 years to a terminal blast phase that is refractory to treatment. Since the blast phase of CML is like AML, the two may be confused if the chronic phase of CML was not recognized. *The blast phase may be focal or multifocal in marrow, and is best looked for by marrow core biopsy.* In addition, the blast phase may begin in an extramedullary site, making it important to examine any enlarging lymph node or other new proliferative lesion. Two thirds of the cases of human CML in blast phase are of the granulocytic lineage (M-BP) and resemble (AML M1-2) type or of granulocytic–monocytic (M4) type. Cytochemical reactions tend to be less intense than in the de novo AML and the blasts usually express CD13 and CD33. A rare type of myeloid blast phase is termed mixed-myeloid and is characterized by atypical appearing blasts of all three myeloid, erythroid, and megakaryocytic lineages. A third or less of human CML enters the blast phase with a lymphoid phenotype (L-BP). The L-BP blasts have very predominantly B-cell expression and mark with pan-B-cell reagents CD19 and CD20 and also co-express CD10. The blasts are TdT (terminal deoxynucleotidyl transferase)+ but do not express surface or cytoplasmic immunoglobulin.

While much has been learned about the CMPDs, *CML continues to be a fatally progressive disease.* The "designer" chemotherapeutic drug Cleevec has anti-tyrosine kinase activity and induces remission in human CML. Those cases failing remission after Cleevec therapy have developed a single amino acid substitution in the kinase fusion protein that prevents the drug from binding to it.

Chronic myelogenous/granulocytic leukemia

Chronic myelogenous leukemia (CML) is recognized most frequently in mature dogs and cats and probably occurs in all species. Males cats are more often affected than females. The chronic form of myeloid leukemia CML is *less common than the acute form (AML).*

In contrast to the acute myeloid leukemias, there is a history of weight loss extending over several months with recurrent inappetence and diarrhea and often several treatments for slow-healing superficial lesions. Clinically there is mucosal pallor, dullness of hair, loss of condition, splenomegaly and increased heart rate. Lymph nodes are of normal size or slightly enlarged. The course is 1–4 years or longer. Late conversion to an acute leukemia is seen less often than in humans, probably because animals with this disease are usually destroyed when they enter the accelerated phase and prior to the development of a blast crisis.

Anemia is mild to moderate, nonresponsive, and less severe in dogs than in other species. A few relatively mature rubricytes are usually present plus a small number of fragmented and large red cells in a normochromic, normocytic or mild hypochromic background. The leukocyte count is usually $>50 \times 10^9$/L and often exceeds 200×10^9/L. Howell-Jolly bodies are usually present as a result of splenic overload, particularly if the leukocyte count is markedly elevated. By a similar mechanism, some hypersegmented neutrophils will be present and more prominent the higher the leukocyte count. *The major feature of chronic myeloid leukemia is that segmented neutrophils are always present in the peripheral blood and usually predominate.* Malignancy may occur in any of the three granulocytic lines, but *neutrophils are most often affected.* Leukemia involving the eosinophil line is seen most frequently in cats and basophil tumors in pigs. Secondary granulation is usually reduced, particularly as the disease progresses, and there may be toxic vacuolation (Fig. 2.21A). There is usually a reasonably synchronous distribution of myeloblasts to neutrophils, with the exception that myelocytes exceed the number of metamyelocytes. Myeloblasts are rare in peripheral blood and usually not found in a differential count of 100 cells. Cytoplasmic basophilia is usually mild and granulation is apparent in promyelocytes and myelocytes (Fig. 2.21A). There is usually a mild increase in normal appearing basophils. Platelet levels may be normal or increased but are usually around 100×10^9/L and with progression, deficiency may become limiting to life. Platelet granulation may be normal but is more often reduced, and there are occasional very large platelets.

Aspirated marrow is hypercellular during the chronic phase of CML with a myeloid to erythroid ratio of 50 or higher and a marked increase in myelocytes, metamyelocytes, and band neutrophils which, with a few segmented cells, occupy more than half of the marrow volume. Marrow basophilia and eosinophilia are commonly present. Myeloblasts are <5% of marrow cells and may total 10% combined with promyelocytes. Erythropoiesis is synchronous and never as deficient as in the acute leukemias. Hemosiderin is normal or reduced and megakaryocytes are at normal levels for long periods, but become deficient as the disease progresses and becomes more aggressive. Macrophages are noted to be atypical in a high proportion of human CML and may have blue cytoplasm due to the presence of birefringent crystals. The character of the cytoplasm may vary from faintly granular "tissue paper"-like to gray-green to clear pale blue and referred to as "sea-blue histiocytes." Similar cells have not been recognized in animal CML.

Grossly there is pallor and usually emaciation. There may be widespread focal hemorrhages, and enteric bleeding is common as are chronic oral or skin ulcers. The spleen is always enlarged, dry, and fleshy and may be many times normal size. The liver is enlarged to a variable degree, pale with an anemic lobular pattern, and may have focal hemorrhage, infarction, or infiltration. The nodes are irregularly enlarged, often due to septic drainage from secondary disease. There may be focal lesions in other organs but they are usually minimal. All marrow cavities are uniformly deeply reddened.

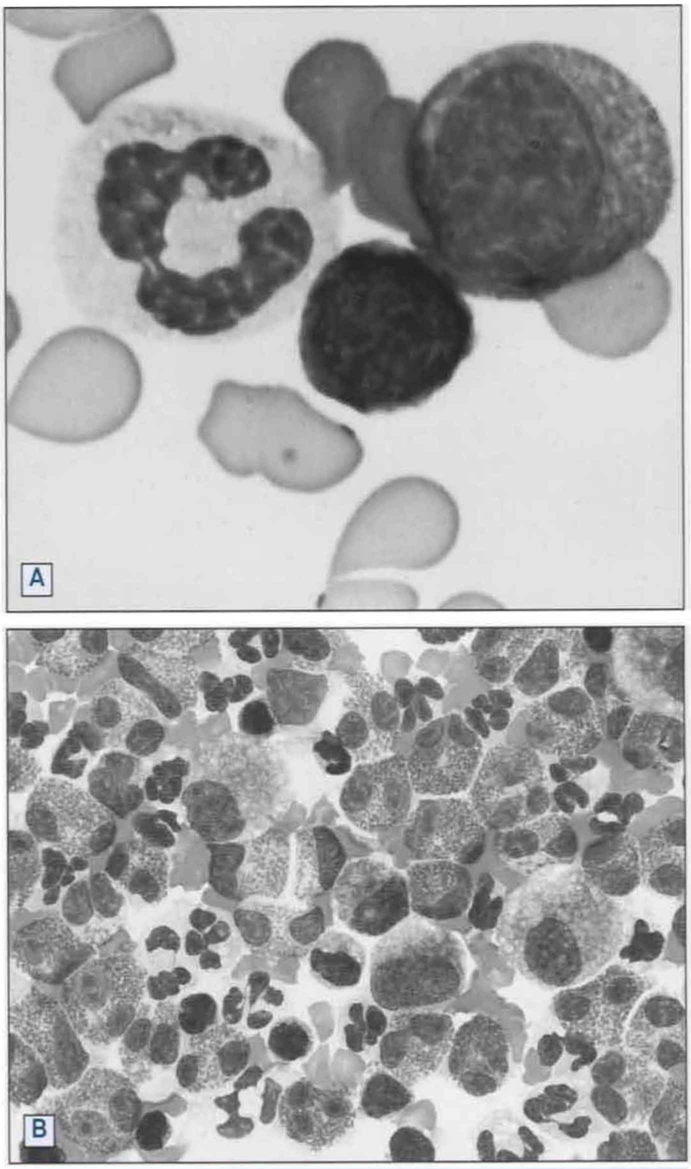

Figure 2.21 A. Chronic granulocytic leukemia, feline blood. Malignant promyelocyte (right) with a large poorly granulated neutrophil, probably the progeny of malignant precursors. There is nonresponsive anemia and mycoplasmas (hemobartonellae) are present on red cells (center). Benign basophilic rubricyte (center), in the absence of polychromasia, indicates myelophthisic erythroblastosis. **B. Hypereosinophilic syndrome** in a cat: bronchoalveolar lavage. A high proportion of mature eosinophils accompanied by neutrophils, large alveolar macrophages and a few small lymphocytes.

Histologically, the bone marrow is solidly cellular with dense cell packing and reduced sinus area. Myelocytes, metamyelocytes and bands predominate with numerous giant metamyelocytes. Erythropoiesis is relatively much reduced, but may be near normal on an absolute basis considering the greatly expanded marrow cavity. Megakaryocytes may be numerous and are hyperlobulated without the usual condensation to a single nuclear mass. They tend to have reduced cytoplasmic volume in proportion to nuclear size (ineffective thrombopoiesis). Primitive cells are numerous and tend to cluster in laminar fashion near bony trabeculae and around vessels in layers much thicker than the normal level of 1–3 cells to 5–10 cell layers. *An increase in depth of the primitive cell layer presages onset of the accelerated phase.* These proliferating cells have round or oval nuclei with coarsely granular chromatin and prominent single central pink nucleoli. Their cytoplasm is abundant and moderately amphophilic. Lymph nodes vary depending upon whether they are secondarily infected, but tend to have follicular hyperplasia with reduced cell density. Mature tumor cells may fill the peripheral sinus and permeate the capsule with cells in rows between the collagen layers. Primitive tumor cells will variably colonize the medullary cords while the mature cells predominate in sinuses. There is variable colonization of the medullary sinuses. This is most obvious if the tumor is of the eosinophil or basophil type, and if colonization is extensive it is often accompanied by medullary sclerosis. Benign extramedullary hematopoieses will also colonize the medullary cords and can be recognized by the presence of megakaryocytes. As the tumor progresses, the benign cells become displaced to the adjacent medullary sinuses.

The splenic capsule is thin and focally bridged. Follicles are present and small but sharply delineated with low cell density and reduced thymic cuffs. The sinuses are hypercellular containing focal clusters of primitive cells with prominent cytoplasmic basophilia, and also some mature cells but fewer than in the marrow. Tumor cells colonize the subendothelial areas of muscular veins and constitute a useful marker for the presence of leukemia/lymphoma. Hemosiderin is not increased and may be deficient if there has been recurrent hemorrhage.

The liver has both focal and sinusoidal involvement, the latter in transit and the former consisting of fixed leukemic infiltrates around both portal triads and the large veins. In perivenous areas, tumor cells replace hepatocytes within the endothelium of the hepatic cords forming a hematopoietic tissue and sinus relationship similar to that of marrow. Virtually all other tissues may be focally invaded, especially adrenal medulla, renal cortex around arterioles and, less regularly, the heart, reproductive, pulmonary and enteric systems. Lesions of cachexia are present in advanced cases.

Chronic myeloid leukemia must be differentiated from leukemoid reaction and from **hypereosinophilic syndrome** (Fig. 2.21B) *on the absence of blasts in the peripheral blood, an inflammatory target for increased myeloid production, and tissue destruction by the infiltrating tumor cells.*

Chronic neutrophilic leukemia

Chronic neutrophilic leukemia (CNL) is rarely recognized in humans and has not been characterized in animals as a disease entity distinct from the CMPDs with "pure" neutrophil proliferation without accompanying changes in the other cell lineages. As such, it is more difficult to differentiate from the leukemoid reaction which tends to be an ephemeral response. The disease CNL in humans is recognized by sustained neutrophilia with granulocytic predominance in the marrow, and hepatosplenomegaly without presence of the Philadelphia chromosome in the tumor cell line.

Chronic eosinophilic leukemia/hypereosinophilic syndrome

Chronic eosinophilic leukemia (CEL) in humans is characterized by the *presence of the Philadelphia chromosome and the BCR-ABL fusion gene.* Sustained eosinophilic proliferation in the absence of the t[9;22] translocation is considered the criterion for diagnosis of the *hypereosinophilic syndrome* (HES). Chronic increase in eosinophil proliferation of either benign or malignant cause will result in tissue destruction in sites of eosinophil deposition due to release of the characteristic granules. CEL in animals is like CML of the neutrophil type with the exception that there will be marked collagenous fibrosis of peripheral tissues where eosinophils are concentrated. *Reactive eosinophilia* is usually of short duration with eosinophil counts in the 1.5×10^9/L range and an obvious target for the cellular production. Common causes of reactive eosinophilia include parasitism, asthma, eosinophilic enteritis and the eosinophilic granuloma complex, the latter seen primarily in cats. Both CEL and HES are primarily disease of cats. *HES and reactive eosinophilia can be distinguished from truly malignant CEL by the presence of blasts in the blood in CEL and by a greater shift to immaturity of eosinophils in the marrow and more severe anemia with a greater reduction in erythropoiesis* (Fig. 2.22). Marrow blasts are increased in CEL but seldom reach the 10% level for combined blasts plus promyelocytes that may be present in CML of the usual type. Oddly, although there may be quite marked fibrosis in liver, lung, nodes and spleen in CEL, there is only mild reticulin proliferation in marrow.

Granulocytic sarcoma

Granulocytic sarcoma or *chloroma* is the *extramedullary growth of focal granulocytic neoplasms, which may be of neutrophil or eosinophil type*

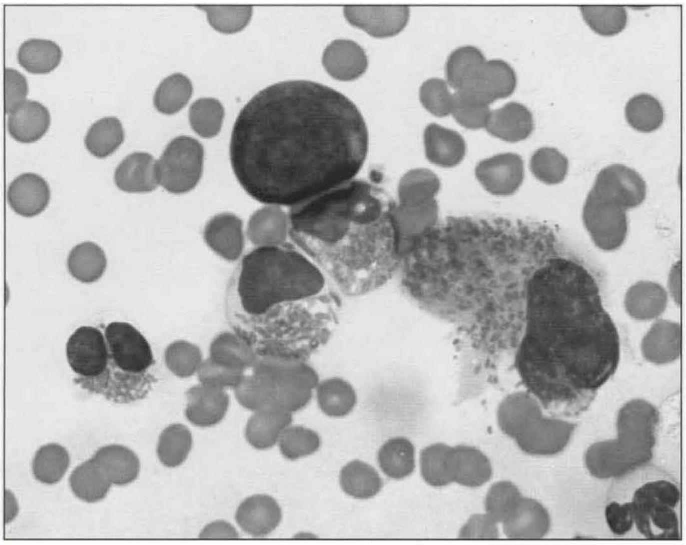

Figure 2.22 Chronic myelogenous leukemia, eosinophil type: feline bone marrow. Myeloblasts with injured eosinophil promyelocyte and maturing eosinophils.

(Fig. 2.23A–D). They are initially aleukemic and have variable differentiation, which, if minimal, usually leads to classification as lymphoma. They have typical granulocytic esterase (chloroacetate esterase, CAE) staining, and the ephemeral green hue on exposure to air is presumably due to a high level of myeloperoxidase. The disease in dogs tends to involve lung, gut and skin, but any tissue can be initially involved and skeletal muscle is characteristically affected in cattle. *There may be progression to acute myeloblastic leukemia* within months of biopsy. Most cases are diagnosed at autopsy. The detection of granulocytic sarcoma in an animal with a previous diagnosis of myeloid leukemia is indication of an accelerated phase with rapid progression and reversion to a less differentiated cell type. The major presentation of granulocytic sarcoma in humans follows 4 patterns of which the least common is as *an isolated mass without progression to acute leukemia, which would appear to be the most common presentation in animals*. The others are: as a localized lesion in patients who have AML, as a sign of impending conversion to AML in patients with MDS, and as a presenting lesion in the diagnosis of de novo myeloid leukemia.

Focal proliferation of eosinophils and precursors will result in *fibrosis* presumably as a result of tissue injury by lysosomal proteins. *Granulocytic sarcoma must be differentiated from benign hypereosinophilic syndrome and from eosinophil leukemia.* Cytochemical differentiation from lymphoma may be assisted by thin sections at 1–2 μm, in which the typical cytoplasmic granulation is most apparent, and by routine immunohistochemistry for B- and T-cell markers.

Mast cell leukemia

Mast cells are widely distributed in connective tissues as a heterogeneous population. In the mouse and likely other species, the mast cell and the basophil share a common precursor. Neoplastic proliferation of mast cells to form *solitary or multiple tumors* is described in Vol. 1, Skin and appendages and in Vol. 2, Alimentary system. Diseases of the mast cell system in humans are relatively rare and most involve urticarial eruptions in the young. In contrast to animals, mast cell disease in humans involving the skin has a relatively much better outcome than systemic mast cell disease which almost always involves the bone marrow. *Systemic mastocytosis* involving primarily the hematopoietic organs in a pattern common to the leukemias is a rare disease seen primarily in humans and cats. Systemic mastocytosis occurs independently of cutaneous or alimentary mastocytoma. Mastocytemia may or may not be present but tends to be intermittent; *detection of mast cells in circulation is best accomplished on smears of buffy coat.* The hemogram may be normal or there may be eosinophilia and anemia.

The usual presenting signs of systemic mastocytosis in the cat are *vomiting and splenomegaly*. Gastric and duodenal ulceration is observed to accompany visceral and systemic mast-cell neoplasms, and is presumed to be caused by high levels of histamine produced by the neoplastic cells. The bone marrow may be involved, usually in a focal manner. The mast cells in marrow tend to be paratrabecular and are present both in mononuclear and spindle-shaped forms that resemble fibroblasts. There is usually a mixture of surrounding cells including eosinophils and lymphocytes. If frank leukemia is present, the marrow mast cells are more mononuclear and there is much more nuclear atypia. Nucleoli tend to be inconsistently present and their size and frequency do not appear to be of independent prognostic value. In the cat, splenomegaly which is often massive is consistently present. The spleen is firm and brown and there may be irregular white fibrous thickening of the capsule. Microscopically, the architecture of the splenic pulp is effaced by sheets of mast cells in diffuse distribution. The cytoplasm is bland and abundant and special stains are necessary to demonstrate the specific granules.

Hepatomegaly is frequently present. The infiltration of mast cells in the liver is diffuse and produces a fine stippled appearance when the triads are mainly infiltrated. Larger accumulations of the malignant cells in irregular foci may be visible as pale foci on the surface. The infiltrations in kidney, bone marrow and other organs tend to be more discrete than in the spleen and liver. *The major differentials to be considered in mast cell leukemia are AML of the M3 hypergranular type, manifestations of primary idiopathic myelofibrosis, and some cases of malignant fibrous histiocytoma that may have both eosinophilia and mastocytosis.* In animals, most cases of systemic mast cell disease have the diagnosis confirmed by the use of toluidine blue or other blood stains. Mast cells in animals, including malignant proliferations, generally stain with chloroacetate esterase stains in cytological preparations and with vimentin and lysozyme in paraffin-embedded tissues. In human diseases, the mast cells stain negatively for the integrins CD11a and b and for CD18, whereas basophils are positive for all three. Mast cells mark positively with CD117 [c-kit] and basophils are negative for this receptor, providing a means of distinguishing precursors of both cell lines. In both humans and animals, mast cell proliferations are heterogeneous in staining reactions in the same site in the same species which may in part be due to partial degranulation.

Chronic idiopathic myelofibrosis/myeloid metaplasia with myelofibrosis

Chronic idiopathic myelofibrosis (CIMF) is the term that succeeds a variety of names for this same condition including *myeloid metaplasia with myelofibrosis* and *agnogenic myeloid metaplasia.* CIMF is the condition characterized by *clonal proliferation of bone marrow hematopoietic cells accompanied by the formation of connective tissue in the bone marrow as an event secondary to the hematopoietic proliferation.* Since by definition the disease is caused by excessive proliferation of hematopoietic cells with the presence of mobile stem cells that can move to other sites as the marrow becomes fibrotic, CIMF is usually accompanied by splenomegaly. Diagnosis is usually made when a hematopoietic dyscrasia evident in the peripheral blood prompts a bone marrow biopsy that results in a failed attempt to aspirate marrow – a "dry tap" – and is followed by a marrow core. Myelofibrosis in the marrow core may take the form of focal or diffuse reticulin sclerosis or focal or diffuse deposition of actual collagen. In well-advanced CIMF, there will be complete or almost complete phthisis of all marrow blood precursors, with the tissue consisting of a mixture of reticulin and collagen fibrosis and a few remaining fat cells. The only evidence of the original function of the tissue may be scattered hemosiderin-bearing macrophages that indicate a prior site of hematopoiesis.

In general, *CIMF is a disease characterized by inappropriate myeloid hyperplasia with synchronous maturation and without excess blast cells where the diagnosis of a leukemic process cannot be justified.*

CIMF occurs in dogs and cats. It is nearly always insidious in onset, and there is a history of reduced activity and weight loss. There is mucosal pallor and often minor oral ulcerations, and a history of recurrent and slow-healing skin lesions. Lameness associated with deep bone pain may be present as in myeloma, and the spleen is usually enlarged. The course is prolonged, generally 6 months to a year or more, usually with elective termination due to intractable anemia and recurrent infections.

Anemia is a constant finding even in the early "cellular phase" associated with high leukocyte counts, and is seen with variable degrees of hypochromia, anisocytosis and characteristic tear-drop-shaped red cells. Polychromasia is inappropriately mild, but relatively mature rubricytes are present as well as metamyelocytes as part of the *leukoerythroblastic reaction.* The leukocyte and platelet counts are increased in the early cellular phase and decreased later in the fibrotic phase of marrow failure. Hypersegmented neutrophils and toxemic changes are usually present in the later stages, but the early phase may have few of these and CML may be a differential consideration. Platelet size and shape is variable. Marrow aspirates are usually fibrillar and sparsely cellular with numerous bare stromal cell nuclei. The bone marrow is uniformly reddened and shells out of the femoral cavity in a cohesive cylinder.

Microscopically, the bone marrow loses its normal tendency for artefactual "cracking" during histological processing and is architecturally solid with few and irregular fatty areas. Cell density is reduced, as is sinusoidal area. The intercellular interstitium is pale, proteinaceous and not obviously fibrillar. In some areas, the specialized cells may be arranged in single file rows suggesting containment by reticulin sclerosis. Only a small proportion of cases survive until there is obvious collagen birefringence. With reticulin stains, the fiber proliferation is seen to be diffuse and spreading out from its normal perivascular location to invest individual marrow cells. Like the myelodysplastic syndromes, there is often venous ectasia with intravascular hematopoiesis. Stromal nuclei are increased and evident by their oval shape and indefinite cell boundaries. By the time collagen is demonstrable, hematopoiesis is absent and the extent of prior myeloid hypertrophy is indicated by hemosiderin-bearing macrophages surviving in poorly cellular areas of collagen matrix. The remaining hematopoiesis is largely granulocytic and megakaryocytic, with little erythropoiesis, and scattered foci of small lymphocytes (Fig. 2.24). Basophilic cells, which are prominent in early aspirates, are present but inconspicuous.

The spleen has follicular preservation and occasionally prominent hypertrophy. The sinus areas are solidly cellular and have obvious trilineage hematopoiesis. The liver has both periportal and sinusoidal colonies of hematopoietic cells, and similar foci with varying lineage can be found irregularly in almost all tissues except muscle. The lymph nodes are variable but usually enlarged with thickened capsules, medullary follicles, focal hematopoiesis and generalized sclerosis. This tendency for fibrogenesis to follow hematopoiesis is also evident

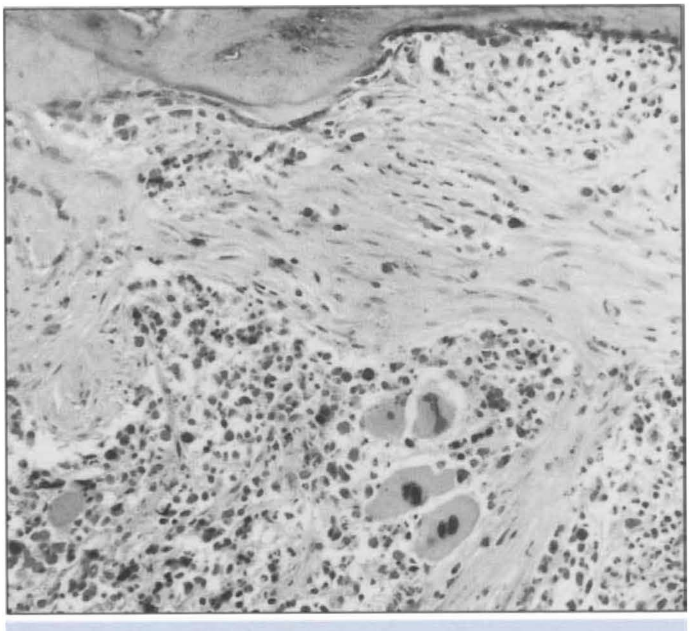

Figure 2.24 Myelofibrosis in dog marrow causing myelophthisic anemia.

in the spleen and liver, and suggests that the prolonged hyperplasia is attended by release of mediators that have been related to the megakaryocytic system and platelet-derived growth factor. *Unlike the myelodysplastic syndromes, CIMF regularly terminates in myelofibrosis not acute leukemia.* CIMF must be distinguished from reactive hyperplasia where there is a target for the increased cellular output, and from both myelodysplasia and CML where early asynchrony with increased blasts indicate a more aggressive diagnosis.

Polycythemia vera

Polycythemia vera (PV) is a *rare disease seen mainly in dogs and cats* but occurs in cattle and can be induced in mice by the Friend leukemia virus. Mouse studies have shown that the "anemic" and "polycythemic" strains of this retrovirus interact with early and late acting genetic loci to produce either erythremic myelosis (M6) or polycythemia vera. In the latter disease, the erythroid stem cells will grow in culture without erythropoietin stimulation and were felt to be an autonomous tumor clone. Later work shows that other growth factors are involved in the erythroid hyperplasia, including IL-3, GM-CSF, and insulin-like growth factor (IGF-1) which appears to act cooperatively with erythropoietin (EPO). The endogenous erythroid colonies that grow in culture independent of EPO may be responding to minute amounts of insulin-like growth factor (IGF-1). The etiology of PV is unknown and, unlike the CMPDs, there are no consistent cytogenetic abnormalities.

The disease in humans is accompanied by leukocytosis and thrombocytosis and trilineage marrow hyperplasia in what is known as the "proliferative or erythrocytotic phase," which progresses to reticulin myelofibrosis and in most cases to a "spent phase," with marrow failure in most and acute leukemia in a minority, usually of the myeloid type. Leukemic transformation appears more common in patients treated with ^{32}P and chlorambucil than in those treated by phlebotomy. In humans, the disease is rare in patients under 60 years and most cases are diagnosed because of thrombotic sequelae. The standard criteria for making a diagnosis of PV in humans include the documentation of increased red cell mass to rule out plasma volume contraction or dehydration. Other criteria include normal arterial oxygen saturation and splenomegaly. If splenomegaly is absent, two additional abnormalities must be present, which might include leukocytosis, thrombocytosis, elevated neutrophil alkaline phosphatase activity, or elevated vitamin B12 levels.

Animals with polycythemia vera do not regularly develop thrombocytosis nor apparently myelofibrosis. This difference suggests that the myelofibrosis of the human disease may result from chronic megakaryocytic hyperplasia of the proliferative phase and attendant growth factor(s), or that animals with PV are more often terminated prior to the "spent" or marrow failure stage.

Affected animals are presented with reduced exercise tolerance and often polydipsia and signs of neuromuscular dysfunction, including head tremor and paraparesis. Clinically, there is mucosal congestion and cyanosis with labored respiration and signs of hemorrhage including epistaxis, hematemesis, hematochezia, and hematuria. Lymph nodes are normal, but occasionally there is splenomegaly. Thrombotic foci may be present and add to the hindlimb weakness. Males are affected more often than females, and the course is usually limited to months because of difficulties in management.

Hematologically, there is *marked erythrocytosis* with red cells in the $10–15 \times 10^{12}/L$ range, hemoglobin of 200–250 g/L and a hematocrit of 65–80%. The red cells are normochromic and normocytic unless there are thromboses, when poikilocytes will be present. Polychromasia or reticulocytes are usually not present, and the platelet count is low or normal. About one-third of cases have mature neutrophilic leukocytosis of up to $30 \times 10^9/L$. *Normal blood oxygen levels rule out secondary polycythemia.* The plasma volume is reduced, but the red cell mass is increased and may be doubled. Plasma iron turnover is greatly increased, and red cell life span is essentially normal.

Aspirated marrow has synchronous trilineage hyperplasia with cell proportions near a myeloid:erythroid ratio of 1.0. The cellularity is very high with little remaining fat.

Postmortem findings include generalized congestion and cyanosis with a tendency to arterial thrombosis. The spleen is enlarged in about 10% of cases, and bone marrow is diffusely reddened. Microscopically, there is dilation of hepatic sinusoids with hepatocellular atrophy and hyperpigmentation. The marrow has pancellular hyperplasia with high cellularity and reduced iron. There is splenic sinusoidal distention and congestion, compatible with increased blood volume.

Polycythemia vera must be distinguished from secondary polycythemia which is less rare and usually due to vascular anomalies causing anoxia. Rarely, primary or metastatic tumor in the kidney may also result in an erythropoietin-dependent polycythemia.

Essential thrombocythemia/megakaryocytic myelosis

Essential thrombocythemia (ET) is the chronic counterpart of acute megakaryoblastic leukemia (M7). The disease in humans is regarded as a *clonal disorder*, but no consistent cytogenetic, morphologic or other laboratory marker has been associated with ET. In humans and animals, the disease is characterized by *sustained high-level thrombocytosis with marrow megakaryocytic hyperplasia.* ET is a rare disease of dogs and cats generally over five years of age with a clinical course of 1–3 years. *The disease must be distinguished from reactive thrombocytosis,* which is rarely persistent except in iron deficiency where the platelet counts are much below those of ET and the red cell changes are highly suggestive of the correct diagnosis. Other MPDs and the myelodysplastic syndromes need to be considered, but the blast cell count is low and the early asynchrony in marrow is largely limited to the megakaryocytic lineage.

Clinically, ET is characterized by bleeding and thrombosis of the tips of tail and ears and by massive thrombocytosis. Hematologically, there is *marked nonresponsive anemia* with mild anisocytosis and hypochromia and an occasional oval red cell. The leukocyte count is in the normal range, usually with reduced neutrophils and mild left shift, and mild to moderate basophilia, the latter being easily overlooked as the basophils are usually poorly granulated. The platelet count may be low or normal, but is most often dramatically increased to 2000–4000 × 10^9/L or higher which imparts a distinct blueness to the stained blood film. At any platelet level, there are marked morphologic changes with wide size variations, frequent vacuolation with pale basophilia, and irregular and reduced granulation (Fig. 2.25). The "shift" platelet reaction is marked, and functional tests of platelet activity, such as aggregation and clot retraction, are usually reduced. This thrombasthenia is made evident by serious hemorrhage resulting if even small amounts of aspirin are given to alleviate thrombosis in extremities.

Aspirated marrow is hypercellular with myeloid hyperplasia and early asynchrony involving the megakaryocytic and basophil lines, and erythroid phthisis with loss of mature granulocyte reserves. Hemosiderin has a coarse pattern and is increased in amount. With progression of the disease, aspiration of marrow is prevented by myelofibrosis and a core biopsy is required. Marrow aspirates are hypercoagulable, and nucleated cells are injured by fibrillar strands and obscured by masses of coherent platelets.

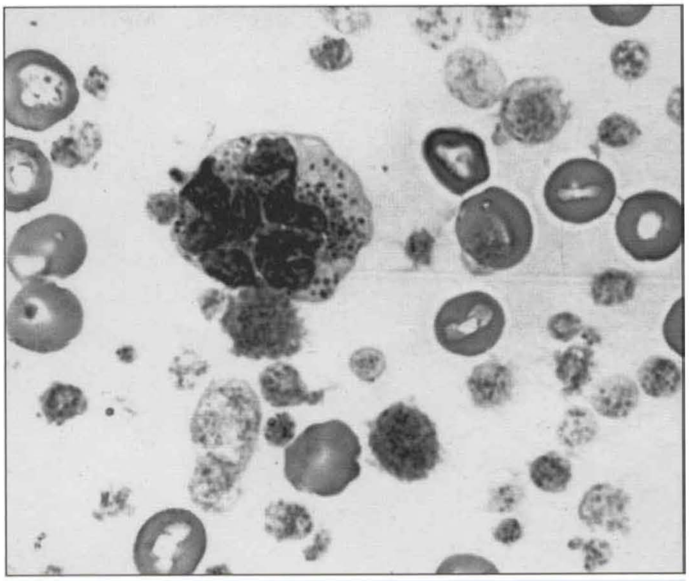

Figure 2.25 Essential thrombocythemia, canine blood. Marked anemia, largely normocytic and normochromic with severe thrombocytosis; platelets vary markedly in size, basophilia, and granulation. The cell in the center is an atypical basophil.

At postmortem, most tissues are pale, and the spleen is enlarged several times and dark, with a dry fleshy cut surface. The liver is symmetrically enlarged, dark to deep brown with rounded and notched borders. The kidneys are of normal shape and size but deep brown. The bone marrow is uniformly dark red and highly cohesive. Lymph nodes are of normal size.

Microscopically, the bone marrow is solidly cellular with generalized increase in reticulin fibers and focal reduction in cell packing where sclerosis is most advanced. There is massive megakaryocytic hyperplasia, often with normal cytoplasmic volume, and increased basophilia and hyperchromatic nuclei, but otherwise with little atypia. Isolated megakaryocytes are irregularly distributed in cortical areas of lymph nodes. Liver cells are atrophic with intrahepatic cholestasis, and sinusoids are 2–3 times normal width with few red cells and many megakaryocytes. Portal infiltration is mild and irregular. The spleen has lymphoid atrophy with hypercellular sinus areas which resemble bone marrow. Most other tissues are minimally affected.

Myeloproliferative disease, unclassifiable (MPDU)

Animals may be presented with anemia and hyperplastic marrow and a spectrum of changes that are not typical of any of the diseases included in the CMPDs. If the cells are of myeloid origin and the blast cell level is below the 20% required for AML and less than 10% with some blasts in the peripheral blood, then a diagnosis of myeloproliferative disease, unclassifiable may be an appropriate working classification until the condition evolves into a more typical pattern. The diagnosis of MPDU may be thought of as a counterpart of acute myeloid leukemia not otherwise categorized for those myeloproliferative diseases with low blast cell counts and, dysplastic changes and uncertain lineage.

Myelodysplastic/myeloproliferative diseases

Chronic myelomonocytic leukemia (CMML)

Chronic myelomonocytic leukemia (preleukemia syndrome) is largely a disease of dogs over 5 years of age, and is likely under recognized in other species. The disease is characterized by persistent monocytosis with increased marrow monocytic precursors and variable prominence of trilineage dysplasia. There are circulating blasts that may be mistaken for atypical lymphocytes, and the marrow blasts plus promonocytes seldom exceed 10%.

There is a history of anorexia, lethargy, weight loss and reduced exercise tolerance. Affected dogs may have a poor hair coat and mucosal pallor, and often oral ulcerations. There is usually mild recurrent pyrexia with poor healing of minor injuries. The course is 6 months to 1–2 years. Some cases evolve into acute leukemia, but most are terminated because of recurrent infections and thrombocytopenic hemorrhage. Complete recovery probably does not occur. In CMML of humans, the criteria for diagnosis of this disease are an increase in marrow blasts in the 5–15% range but less than the 20% required for AML M5a or b.

Dogs with chronic myelomonocytic leukemia have mild-to-moderate nonresponsive anemia with mild anisochromia, anisocytosis, poikilocytosis and phthisic rubricytosis (leukoerythroblastic reaction). Most animals are thrombocytopenic with fewer than 100×10^9/L cells that have a relatively uniform basophilia and normal granulation. The leukocyte count is usually 4– 5×10^9/L, but may be as high as 30×10^9/L if animals are given steroid. Typically, there is neutropenia with about 1×10^9/L mature granulocytes, often with an equal number of cells as immature as myelocytes. Secondary granulation is reduced, and there is at least moderate toxemia and often Doehle bodies. Cases with low neutrophils and little immaturity tend to have some hypersegmentation. Lymphocytes are low normal. There are characteristically 1–4×10^9/L immature monocytes. Some are as young as promonocytes and have nucleoli (Fig. 2.26).

Aspirated marrow is always hypercellular and resembles refractory anemia with excess blast cells (Fig. 2.27A). There is early myeloid hyperplasia and loss or absence of granulocyte reserves, which paradoxically may be present concurrently with severe neutropenia. There is at least relative erythroid and megakaryocytic phthisis and qualitative changes are present, suggesting ineffective hematopoiesis (Fig. 2.27B). Marrow iron is coarse and increased.

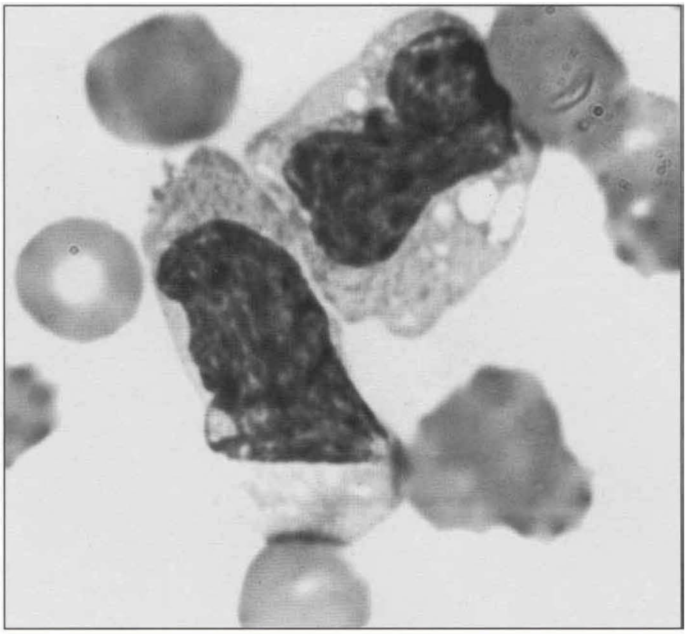

Figure 2.26 Chronic myelomonocytic leukemia, canine blood. Atypical "monocytoid" cells that on esterase staining appear to be of the neutrophil series.

At postmortem, there is anemia with normal lymph nodes and mild splenomegaly. Thrombocytopenic hemorrhage may be present. The microscopic findings are similar to those in refractory anemia with excess blast cells.

Esterase stains may be required to identify lineage if there is atypia and immaturity in both the neutrophil and monocytic systems (Table 2.2). *Chronic myelomonocytic leukemia can be differentiated from acute myelomonocytic leukemia on the basis of a longer course and lack of blast cells in the peripheral blood.*

Atypical chronic myelogenous leukemia (aCML)

The name aCML has been applied to a specific human condition characterized by a disease that is in most respects like the majority of CML cases but lacks the BCR-ABL fusion gene. *The major differences between CML of the Ph+ type and aCML are that monocytes are more prominent in aCML and may suggest a diagnosis of CMML, and basophilia characteristic of both AML and CML is usually absent.* An

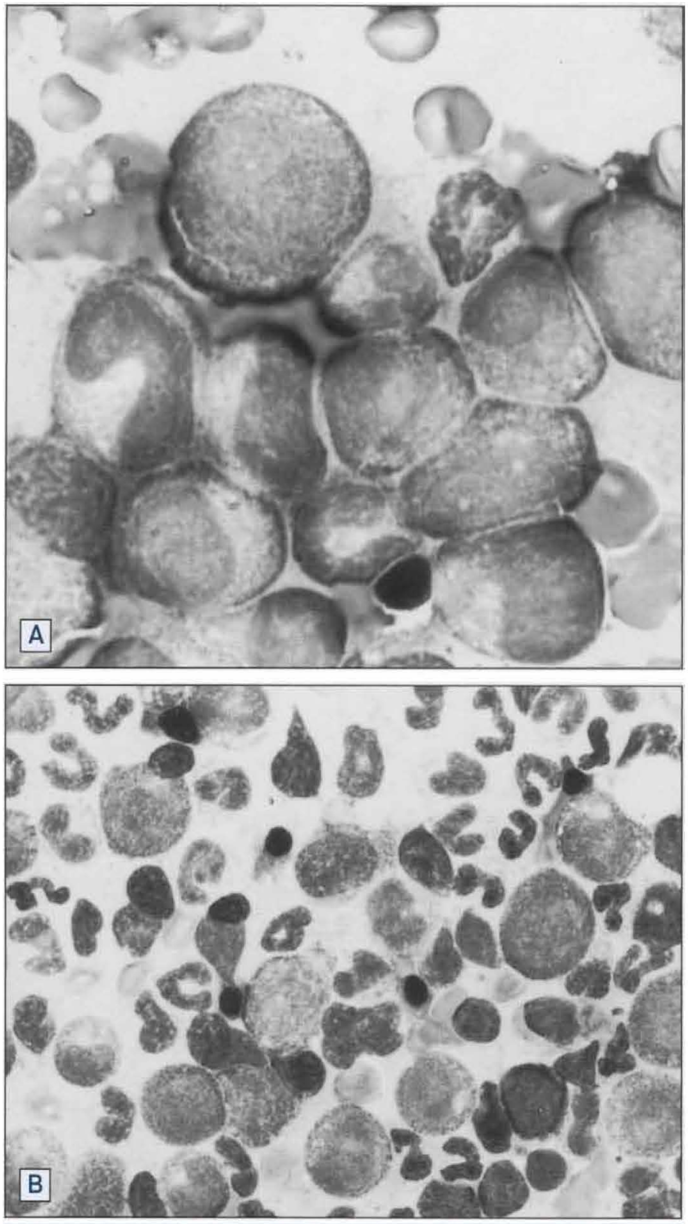

Figure 2.27 Chronic myelomonocytic leukemia in a dog, marrow aspirate. **A.** Area of early myeloid asynchrony with giant metamyelocytes. **B.** Paradoxical myeloid hyperplasia with increased mature granulocyte reserves and moderate erythroid phthisis.

unusual characteristic of aCML which may occur in animals is a type of dysplasia in the neutrophils series called "abnormal chromatin clumping." The change consists of very hyperchromatic chromatin arranged in prominent chromocenters each of about the same size of 0.5–7 μm and with added prominence because of surrounding parachromatin clearing. There are also pseudo Pelger-Huet nuclear changes and dysplastic changes in both the erythroid and megakaryocytic lineages. The peripheral blood red cells have frequent macro-ovalocytosis and there is usually thrombocytopenia.

Juvenile myelomonocytic leukemia (JMML)

Juvenile myelomonocytic leukemia is a disease of children generally less than 3 years of age. JMML has a type of genetic specificity in that it is Ph- and BCR-ABL negative and primarily involves the neutrophil and monocytic cell lines. The cells of this tumor also have a unique ability to grow in culture without added GM-CSF. This capability is lost by removing the monocytes and other adherent cells from the culture inoculum or by adding antibody to GM-CSF. The level of GM-CSF in spontaneously growing cultures is not above that of control levels, which suggests that there is hypersensitivity to GM-CSF as the basis for this syndrome. The patients are presented with fever and often pneumonia. Splenomegaly is always present, and half of cases have lymphadenopathy and a macropapular rash. There is leukocytosis of characteristically 10×10^9/L, of which at least 10% are monocytes accompanied by anemia and thrombocytopenia. The blast cell count including promonocytes is usually less than 5%. An unusual abnormality that constitutes a useful laboratory test is the presence of at least 10% of fetal hemoglobin. Treatment by chemotherapy is usually ineffective.

Myelodysplastic syndromes (MDS)

The myelodysplastic syndromes (MDS, dysmyelopoietic syndromes) are a *diverse group of clonal disorders of hematopoiesis characterized by refractory cytopenias accompanied by qualitative and quantitative dysplastic changes in marrow cells coincident with ineffective blood cell production.* About 20% (17–40%) of human cases terminate in acute myeloid leukemia; in animals most cases terminate or are terminated with marrow failure. These diseases were first felt to be maladies of old age, however it now appears that myeloproliferative disease in the young is preceded by a prodromal phase of myelodysplasia that has a high probability of evolving into acute myeloid leukemia. Thus, *myelodysplasia is a syndrome of clonal instability* that tends to evolve into acute myeloid leukemia with a high probability of progression in the young and a lower likelihood of progression in the aged. In humans, 80% of cases are characterized by cytogenetic abnormalities with determination of this diagnostic procedure considered an essential part of the evaluation of patients with MDS. In animals, cytogenetic changes are as yet undefined. Mechanistically, the stem cells in MDS are less responsive to GM-CSF than normal, whereas in acute myeloid leukemia they are hyperresponsive.

The term "myelodysplasia" replaces the previous label of "preleukemia," and in veterinary practice is a preferable diagnosis for an animal that might otherwise survive the disease but not the diagnosis. The FAB classification for myelodysplasia (1982) recognized *5 variants of ineffective myelopoiesis*, including refractory anemia with (RARS) and without (RA) ringed sideroblasts, refractory anemia with excess blasts (RAEB), and in transition to acute leukemia (RAEBt), and chronic myelomonocytic leukemia (CMML). The major utility of this classification was that patients with RA and RARS tended to have long survival while those with the other variants did not. The revised WHO Classification (2001) *proposes 6 variants of MDS* including RA, RARS, RAEB and 3 new categories: refractory cytopenia with multilineage dysplasia (RCMD), the 5q− syndrome, and MDS unclassifiable. The category CMML is placed in a new subdivision of myeloid dyscrasia that lies between frank acute myeloid leukemia (AML) and the myelodysplastic syndromes as they have been previously recognized. This new category is termed "myelodysplastic/myeloproliferative diseases" and includes 3 disease entities including CMML, plus atypical chronic myelogenous leukemia (aCML), and juvenile myelomonocytic leukemia

(JMML). With much additional experience since the introduction of the FAB classification, the WHO system categorized the MDS entities on a prognostic basis based on cytogenetic changes. Those MDSs involving only minor injury to chromosomes (5q− only or 20q− only) were placed in the "good" category, and "poor" with at least three complex chromosome abnormalities or with errors in chromosome 7, and in an "intermediate" risk category with other cytogenetic abnormalities. The application of this information led to the proposal for the myelodysplastic/myeloproliferative disease grouping to demonstrate the need for aggressive management of the 3 entities CMML, aCML, and JMML.

In general, the primary MDSs, that is those occurring without prior chemotherapy or other toxic exposure, are largely diseases of maturity in both humans (>50 years) and animals. The MDSs are much less common in children but those that do occur are aggressive lesions, primarily monosomy 7 and juvenile myelomonocytic leukemia JMML. This level of categorization in animals must await sequenced genomes and the development of diagnostic probes, since the greater number of chromosomes in animals makes cytogenetic analysis in these species much more difficult than in humans. In animals as in humans, most cases of MDS present with some aspect of marrow failure, usually recurrent infections due to deficits in neutrophils or nonresponsive anemia often associated with thrombocytopenic bleeding. Hepatosplenomegaly or lymphadenopathy are not usually present, but autoimmune disease involving marrow, skin or other areas may cloud recognition of underlying MDS. Fortunately, *there are in animals as in humans subtle but definable morphologic and quantitative changes in marrow and blood that enable the diagnosis of MDS to be made on currently available skill and technology*. The quantitative changes include early asynchrony or the inappropriate presence of increased numbers of myeloblasts that may be of type 1 or 2 (see AML, p. 125). Morphologic changes may involve one or all of the 3 leukocytic, erythrocytic or megakaryocytic lineages. Dysplastic changes in the neutrophil line include variations in cell size, decreased or abnormal granulation, and hypo- or hypersegmentation. In addition in most species of animals, giant metamyelocytes may be present in marrow and occasionally with the "donut" or rodent cell configuration. Erythroid dysplasia is manifested by asynchrony of nuclear and cytoplasmic development, megaloblastoid nuclear chromatin with finely distributed, less densely stained chromatin, and abnormalities of nuclear shape including lobulation, multinuclearity, pseudopodia and fragmentation. The resulting red cells will have increased variation in hemoglobin saturation and shape changes, including ovalocytes, dacryocytes (tear-drop shapes), and anisopoikilocytosis. Dysplasia in the megakaryocytic line includes marked variation in cell size with both very small and very large cells, both with nonlobulated nuclei: the larger may have very finely dispersed chromatin that lacks normal staining density like the megaloblastoid changes in the erythroid line. Dysplastic changes in megakaryocytic cytoplasm include asynchrony of nuclear and cytoplasmic maturation seen as pyknotic nuclei in small cells with little cytoplasm or in large cells with retention of largely agranular or hypogranular cytoplasm. In addition, there may be peripheralization or "rimming" of cytoplasmic basophilia and eccentric placement of cytoplasm, and even apparent phagocytosis of red cells.

The bone marrow in these syndromes is most often hypercellular (Fig. 2.28A), but hypocellular variants occur. Architectural abnormalities in marrow include topographic distortion with loss of the normal orientation of myelopoiesis near endosteum, and more centripetal location of erythroid islands, to a random distribution of lineages with loss of clustering of rubricytes. There is an irregular increase in stroma, which may be diffuse terminally accompanied by ectasia of sinuses with intravascular hematopoiesis. Plasmacytic cuffing of small vessels is increased, and there is increased remodeling of bone.

The usual clinical presentation is of a *thin lethargic animal with pale mucous membranes and a history of chronic recurrent infections often involving the respiratory tract*. While refractory anemias are relatively common in the cat and dog, *the types of myelodysplasia most commonly recognized in animals (as distinguished from most commonly occurring) are a form of RAEB in the cat and CMML in the dog.*

Refractory anemia with excess blast cells (RAEB)

RAEB is a disease of humans and dogs and cats and likely other species where hematologic dyscrasias are given less attention. The disease in cats was felt to be a syndrome of FeLV infection, but since infection with that virus is now much less common but refractory anemia continues to occur, it must be assumed that feline RAEB results from a variety of causes. In all species, there is *nonresponsive pancytopenia and hyperplastic marrow with excess small (type 1) myeloblasts. The diagnostic criterion for RAEB is a level of marrow blasts increased to at least 5% and less than the 20% required for the diagnosis of AML.* The WHO classification divides the disease into two groups based on risk for progression to AML with those cases with 5–11% blasts in marrow termed *RAEB-1* and with 12–19% blasts *RAEB-2*. Further, in the human disease, focal areas of clustered blasts and promyelocytes may be present in marrow (*abnormal localization of immature precursors, ALIP*) and, if 3 or more are found, the disease has a higher risk of conversion to AML. The disease occurs in young mature animals without apparent sex predisposition. The course is 1–6 months, occasionally followed by recovery. Most animals are killed because of recurrent infections due to marrow failure.

The anemia is moderate to marked, mildly hypochromic and macrocytic with anisocytosis but no polychromasia. Both ovalocytes and nucleated red cells may be present in blood. The leukocyte count is generally below 5×10^9/L and there is neutropenia with moderate left shift. The neutrophils have reduced secondary granulation, diffuse basophilia, and toxic vacuolation. There is usually moderate thrombocytopenia with a lot of variation in size, mild uniform basophilia, and poor granulation.

Aspirated marrow is characteristically 60–80% cellular as determined by the proportion of cellular to fatty areas. There is early asynchronous maturation with as many as 5–10% blast cells, loss of granulocyte reserves, and an apparent "maturation arrest" at the myelocyte–metamyelocyte level. Most of the blasts are myeloid, but they are poorly granular and may be mistaken for lymphocytes, except that promyelocytes are increased and may be expected to be progeny of the atypical blasts (pattern recognition on the basis of "knowing them by the company they keep"). The erythroid nuclei have marked contrast between large chromocenters and clear areas; dyserythropoiesis with multinucleation is present to a variable degree. Since the early myeloid hyperplasia is not followed by mature reserves, the myeloid:erythroid ratio remains near 1.0. The megakaryocytes are normal or decreased but not increased. They have large "monocytoid" nuclei without normal lobulation. Cytoplasmic basophilia remains high in maturing cells and granulation is decreased. Marrow iron is coarse and increased.

At postmortem, there is pallor and emaciation with mild splenomegaly. Lymph nodes are normal or mildly enlarged. Secondary lesions of pleuritis, pneumonia and lymphadenitis are usually prominent. The bone marrow is uniformly pale, pink and opaque without serous atrophy, and is moderately cohesive.

Histologically, the bone marrow has high cellularity and focal absence of fat (Fig. 2.28A, B). Cell density may be variable due to reticulin sclerosis. Cytologically, 60% of the cells present appear primitive with round vesicular nuclei, prominent single nucleoli, and a thin rim of highly basophilic cytoplasm. Erythropoiesis is patchy with reduced cellular packing or density, and few mature rubricytes are present. Dyserythropoiesis is more prominent than on cytological preparations. Megakaryocytes appear immature due to irregular lobulation and low cytoplasmic volume. Marrow germinal centers may be present and numerous. The liver usually has some degree of periacinar ischemic degeneration, but hematopoiesis is minimal or

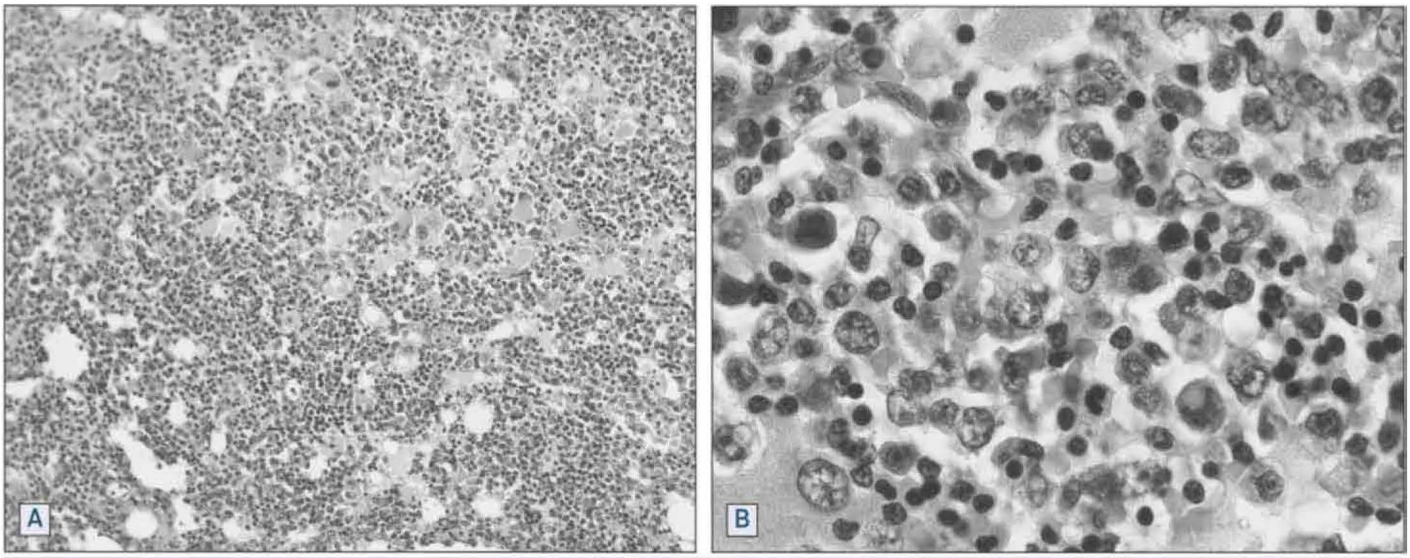

Figure 2.28 Myelodysplastic syndrome refractory anemia with excess blasts, feline bone marrow. **A.** There is almost complete loss of fat cells but with reduced density of remaining cells and dilation of marrow sinusoids. **B.** Detail of (**A**). There are increased numbers of large vesicular nuclei (early myeloid asynchrony) with loss of marrow granulocyte reserves. Most of the erythroid precursors are late stage with dyserythropoiesis characterized by abnormally lobulated erythroid nuclei.

absent. There is splenic follicular hyperplasia and increased sinus histiocytes. There are some paratrabecular megakaryocytes, but hematopoiesis is not prominent. The lymph nodes have follicular hyperplasia with medullary follicles and medullary cord hyperplasia. Neutrophils are not prominent either in sites of inflammation or their draining nodes because of the neutropenia.

Refractory anemia with ringed sideroblasts *occurs in animals on experimental diets deficient in vitamin B6.* Wintrobe and co-workers studied the function of this vitamin in swine, where its deficiency was found to be associated with a hypochromic microcytic anemia with iron overload. Biochemically, B6 is required for the formation of levulinic acid, in the early synthesis of the porphyrin rings of hemoglobin, and is the rate-limiting step in hemoglobin production when deficient. As a result of inability to form the protoporphyrin molecule, iron is not utilized but its absorption from the diet is increased. Iron accumulates in marrow macrophages but also in the mitochondria of developing rubricytes in stainable quantities seen with Prussian blue stain as "ringed sideroblasts." The MDS of the same name became recognized because of a syndrome of human refractory anemia with ringed sideroblasts that did not respond to supplemental vitamin B6. The MDS of this type is not currently recognized in animals. In humans with RARS, anemia is always present and of moderate degree with an unusual dimorphic pattern in red cells with some well saturated and a third or more very hypochromic and with the range and degree of poikiocytosis seen in iron-deficiency anemia. Occasionally stainable iron aggregates (Pappenheimer bodies) are present in peripheral red cells, visible as basophilic inclusions in routine blood stains and most likely to be seen if there is splenomegaly or asplenia. The platelets and neutrophils are normal in number and morphology, and there is marrow erythroid hyperplasia with >15% of rubricytes at all stages with stainable iron granules. The megakaryocytes and granulocytes appear normal morphologically and numerically. Some 50–10% of human RARS evolve to AML, and, if the anemic form is accompanied by trilineage dysplasia, the risk of malignant transformation is greater.

Myeloid metaplasia with myelofibrosis (MMM)/ chronic idiopathic myelofibrosis (CIMF)

Idiopathic myelofibrosis also known as *agnogenic myeloid metaplasia* is recognized as a clonal disorder of hematopoietic precursors and is *considered a type of chronic myeloproliferative disease (CMPD)* rather than a syndrome of myelodysplasia. See Chronic leukemias/myeloproliferative diseases, above.

Myelodysplastic syndrome, unclassified

The unclassified category of MDS includes those cases that are characterized by absence of blasts in the peripheral blood, minimal or no detectable increase in marrow blasts, with dysplasia in one or more marrow cell lineages, and refractory cytopenia of one or more cell lines in the peripheral blood. An appropriate working diagnosis would be MDS with refractory anemia, neutropenia, thrombocytopenia, or pancytopenia, as the case requires, to provide a mechanistic understanding of the principal abnormalities involved. The major criterion for use of this diagnosis is that *there must be evident and repeatable morphologic verification of dysplastic changes in one or more marrow cell lines.* A recurring syndrome where this diagnosis is appropriate is the cat or dog or other species that is presented with a moderate or severe nonresponsive anemia without thrombocytopenia or neutropenia but with marked marrow erythroid hyperplasia accompained by dyserythropoiesis but without an increase in marrow blasts. There may be dysplastic changes in the megakaryocytic, but not usually in the neutrophilic, line, and *the major differential diagnosis is the distinction from AML of the M6 type or acute erythroid leukemia.*

Since in animal medicine the cytogenetic differentiation between AML and MDS is not currently available, the rational management of these cases is to apply conservative therapy until it is apparent that it is not effective, and then more aggressive measures that would be appropriate for a diagnosis of frank leukemia.

HISTIOCYTIC AND DENDRITIC CELL NEOPLASMS

Macrophages and dendritic cells are nonlymphoid mononuclear cells that are intimate participants in both the immune and nonimmune inflammatory reactions. They are involved to a minor or greater extent in the neoplastic processes of the various cells of both the myeloid and lymphoid neoplasms. In some diseases, these cells are themselves the principal cells involved in the hyperplastic or neoplastic process.

The **monocyte/macrophage/histiocyte cells** are marrow-derived from primitive myeloid precursor cells. The pattern of maturation is *from marrow precursor to monoblast, promonocyte, monocyte, and with further stimulus to histiocyte/macrophage,* with those latter two terms being used as synonyms. Macrophages express MHC class II DR receptors in most mammals and in chickens as well as a number of CDs (cluster designations) with the complement of CD: 45,11, 13,16 d 62 and cytoplasmic lysozyme varying in composition in various domestic animals. Cytochemically, macrophages stain positively for nonspecific esterase, acid phosphatase and lysozyme. They have receptors for a wide range of proteins including Ig's, complement, coagulation factors, some hormones and cytokines, including TNF, IL-1, INF-γ, and GM-CSF. Macrophages themselves are able with stimulation to produce a range of cytokines and growth factors and participate in nonimmune resistance to microorganisms. Macrophages become increasingly resistant to intracellular organisms by a process of activation under the influence of INF-γ and are able to recognize and clear apoptotic cells.

Dendritic cells have markedly different morphology (dendritic) to other mononuclear cells characterized by *long cytoplasmic tendrils* that in interdigitating cells are connected to others by desmosomes. The designation of dendritic, while indicating morphology, does not define histogenesis, and *includes Langerhans cells, indeterminate and veiled cells, interdigitating dendritic, follicular dendritic, and dermal dendrocytes.* Dendritic cells appear to arise from two lineages, myeloid and lymphoid. The **myeloid stream** evolves from CD34+ marrow precursor cells that differentiate under stimulation from GM-CSF and TNF-α to immature nonactivated Langerhans cells. In humans, the Langerhans cells are characterized by the presence of an ultrastructural organelle called the Birbeck granule which is a slender structure with a small bulb at one end that evoked the name "banjo" cell. These granules are present in the Langerhans cells of cattle but not in dogs and largely unknown in others. Langerhans cells express CD45 and CD1 and have intracytoplsmic MHCII products required for antigen-processing and antigen-presentation functions in interaction with B- and T-cell lymphocytes. In response to inflammatory cytokines or microbial antigens, Langerhans cells mature to dendritic cells with abundant surface MHCII complex. In this state, they migrate through the tissues as veiled cells to the paracortical areas of draining lymph nodes. In canine skin the Langerhans cells express CD1 and reside both within the epidermis and in the dermis located near postcapillary venules. In human skin, an indeterminate cell is identified that is morphologically and antigenically like the Langerhans cell but lacks the Birbeck granule; they are of indeterminate status and are thought to be either precursors or direct descendents of Langerhans cells. With activation by cytokines within the skin, the Langerhans cells in their "trained" state arrive in the node cortex having lost CD1 expression and complement receptors, but have surface MHC activity and as antigen-presenting cells (APC) they are able to produce an array of cytokines that interact with local paracortical T cells in the initiation of cellular immunity. An alternative pathway is proposed for the myeloid dendritic cells, which suggests that they differentiate under appropriate cytokine stimulation (TNF-α, IL-4) and become mature dendritic cells that circulate in the blood and home to sites of inflammation. A dermal dendrocyte/dermal dendrophage that is normally in the perivascular area of the papillary dermis is distinct from both the indeterminate and Langerhans cells and may have a role in humoral immunity by migration to become the follicular dendritic cell.

The second stream of dendritic cells of **lymphoid origin** are derived from committed marrow lymphoid precursors and migrate to the medulla of the thymus. In that area and under stimulation from IL-3, they differentiate to dendritic cells that then migrate to the paracortex of lymph nodes by traversing the postcapillary venules as plasmacytoid appearing T cells. Once in the node paracortex, the myeloid and lymphoid dendritic cells are not distinguishable but may have different functions with the lymphoid cohort responsible for immune tolerance. The dendritic cells of the germinal or follicular centers are believed to be of marrow origin and arrive in the nodes in afferent lymph where they are identified in the subcapsular sinuses by the KIM-4 marker. They subsequently migrate to the outer cortex and form a reticular network in the germinal centers being joined by thin branching cytoplasmic processes that link between cells by desmosomes. *The follicular dendritic cells are antigen-presenting cells* and retain immune complexes on their cell surfaces. They become multinucleated and are visible as the epitheliod appearing cells in germinal centers that have recently undergone severe lympholysis.

Macrophage/histiocytic neoplasms

Hemophagocytic histiocytic sarcoma (malignant histiocytosis)

Histiocytic sarcoma (HS) is the nonleukemic tissue phase tumor of the mononuclear phagocyte system. The older names are derived from the pattern of involvement where the disease involves lymph nodes. Thus, *malignant histiocytosis is the neoplastic counterpart of benign sinus histiocytosis when the sinus type of node involvement is apparent.* In contrast, the less-favored term "true histiocytic lymphoma" has been suggested as the designation for those neoplasms of malignant macrophages where effacement of node architecture is present, as in the aggressive large-cell lymphomas. *HS is a rapidly progressive disease characterized by proliferation of markedly atypical histiocytes which are usually avidly erythrophagocytic. The disease is rare and usually occurs in mature cats and dogs.* Clinically there is fever, depression, weight loss, irregular lymphadenopathy and most frequently hepatosplenomegaly.

Hematologically there is rapidly progressive anemia that is initially responsive and within a few weeks progresses to nonresponsive pancytopenia with marrow failure. The disease may be first noticed and diagnosed by an enlarged node that on aspiration yields very large cells with nuclei as large as hepatocytes and nucleoli as large as red cells. The cytoplasm is finely granular and stains positively with α-naphthyl acetate esterase and negatively for myeloperoxidase. Erythrophagocytosis is not present in all tumor cells, and hemosiderin in the absence of red cells indicates previous activity. In some cases, as many as 100 red cells may be identified within a single malignant histiocyte, which indicates that the anemia is initially due to intracellular hemolysis and later to both destruction and impaired production. A benign counterpart described in humans is termed "infection-associated hemophagocytic syndrome" and is thought to be induced by viral or other infectious agents, but has not been recognized in animals. Grossly, there is pallor, and hemorrhage may be present if thrombocytopenia has been severe. There is irregular firm enlargement of lymph nodes, which are dark on cut surface, and enlargement of spleen and liver, both of which may be focally infiltrated and infarcted. Bone marrow is irregularly reddened, and the disease usually advances so rapidly that fatty areas remain. Histologically, the tumor cells have distinct cytoplasmic borders, large round or oval often paired nuclei, prominent nucleoli, and abundant pale cytoplasm, often with ingested red cells and hemosiderin and less often platelets and leukocytes. The tumor cells may be discretely packaged and even mildly encapsulated in spleen and liver (Fig. 2.29A, B), or in more diffuse and infiltrative distribution as is more common in nodes and marrow. The diagnosis may need to be confirmed by histochemistry, but *the severe atypia and phagocytic tendencies suggest the correct interpretation.*

Most of the seminal papers on this subject were published before the advent of immunohistochemistry and detection of germ line genes for the B- and T-cell receptors. Where paraffin blocks have been available for review, many of the older papers describing HS are based on a mixture of diseases including B- and T-cell lymphoma, and benign infection-associated hemophagocytic syndrome. The human syndrome of "*histiocytic medullary reticulosis*" described a disease of malignant macrophages that was characterized by anemia, fever and weight loss with hepatosplenomegaly and widespread erythrophagocytosis, and seems to most closely fit the disease of HS as it is seen in dogs and cats.

Dendritic cell neoplasms

Langerhans cell histiocytosis (LCH)

The histiocytic diseases of animals arising from Langerhans cells are very largely diseases of *young dogs*. The dendritic cell neoplasms of both humans and animals are relatively recently defined lesions, and some migration of the terminology is to be expected. It is instructive that the current WHO classification system of hematopoietic and lymphoid neoplasms is the first major classification system to include a listing of dendritic cell neoplasms. Some interweaving of human and animal disease is required to apply the current WHO system to the dendritic cell diseases as seen in animals. There is however, a remarkable similarity of dendritic cell neoplasms in humans and animals.

Cutaneous histiocytoma is dealt with in the chapter on skin (See Vol. 1, Skin and appendages) but for clarity of organization all of the diseases arising from Langerhans cells are dealt with here. Histiocytoma is a frequently occurring, benign and usually solitary cutaneous neoplasm of dogs. *Histiocytomas are tumors of nonactivated epidermal dendritic or Langerhans cells* and as such express CD1, the defining antigen of dendritic antigen-presenting cells. They also express CD11c and MHC II, but not CD90 (thy1) or CD4, the latter being the marker for activated dendritic cells. Histiocytomas stain positively for vimentin but not lysozyme or myeloperoxidase. The histology of the lesions is described in Vol. 1, Skin and appendages. The human counterpart of histiocytoma (LCH) is primarily a pediatric disease with a median age of occurrence of less than 5 years. Unlike the disease in dogs with no gender predilection, in humans there is about a 2 to 1 male to female predominance. While the disease known as *Langerhans cell histiocytosis* or "solitary eosinophilic granuloma" in children may present with a single lesion like the dog, it is much more likely to be a deep-seated neoplasm involving bone, lymph node or lung, and more comparable to the disease in dogs known as systemic histiocytosis.

A much less common presentation of Langerhans cell disease in the dog is **cutaneous reactive histiocytosis**, wherein *lesions are multifocal and the result of proliferation of activated interstitial or dermal dendritic cells*. As such, they express CD1, CD11c, and MHC class II as in cutaneous histiocytoma but also CD90 (Thy1) and CD4. In cutaneous reactive histiocytosis, there is involvement of the deep dermis and subcutis with the superficial dermis inconsistently affected; epidermotropism is not a feature of the disease. The lesions of cutaneous reactive histiocytosis develop around the deep dermal vessels and are both angiocentric and occasionally angioinvasive with a mixture of lymphocytes and other inflammatory cells as well as the dendritic cells. Invasion of draining lymph nodes may occur. *This disease is not malignant but an immunoregulatory disorder*, and as such the lesions may respond to corticosteroids or other immunosuppressive therapy.

Systemic reactive histiocytosis

Systemic reactive histiocytosis is seen as a familial disease of Bernese Mountain Dogs and sporadically in other breeds. The disease is characterized by *multifocal involvement of skin by proliferating activated dermal or*

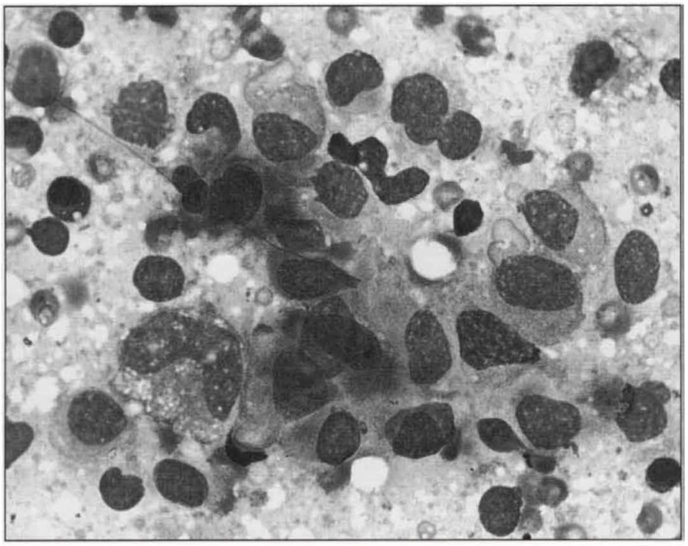

Figure 2.30 Systemic reactive histiocytosis, aspirate of a subcutaneous mass near the stifle joint of a Bernese Mountain Dog. The tumor nuclei are large and relatively bland without nucleoli and accompanied by abundant uniformly stained pale cytoplasm. (Courtesy of RM Jacobs.)

interstitial dendritic cells, and as such the invading cells express the identical constellation of antigens as seen in cutaneous histiocytosis. While the skin is consistently involved and in the same manner with angiocentric investment of deep dermal vessels with a polymorphous cellular infiltrate, there is also involvement of one or more of ocular and nasal mucosa, lymph nodes, lung, spleen, liver and bone marrow. Because of the involvement of vessels, *there may be focal infarction and the resulting mixed cellular reaction may suggest the presence of an infectious agent causing a granulomatous reaction*. The invading dendritic cells have bland chromatin with fine even distribution and normal staining density (Fig. 2.30). Nucleoli are small or unapparent, but the nuclear membranes are irregularly folded or creased giving characteristic linear nuclear clefts and grooving. Mitoses are relatively rare. The cytoplasm is abundant and of uniformly ground-glass density with indistinct cell boundaries. Like cutaneous histiocytosis, *the systemic disease is not malignant but an immunoregulatory disorder that may respond to aggressive immunosuppression.*

The multifocal but unisystem Langerhans cell histiocytosis (LCH) of humans is the disease formerly known as *Hand-Schuller-Christian syndrome* with the primary system of involvement usually bone. Finally, the multifocal and multisystem LCH disease of humans was known as *Letterer-Siwe syndrome* and is primarily a disease of infants and young children with strong male predominance. In general, the prognosis in these human conditions is most dependent on the extent of system involvement since the cells are cytologically similar in all variants of the dendritic LCH neoplasms. Patients who present with only one site involved seldom develop disseminated disease. Oddly, the absence of bone lesions is a poor prognostic sign and the presence of multiple osseous lesions is associated with a favorable outcome.

Histiocytic sarcoma

Histiocytic sarcoma has a breed disposition similar to that of systemic reactive histiocytosis and may occur as a solitary lesion or multiple lesions with rapid spread. *Histiocytic sarcomas result from the proliferation of dendritic antigen-presenting cells.* Tumors of this derivation have the immunological expression of CD1, CD11c, and MHC class II. They are variable in expression of CD90 and are negative for CD4 and are thus like cutaneous histiocytoma, but are negative for E-cadherin and have a much more aggressive cytomorphology. The primary sites for histiocytic sarcoma are on the limbs and typically overlying a joint such that curative excision is not possible. In disseminated disease, the more common sites include skin, lung, lymph node, bone marrow, spleen, and occasionally brain. Histologically, histiocytic sarcoma is characterized by marked cytologic variability accompanied by inflammatory cells and vascular invasion resulting in multifocal ischemic necrosis. Treatments are ineffective.

Follicular dendritic cell sarcoma

This neoplasm is uncommon in humans, and may occur as histiocytic sarcoma of nodes in dogs. The median age of human patients is 40 years with equal sex distribution. Most cases present with an enlarged cervical or axillary lymph node, but extranodal occurrence may involve the oral cavity, tonsil, gastrointestinal system and breast. *A differential diagnosis that may be important in animals is the similarity of follicular dendritic cell sarcoma to inflammatory pseudotumor of the spleen and liver of dogs.* The biology of the follicular dendritic cell sarcoma is more like that of a stromal sarcoma than of a lymphoid tumor, with local recurrence more frequent than metastatic disease. These lesions can be large – usually 5 cm diameter in the periphery and as much as 20 cm in the abdomen. Histologically, the tumor has a spindle cell morphology often in a whorled or storiform pattern. Multinucleation is present and the nuclei are elongated with fine granular chromatin, and nucleoli are small and distinct. There may 5–10 mitoses per high-power field. The tumor cells closely resemble normal follicular dendritic cells in their complement of markers. They are consistently negative for CD1, desmin and keratin, and endothelial markers. They stain weakly with CD45 and consistently with vimentin, complement receptors, and the follicular dendritic marker R4/23.

LYMPHOID NEOPLASMS

Classification systems for lymphoid neoplasms

There has been a tremendous increase in understanding of benign and malignant lymphoid proliferation in the latter half of the twentieth century. Up until the time of World War II, some restricted the use of the term *lymphosarcoma* to well-differentiated lymphocytic proliferations, while others used the term, without regard to cytological differences, for all primary malignancies of lymph nodes. At the same time, others used the term *reticulum cell sarcoma* for large-cell lymphomas regardless of varying cytologic type. In 1942, **Gall and Mallory** reviewed 618 cases of human lymphomas and suggested a classification system including four entities: *Hodgkin disease, lymphosarcoma, reticulum-cell sarcoma, and giant follicular lymphoma.*

While this system received widespread use, it was apparent that the cellular heterogeneity of lymphomas and, the widely apparent inability of pathologists to fit all observed lesions into these four categories, provided the basis for further systems with more cytologic specificity.

Following a study of lymphomas in American servicemen recruited during World War II, Henry **Rappaport** pointed out the biological uniqueness of follicular lymphomas. Subsequently, in 1956, Rappaport proposed a classification for lymphomas that divided all lesions into "nodular" or "diffuse" categories at the architectural level, with the following categories based on cytologic type: *lymphocytic, well differentiated; lymphocytic, poorly differentiated; mixed lymphocytic–histiocytic; histiocytic; undifferentiated.*

Classification systems at this time were based on the concept that small, normal-appearing lymphocytes were end-stage cells without the ability to divide. Following this understanding, lymphoma of *lymphocytic, well-differentiated* type corresponded to our current understanding of the cells of chronic lymphocytic leukemia and small lymphocytic lymphoma, where the cells closely resemble normal lymphocytes of the thymic cortex. The *lymphocytic, poorly differentiated* category included cells now termed "intermediate" lymphocyte type. In this intermediate type, the nuclei were slightly larger and had greater internal nuclear detail than small mature lymphocytes, but lacked nucleoli. Neoplasms with this nuclear type with slightly increased amounts of eccentric cytoplasm were subsequently termed intermediate *lymphoplasmacytoid,* and those with greater cytoplasmic volume were called *lymphoplasmacytic.*

A major contribution of Rappaport was the recognition that within the group of lesions categorized as "lymphocytic, poorly differentiated," most were relatively indolent lymphomas with very slow progression, while one subtype had a very aggressive behavior with rapid progression. This aggressive cell-type was subsequently recognized as an entity and termed *lymphoblastic lymphoma.* Thus, establishing the understanding that *small-cell size is not in itself an indication of an end-stage cell without the ability to divide.*

It is at this point that the terminology of lymphomas in veterinary medicine diverged from human pathology, with the term "*lymphoblastic*" in animal reports being applied indiscriminately to large-cell lymphomas. The result of this divergence in the application of terms has meant that the *lymphoblastic lymphomas* of animals, as defined in the human context, have been very slow to come into general recognition. This has been particularly troublesome to veterinary oncologists because *lymphoblastic lymphomas* of animals, of B- and T-cell type, tend to respond very poorly to treatment, thus reducing the credibility of our accuracy in prognosis in advising owners of what can be expected as a result of undergoing treatment for lymphoma in any particular case.

The initial Rappaport classification was based on the assumption that any of the cytologic subtypes of human lymphoma could occur in either a nodular or diffuse form. As more experience with nodular lymphomas was achieved, it became apparent that only three subtypes of nodular lymphomas occurred with any frequency, and they subsequently became known as the small-cleaved cell, mixed small-cleaved, large-cell, and predominantly large-cell types. Consequently, the Rappaport classification was modified to separate lymphomas into the *nodular types* for which the names proposed at that time were *lymphocytic poorly differentiated, mixed lymphocytic–histiocytic, and histiocytic.* At the same time, the list of *diffuse lymphomas* was *extended to include lymphocytic of intermediate differentiation, a Burkitt type of undifferentiated lymphoma, as well as histiocytic and lymphoblastic.*

At this time, histochemistry was still in relative infancy and the specificity of esterase stains to differentiate monocyte–macrophage lineage from lymphoid lineage was not in use. As a consequence, there was a lot of confusion over the terminology of large-cell lymphomas with the terms of *reticulum-cell sarcoma* and *histiocytic lymphoma* all being used. Later, recognition of histiocytic sarcoma and malignant histiocytosis as specific diseases of the monocyte–macrophage lineage led to the use of the term "true-histiocytic lymphoma" as a designation for poorly differentiated solid tumors of the monocyte–macrophage system.

The modified Rappaport system of classification was widely used and brought much more confluence in the use of terminology by hematopathologists. Even today, more than 60% of lymphomas seen by human pathologists outside of medical centers are confined to the three entities of diffuse large-cell lymphoma, follicular lymphoma, or Hodgkin lymphoma. It is therefore understandable that, for most purposes, the modified Rappaport classification was widely favored. The need for further subdivision of lymphoid classification systems was driven by the dual recognition that small lymphocytes were not end-stage cells and that increased information on immune-cell function demonstrated that there were two principal classes of lymphocytes, thymic and bone marrow derived types, which are morphologically identical, but functionally heterogeneous. The development of two further systems of lymphoid classification, both appearing in 1974, were the *Kiel system* which was predominantly used in Europe and proposed by Karl Lennert, and in the United States, the *Lukes-Collins* classification system.

The **Kiel classification** divided lymphomas into *low-grade and high-grade malignancies* and introduced the term "*centrocytic*" for follicular neoplasms of small cells and "*centroblastic*" for large-cell follicular lymphomas. In this classification, Rappaport's follicular lymphoma of the mixed lymphocytic–histiocytic type became centroblastic–centrocytic and the term "lymphoplasmacytoid" was added to identify a subdivision of lymphocytic of intermediate differentiation, being a small-cell lymphoma of indolent type with a more abundant and slightly eccentric cytoplasm. The high-grade malignancies in the Lennert classification included centroblastic, lymphoblastic and Burkitt type, and introduced the new term "immunoblastic."

In the **Lukes-Collins classification**, the lymphomas were divided into *T-cell and B-cell types.* The *T-cell types* included small lymphocytic lymphoma and mycosis fungoides plus convoluted lymphocytic and immunoblastic sarcoma of T-cell type. The *B-cell types* included small-cell lymphocytic lymphoma, plasmacytoid lymphocytic lymphoma, as well as the follicular lymphomas and an immunoblastic sarcoma of B-cell type. The Lukes-Collins classification is based on the assertion that B- and T-cell type could be distinguished morphologically with oversight stains. One of the underlying assumptions behind this assertion was that lightly indented, or *cleaved-cell* lymphomas of small- and large-cell type, were likely to be B cells and of germinal center origin, while *convoluted* cells, which are those seen in mycosis fungoides and the Sezary syndrome, are likely to be of T-cell type. Again, with further experience, it became apparent that while the cells of follicular lymphoma could be assumed to be of B-cell type, *the cytologic features described for differentiating diffuse lymphomas into B- or T-cell phenotypes were unreliable.*

By 1980, there were *6 leading classification systems proposed for the diagnosis of lymphoma* and tremendous confusion among pathologists, both nationally and internationally, and particularly between pathologists and oncologists. As a consequence, the National Cancer Institute assembled an international cadre of hematopathologists who were asked to classify 1175 cases of human non-Hodgkin lymphoma that were staged and treated in a consistent manner with each pathologist grading each case by all six classification systems. This study showed that no one system was superior to the others in predicting survival, but *all systems were capable of dividing lymphomas into various degrees of progression as determined by survival rates.* The study resulted in the publication of the **National Cancer Institute Working Formulation (WF)** for clinical usage in 1982. The WF, as it came to be known, divided lymphomas into low, intermediate and high-grade types, and did not attempt to separate B- and T-cell types. The WF was proposed, not primarily as a system of lymphoid classification, but rather as a common language between the other classification systems in use. Since immunohistochemistry was still in its infancy, it was recognized that subdivisions of the working formulation would be made with the identification of phenotypic and genotypic subtypes.

In the latter part of the twentieth century, the WF became widely used for the classification of lymphomas in the United States while the Kiel classification was the system most widely used in Europe (plus a modified system in the UK). With the tremendous increase in the number of cluster designation (CD) antibodies identifying specific subtypes of lymphomas in flow cytometry, but particularly in paraffin-embedded tissues, the Kiel classification was updated in 1992 with lymphomas divided into major categories of B- and T-cell types, with each of these subdivided into low and high grade lymphomas. Subsequently, a US/British/European consortium, known as the *International Lymphoma Study Group*, proposed a **revised European/American lymphoma (REAL) classification** in 1994. The REAL system divides lymphomas into B- and T-cell types with the entities arranged from the more indolent to the more rapidly progressive lesions without specific subdivision into low- and high-grade types of tumors.

During this same era, a **French/American/British (FAB) working group** defined acute myeloid leukemias based on lineage, types M1–M7, and acute lymphoblastic leukemias based on morphology, L1–L3, with L1 and L2 being largely of T-cell type and L3 largely of B-cell type.

Finally, in 2001, a **working group of the World Health Organization** (WHO) completed a summary classification of tumors of the hematopoietic lymphoid tissues that includes all entities, including acute and chronic myeloproliferative diseases and separates lymphomas into B-cell, T-cell and NK-cell lymphomas as well as lymphoid leukemias. The WHO system includes updated classifications for myelodysplastic syndromes, Hodgkin lymphoma, a list of histiocytic and dendritic cell neoplasms, and a subdivision of systemic mastocytoses.

A further issue in the categorization of lymphoid tumors has been the *distinction between lymphomas and leukemias of the same cell type*. Some have long held that chronic lymphocytic leukemia and small-cell lymphocytic lymphoma were merely different manifestations of the same disease. The same can be said for acute lymphoblastic leukemia and lymphoblastic lymphoma. The updated Kiel classification included lymphoid leukemias of small cell B- and T-types, but does not include the continuity of these lesions with lymphomas of the same cell types. The Kiel system includes lymphoblastic lymphomas of B- and T-cell types, but does not include the corresponding acute lymphoblastic leukemias.

The REAL and updated WHO classifications recognize both leukemias and lymphomas of the B- and T-cell lymphoblastic (precursor cell) types, but only the REAL classification recognizes the continuity of both B- and T-cell chronic lymphocytic leukemias with their corresponding small cell lymphomas. In this context, *the REAL classification for lymphoid neoplasms is most applicable to the classification of lymphoid tumors of animals* since, unlike chronic lymphocytic leukemia of humans, the corresponding disease of dogs has been shown to be very predominantly of T-cell derived neoplasms.

In **summary**, *both the revised European/American (REAL) and the very similar WHO systems are appropriate for the classification of animal hematopoietic neoplasms.* The defining strategy of these new systems is that each entity is a fully characterized disease based on all information including cell type, tumor architecture, topography, age, gender, phenotype and in some cases genotype. Both systems recognize and separate lesions that may have similar morphology, but different phenotypes and rates of biological progression. Further, the REAL system can be applied very largely on the basis of routine histochemistry to define B- and T-cell lymphocyte derivation on paraffin-embedded tissues. The application of these systems to reviews of lymphomas in animals and their response to therapy should provide major impetus to the understanding of lymphomas in animals from the standpoint of research on spontaneous lymphoid neoplasms of outbred species, as well as treatment of lymphoid tumors in companion animals.

From an overall standpoint, *the 2001 revision of the WHO classification provides a comprehensive framework for the identification of both myeloid and lymphoid neoplasms as well as the histiocytoses and myelodysplastic syndromes.* It is likely that the current, much greater, understanding of myeloid neoplasms reflected in the WHO classification will permit and encourage more accurate definition of these neoplasms in animals.

Lymphoproliferative disease

Lymphoproliferative disease may be defined as neoplastic proliferation of lymphocytes causing lymphoma or lymphoid leukemia. In general, the lymphoproliferative diseases form a spectrum with lymphoma and lymphoid leukemia at their extremes, and it is not always possible to determine whether the disease in a particular animal is primarily peripheral and a lymphoma, or of bone marrow origin and a leukemia. *The major distinction between leukemia and lymphoma is in the tissue area with the largest mass of tumor cells.* It is now understood that, in malignancies of the lymphoid system, there are always tumor cells in circulation whether or not they are recognized in the peripheral blood. The operative factors in the dissemination of tumors of the lymphoid system are the presence and type of *intercellular cytoplasmic adhesion molecules* (*ICAMs*) on the surface of the tumor cells that mediate adhesion to endothelium and the ability to emigrate to new tissue areas. In benign states, naive lymphocytes leaving the marrow "home" to the cortex of the thymus (*T cells*) and to the Peyer's patches of the intestine (*B cells*), and then to the peripheral tissues on the basis of these adhesion molecules. Malignant lymphocytes mimic this process, and those that do not home to tissue continue to circulate. All intermediate options exist, with no ability to adhere and undergo transmural endothelial passage, or with being tightly homed to the initial site of oncogenesis as occurs in neoplasms of the mucosal-associated lymphoid tissue (MALT) types. As a consequence of this understanding, *the leukemias and lymphomas of the same cell type, whether of acute or chronic cell maturity, are considered different manifestations of the same disease rather than separate entities.*

In lymphoproliferative disease, malignancy in an ontogenically primitive cell is likely to occur in the bone marrow, thus presenting as a leukemia in a young individual with the disease. In contrast, clonal autonomy in a mature lymphocyte is likely to occur in the peripheral tissues in a mature individual with presentation as a lymphoma. In general, the leukemias present with some degree of marrow failure characterized by anemia, thrombocytopenia, or neutropenia, which occurs when 50% or more of the bone marrow is involved by tumor. Under these circumstances, the blood and bone marrow are always diagnostic. In contrast, the lymphomas which involve peripheral tissues tend to leave the bone marrow relatively uninvolved and, at the time of diagnosis, these animals usually have normal hemoglobin, platelet and leukocyte levels.

In comparison to the complex molecular techniques required for identification of myeloid tumors, most of the identification of lymphoid neoplasms is done quickly and relatively cheaply with immunohistochemical reactions to identify B- and T-cell tumors and their various subsets. In general, *it appears that in both humans and animals the B-cell neoplasms have a better survival profile and response to therapy than the T-cell neoplasms.* Currently, it is possible to fingerprint lymphomas on the basis of their spectrum of gene activation. The mRNA is extracted from malignant lymphocytes with preparation of complementary DNA, which is then allowed to anneal with known transcripts on specifically prepared DNA microchips that detect tumor specific sequences in a screen that looks for many thousands of genes in a single analysis. These types of assays are able to detect subsets of tumor types within apparent single morphologic and phenotypic entities. This level of specificity in characterization of neoplasms holds the promise of better definition of the molecular pathogenesis of causation and for more specific and effective therapy.

Precursor B-cell neoplasms

Precursor B-cell lymphoblastic leukemia/lymphoma (B-ALL/LBL)

Lymphoid neoplasms of the B-cell lymphoblastic type are rapidly progressive neoplasms that involve the bone marrow and peripheral tissues in various proportions with the same cell type in all areas. Acute B-cell lymphoblastic leukemia/lymphoma occurs in all species. There is a wide age range, and apparently some predisposition for intact males. The disease is seen most frequently in *calves and cats less than a year of age and in dogs under 5 years.* Prior to use of FeLV vaccines, it was assumed that most hematopoietic neoplasms in the cat were virus-associated, while in the calf under a year, malignant lymphoproliferation is not associated with *Bovine leukemia virus* infection. Most studies on phenotypic identification of B-ALL in dogs and cats have too few numbers for firm projections but it appears that about 60% of the ALL in cats and dogs are of the B-cell type. The phenotype of ALL cannot be predicted by routine stains, and is determined primarily by the use CD3 and CD79α reagents to identify neoplasms of T and B cells, respectively.

The *morphologic characteristics of the acute lymphocytic leukemias* according to the French/American/British (FAB) classification are based on nuclear/cytoplasmic ratio, nuclear size and shape, number and size of nucleoli, and cytoplasmic basophilia and vacuolation (Table 2.3). ALL is also *classified immunologically* in terms of degree of differentiation, and *cytogenetically*, as well as by *etiology and prognosis*. In human ALL, the disease in children is very predominantly (85%) of the L1 type, and a high proportion of these cases attain durable remissions on aggressive therapy. Immunologically, the disease in children is predominantly of early B type with rearrangement of the immunoglobulin gene. In contrast, ALL in adults is predominantly of the L2 type with chromosomal abnormalities occurring in two-thirds of cases, and the response to therapy is much poorer than that achieved in children. The L3 type is the leukemic equivalent of the Burkitt lymphoma cell and is more prone to abdominal and central nervous system spread. Prognosis tends to decline from L1 to L3. With the advent of universal phenotyping of ALL, the classifications based on morphology are less referred to and utilized. In human ALL, more than 80% of cases are of the B-cell type. In terms of the FAB classification, T-cell ALL may of either FAB L1 or L2 type, and the L3 types are predominantly of B-cell type as is the Burkitt lymphoma.

Despite their aggressive appearance, the proliferative fraction of these tumors is actually less than that of their normal counterparts,

Table 2.3 Cytologic correlates in lymphoblastc leukemia

FAB	Lymphoblastic L1	Lymphoblastic L2	Lymphoblastic L3
Incidence (%)			
Humans	80	15	5
Animals	10	60	30
Cytologic features			
Cell size	Small predominantly	Large, heterogeneous	Large, homogeneous
Chromatin	Homogeneous	Heterogeneous	Fine and homogeneous
Nucleoli	Absent or small	Absent or small	Prominent
Cytoplasmic volume	Low	Moderate	Moderate
Cytoplasmic basophilia	Moderate	Moderate	Strong
Cytoplasmic vacuolation	Absent	Absent	Prominent
Nuclear shape	Round, rarely cleft	Irregular clefting common	Regularly oval to round
Phenotype	Primarily T cell	Primarily T cell	Primarily B cell

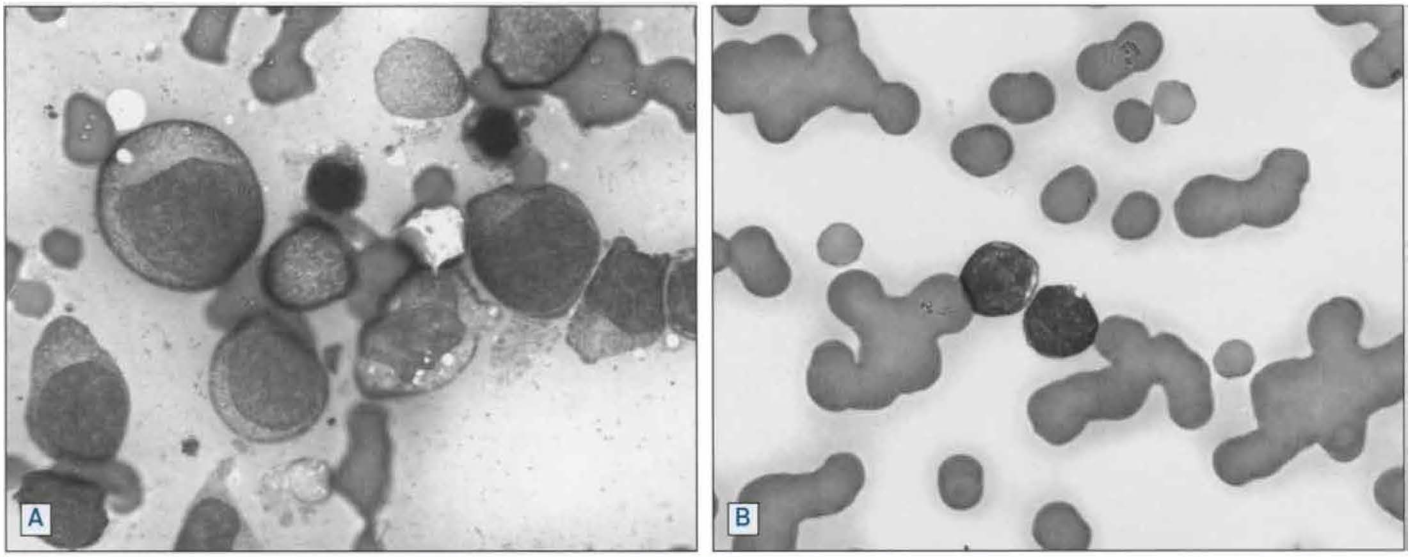

Figure 2.31 Lymphoblastic leukemia in a horse. **A.** Blood. Nuclei of neoplastic cells are approximately 1.5 red cells in diameter with deeply stained chromatin and with several small and inapparent nucleoli. The cytoplasmic vacuoles are the characteristic signature of the L3 leukemia. **B.** Bone marrow aspirate. Neoplastic cells are more variable in size and shape than in blood with homogeneous chromatin and 1 to 3 small nucleoli. Cytoplasmic vacuoles are characteristic of L3. and usually stain positively with Sudan black B.

and therefore cell-cycle-dependent cytoreductive therapy has the potential to injure the host more than the tumor. *In contrast to the acute myeloid leukemias, which compete directly for space with benign stem cells in subendosteal sites, the pattern of lymphoid colonization of marrow is random, and therefore the lymphoblastic leukemias tend not to result in marrow failure as rapidly as the acute or blastic tumors of the myeloid system.*

Since the phenotype of precursor cell leukemia in animals is largely undefined, the pathology of B- and T-cell ALL is also ill-defined. While there is little to suggest B-cell phenotype in the topography of precursor B-cell ALL, the T-cell ALL tends to begin in the thymus and rapidly spreads to the bone marrow.

With the exception of calves, animals are presented with minimal lymph node enlargement. There is some degree of mucosal pallor and splenomegaly, but hemorrhage is less common than with the acute myeloid leukemias. The course is one to two months.

Anemia at presentation is usually mild but tends to be more pronounced in cats. Red cells are normochromic, normocytic, without polychromasia, and there is an occasional poikilocyte. Dogs characteristically have Howell-Jolly bodies, indicating splenic involvement. The total leukocyte count is generally between 80 and 100 $\times 10^9/L$, but may be low or normal. The differential count is 80–100% lymphocytes, and leukoerythroblastosis is usually not present. Neutrophils are usually mature, and often hypersegmented with reduced secondary granulation. Metamyelocytes are occasionally seen, but more immature cells are unusual as are rubricytes.

Cytologically, B-cell ALL cells are intermediate in size with nuclei 2 red cells in diameter, round to oval, with finely distributed densely stained chromatin, indistinct or absent nucleoli, and minimal cytoplasm (Fig. 2.31A). Perinuclear clearing of basophilia with peripheral concentration is characteristic. Histologically, the nuclei of ALL cells are 1.5–2 red cells in diameter and may be small and uniform with inapparent nucleoli (L1), or larger with irregularly cleft nuclei (L2), or larger and of uniform size and shape with prominent nucleoli and highly basophilic cytoplasm often with vacuoles that stain positively for lipid (L3) (Fig. 2.31B). There may be a high level of apoptosis in histological preparations, with a resulting "starry-sky" appearance at low magnification due to a high number of macrophages containing tingible bodies.

A type of large granular lymphocyte tumor occurs in the Fischer rat and in dogs and cats and is considered with chronic lymphoid leukemia. The L1–L3 cell types are characteristic of the majority of the acute lymphoid leukemias seen in animals. A further type of lymphoid leukemia, formerly called "reticuloendotheliosis" and now "hairy cell leukemia," occurs in humans, and is related to infection with the HTLV-II. A counterpart of this disease has been described in cats, but appears to be very uncommon. Hairy cell leukemia has a very variable course in humans, but is generally considered with the chronic leukemias. Since in the cat survival is a matter of weeks after diagnosis, this entity is appropriately considered in the diagnosis of ALL. Morphologically, the tumor cells are characterized by thin cytoplasmic protrusions that are best seen in wet mounts and cytochemically by reaction for the tartrate-resistant acid phosphatase (TRAP) stain. Morphologically, the tumor has specificity in a broad rim of clear cytoplasm and by the manner in which it dilates, colonizes and lines hepatic and splenic sinusoids as well as the portal cuffing more typical of the lymphomas.

In general, in the acute lymphoid leukemias the platelets are usually less than 100×10^9/L and often severely deficient. Immature platelets are rare or absent but there may be confusion with agranular cytoplasm shed from injured lymphocytes.

Aspirated marrow is highly cellular with marked immaturity and trilineage phthisis. Bone marrow lymphocytes are characteristically slightly smaller and more uniform than those in the blood, possibly because of senescence in some of the latter. **Grossly**, there is usually only mild pallor and loss of condition, except in calves which may be cachectic and have marked symmetrical lymph node enlargement. Other species have only mild or irregularly enlarged nodes. The cervical and thoracic viscera are usually normal, except as noted for the calf. The liver is markedly enlarged in the calf with irregular pale areas and a lobular pattern on cut surface. In the cat and dog, the liver may be mildly enlarged. It is usually normal in other species. The spleen is moderately and symmetrically enlarged and is dry and fleshy on cut surface, occasionally with focal pale areas. The femoral bone marrow is uniformly reddened in cats, and may have foci of residual fat in dogs and horses. Calves have almost solid infiltration of all marrow cavities and large areas of infarction with yellow areas of necrosis surrounded by hyperemia. This degree of marrow involvement may be present in calves born with the tumor.

Microscopically, the bone marrow has 90–100% cellularity with a solid field of mononuclear cells. These are usually of medium size with a variable but minor proportion of large and small cells. Nuclei are open and vesicular with central nucleoli, and coarse granular chromatin with irregular deposition on the nuclear membrane. Cytoplasm is moderate in amount and deeply amphophilic. Only an occasional megakaryocyte and rubricyte can be found, and granulocyte reserves are absent. Lymph nodes have intact architecture with follicular atrophy. The cortical cell density is usually low, with tumor cells replacing the small paracortical cells. Postcapillary venules are tightly packed with malignant cells. The spleen has a thinned capsule, follicular atrophy, and solidly cellular sinus areas. There may be foci of necrosis. Benign hematopoiesis is minimal. Subendothelial colonization of splenic large muscular sinuses is well developed. The liver has diffuse sinusoidal and portal colonization. The tumor burden in the sinusoids roughly indicates the level of leukemia. There is irregular sinusoidal dilation, which contributes to the hepatomegaly, and usually some degree of periacinar ischemic degeneration. Foci of tumor may be widespread but are found in the kidney, testes, meninges, bowel, and pancreas.

Acute lymphocytic leukemia must be distinguished from acute myeloblastic leukemia on the basis of lack of cytoplasmic granulation and reaction to esterase stains. The differentiation of precursor cell leukemia from lymphoma of the same cell type is now considered of no diagnostic or prognostic value. Generally, *leukemias present with marrow failure and minimal lymphadenopathy*, whereas *lymphomas have a more normal neutrophil and platelet picture, and may not be anemic unless complicated by enteric hemorrhage. In lymphoma, there are usually localizing signs of peripheral involvement, including lymph node enlargement, central nervous system deficits, or melena.*

Mature (peripheral) B-cell neoplasms

B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma

Chronic lymphocytic leukemia is an acquired clonal lymphoproliferative disorder, usually of B-cell origin, characterized by the accumulation of a relatively uniform population of immunologically incompetent but relatively mature lymphocytes. Cytologically, CLL is characterized by considerable variation in morphology from small cells with mature nuclei and minimal cytoplasm, to cells with nuclei nearly twice the diameter of a small, mature lymphocyte and with relatively abundant cytoplasm. The biological similarities in CLL of the various types of morphology are that they are characterized by a low proliferative rate and prolonged cellular survival. In contrast to many of the myeloproliferative diseases, *molecular and enzymatic studies indicate that the neoplastic clone in CLL involves only the cells apparent in the tumor without involvement of other cells of the myeloid or benign lymphoid systems.* While lymphoblastic leukemia is primarily a disease of the young in both humans and animals, CLL is a disease primarily of humans older than 80 years of age and *animals in late maturity*. In humans, but less so in animals, males appear to be affected more often than females, with an approximate 2:1 ratio. The risk factors for CLL in animals are unknown, but in humans, farmers who utilize an array of pesticides are at greater risk as are workers in the rubber and asbestos industry and those exposed to benzene. Unlike other types of leukemia, CLL in humans is not linked to prior exposure to radiation but genetic factors are involved as *CLL is the most common familial leukemia.* CLL occurs in younger humans and animals in which the clinical course is more variable, and the staging and prognostic criteria utilized for the older population are less useful and reliable. In humans, but not in animals, immunological changes have received a great deal of study in CLL. Characteristically, B-CLL cells have weak monotypic expression of surface immunoglobulin, usually of IgM but also of other types including IgD and even IgG. Human CLL has receptors for CD20, CD22 and CD11c, but CD79b and CD10 are not expressed. By this pattern of receptor development, *human CLL can be distinguished from other mature B-cell neoplasms such as mantle cell, prolymphocytic leukemia, follicular center cell lymphoma, and hairy cell leukemia.*

Cytogenetic changes in human CLL are difficult because of the rarity of mitoses available for analysis. More effective analyses, including fluorescence in situ hybridization (FISH), have assisted this process because the technique can be applied to interphase cells and mitotic activity is not required. These and molecular studies indicate that *karyotypic changes occur in only a minority of cases of human CLL*, with trisomy 12 being the most frequent abnormality found. More common genetic changes include 13q deletion or translocation, 14q+, 11q deletion or translocation, and a series of gene rearrangements involving the *BCL 1,2,3* genes.

The cell of origin of chronic lymphocytic leukemia is believed to be a lymphocyte normally present in peripheral blood at very low numbers and with an immunophenotypic pattern similar to CLL and in tissues present in the mantle cell areas of lymph nodes. The presentation of CLL in elderly humans is so characteristic that bone marrow studies may not be carried out. The minimal diagnostic criteria for human B-cell CLL include a peripheral blood lymphocyte count of at least 5–10 × 10^9/L with sustained lymphocytosis and a predominance of small mature-appearing lymphocytes, with less than 10% being prolymphocytes. Bone marrow cellularity is usually normal or increased, with lymphocytes constituting 20 to 50% of the bone marrow population. Several of the staging systems proposed for human CLL appear to be applicable to the disease in animals. The Binet system of classification includes three levels of presentation based on survival. The *three levels of tumor involvement* are:

1. No anemia or thrombocytopenia, with involvement of fewer than three lymphoid areas.
2. No anemia or thrombocytopenia, with involvement of three or more lymphoid areas.
3. Anemia with less than 100 g hemoglobin/L, or thrombocytopenia of less than 100 × 10^9/L.

Most cases of human and animal CLL maintain a stable cell type for long periods of time, but a small number of cases in both humans and animals evolve into ALL or an aggressive large cell lymphoma termed Richter's syndrome. The bone marrow involvement, which is a factor in staging, may be focal or nodular, interstitial or a combination of these two, or diffuse, with this sequence representing the order of progression and decreasing prognosis.

CLL in animals is primarily a disease of cats, cattle and dogs, usually eight to ten years of age or older. CLL is an insidiously progressive disease with few localizing signs and may be diagnosed without suspicion of disease in animals presented for routine clinical evaluation. The lymphocyte count on presentation in animals is highly variable and, while generally felt to be in excess of 50 × 10^9/L, is occasionally more than 500 × 10^9/L. This range in numbers is likely a function of CLL being diagnosed in animals relatively late in disease progression. It is likely that as routine blood examination in animals presented for annual or routine check-ups become more common, that CLL will become recognized as presenting with lymphocytosis at much lower levels and more characteristic of the situation in human CLL. Typically, anemia on presentation is moderate, normochromic and with minimal anisocytosis and poikilocytosis. Howell-Jolly bodies are occasionally seen, particularly if there is splenomegaly, and polychromasia and rubricytes are typically absent. Early in the course of CLL, neutrophil counts may be normal in absolute numbers and these may be maintained even while the lymphocyte count rises to very high levels and the neutrophils, as a percentage, are reduced to 5% or less of the peripheral blood cells. Thrombocytopenia is present in about 25% of dogs at diagnosis with CLL and is generally of mild degree. Major differences in phenotype are present in the dog as compared to humans. In one study of CLL in dogs, two-thirds of the population had T-cell leukemia and of that group almost half were of the LGL (large granular lymphocyte) type, one of which was likely an NK cell neoplasm. The canine B-cell CLL mark with CD79α and CD21, but unlike human B CLL, do not label with CD5. The phenotype of feline CLL is as yet less defined.

Cytologically, *the cells in the peripheral blood may be of several morphological types or combinations of types.* The most frequently described, but not the most frequently occurring, presentation is with a predominance of lymphocytes that are small with round nuclei that are the same size or slightly larger than the cells of the normal thymic cortex. The nuclei have a "blocky" or coarse chromatin pattern with large chromocenters whose density is characterized by irregular parachromatin clearing and an absence of nucleoli (Fig. 2.32A). The cytoplasm in this cell type is minimal and relatively lightly stained.

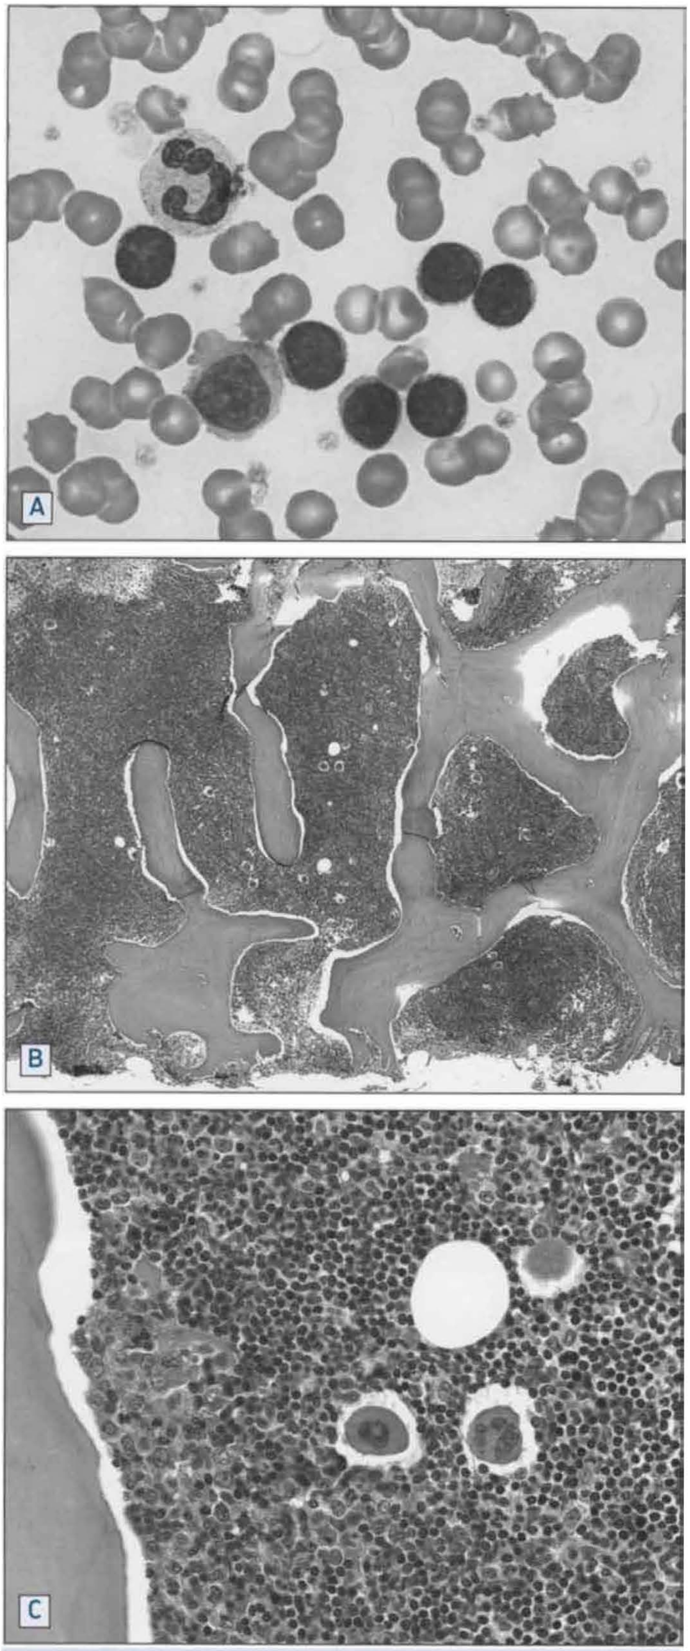

Figure 2.32 B-cell chronic lymphocytic leukemia in a dog. **A.** Blood. Small cell type with nuclei slightly larger than red cells and very little cytoplasm. The larger lymphocyte likely represents the proliferating population and has small nucleoli. **B.** Marrow. Relatively complete replacement of fatty areas by tumor cells represented by darker areas and residual hematopoiesis. **C.** Detail of (**B**). Interstitial pattern of marrow involvement with relatively solid areas of tumor surrounding the fatty vacuole and residual benign hematopoiesis adjacent to bone. (Courtesy of RM Jacobs.)

Cells of similar type are present in the bone marrow or in other sites of involvement. The more common presentation of CLL in animals is with a larger cell type in which the nuclei are round to oval and may be lightly cleft and are characteristically 2 red cells or slightly greater in diameter. The nuclei have densely stained chromatin, again with large chromocenters, with irregular lighter areas of parachromatin, and small nucleoli may occasionally be present. These cells characteristically have abundant cytoplasm in which the nuclei tend to be centrally placed with an irregular cellular shape resulting when the cells are seen in groups. The cytoplasm is lightly basophilic and agranular with perinuclear clearing. *CLL needs to be distinguished from prolymphocytic leukemia* in which the cells are a larger type, with the nuclei generally 2.5 red cells in diameter with accentuation of the large chromocenters and intervening parachromatin areas, one or two small nucleoli and relatively abundant cytoplasm.

Histologically, *the nuclei have the same characteristics as described in cytological preparation* except that the cells appear smaller in diameter and the variation in chromatin distribution is accentuated and more apparent. In both the small and larger cell types of CLL, deposition of chromatin in the nuclear membrane is not seen as in large-cell lymphomas, although chromocenters may impinge directly on the nuclear membranes. When the peripheral blood contains a mixture of cell types with either the small type or the large type predominating, it is likely that the disease began as a small-cell type CLL and is at a stage of progression to an accelerated phase with the larger cells representing prolymphocytes.

At the stage that most animals are diagnosed with CLL, the marrow aspirate is hypercellular with more than 90% of cells similar to lymphocytes in the peripheral blood (Fig. 2.32B, C). Animals with CLL usually are presented in relatively good body condition, often with abundant abdominal fat. *Splenomegaly is always marked in later stages of the disease* and the liver is at least mildly enlarged and palpable. There is generally not lymphadenopathy, and some nodes may be smaller than normal or there may be irregular focal nodal enlargement.

On gross postmortem examination, there is mild pallor with evidence of splenomegaly and the liver is mild to moderately enlarged, pale brown and with a lobular pattern that is more prominent as the anemia becomes more severe. On cut surfaces, the spleen is soft, fleshy, dry and deep red. Focal areas of tumor may appear as white nodules 5 mm or more in diameter in the spleen, liver and renal cortices. The nodes remain mobile and are never markedly enlarged and may be irregularly small or focally enlarged. The femoral bone marrow is uniformly pink in mid-shaft areas and is usually friable with heavy exfoliation on imprint preparation.

Microscopically, the bone marrow has greater than 90% cellularity and is usually seen as a solid field of small cells with occasional fat vacuoles and megakaryocytes (Fig. 2.32B, C). In later stages of the disease, it is not possible to determine whether the pattern of marrow involvement is focal, nodular or interstitial. The liver has tumor infiltration around virtually all triads, and there may be many lymphocytes in the sinusoids lining the hepatic cords. Unlike ALL, the degree of leukemia may not be reflected by the numbers of cells in hepatic cords, which is likely related to the pattern of L-selectins and integrins that determine the endothelial binding and homing pattern of the tumor cells. The spleen has atrophy of the thymic-dependent areas around small arterioles, and it may be apparent that the sinus infiltration is arising from cells around previous follicles or there may be

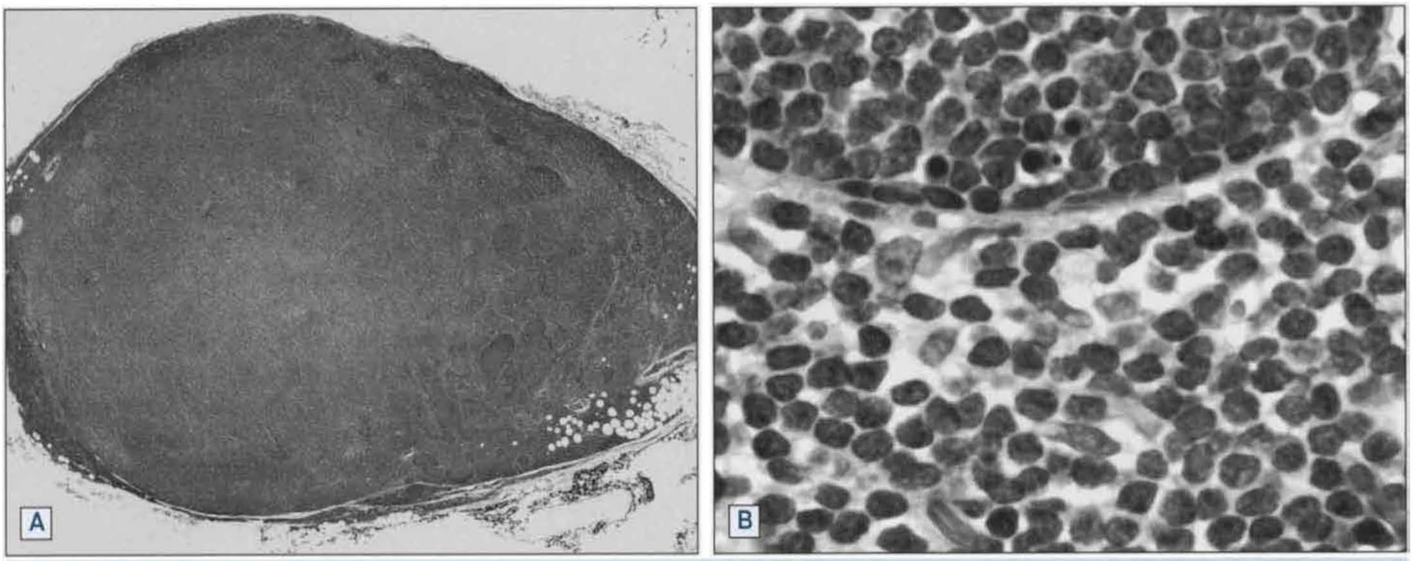

Figure 2.33 B-cell small lymphocytic lymphoma, lymph node, dog. **A.** There is effacement of normal architecture with compression of residual medullary cords and sinuses at the smaller end of the tissue. The irregular darker areas represent dilation of small veins with neoplastic cells, suggesting there is leukemia. The peripheral capsule is thinned and taut with irregular colonization of perinodal tissues. **B.** Detail of (**A**), area adjacent to dilated sinus. Nuclei are small with densely stained chromatin without nucleoli and minimal cytoplasm. Note apoptosis but absence of mitosis.

uniform sinus distention without a prior pattern of involvement being apparent. There is scattered hematopoiesis near the muscular trabeculae, most evident by a few remaining megakaryocytes. There is invariably subendothelial colonization of the large muscular veins. Nodal involvement in CLL is variable with some nodes atrophic with loss of germinal centers and sinus histiocytosis. Involved nodes tend to have diffuse cortical infiltration with dilated postcapillary venules, some of which are markedly dilated with tightly packed lymphoid cells. The tumor cells tend to occupy and expand the medullary cords and to compress and obliterate the sinuses. There is often small vessel dilation in the lung and kidney with many intraluminal lymphocytes, and focal tumor colonization may be found in most tissues including the brain and eye.

"Lymphoma of small lymphocytic cell type" (SLL) is virtually the same disease as chronic lymphocytic leukemia, and the diseases are now considered indistinguishable. If the disease presents primarily as a lymphoma, there are usually some nodes that are quite markedly enlarged and may even be affixed to surrounding tissues by extranodal tumor involvement. Both diseases are characterized by hepatosplenomegaly and progressive anemia, with thrombocytopenia and bleeding tendencies more common when there is a greater progression of tumor involvement in bone marrow than in the peripheral tissues. Histologically, the involved lymph nodes in SLL have a diffuse architecture with marked thinning of the peripheral capsule and focal colonization of the capsule and perinodal structure (Fig. 2.33A). There will be marked atrophy of lymphoid follicles, none of which may be present. Filling of the paracortex extends into the medullary region, with expansion of the medullary cords and compression but not destruction of the medullary sinuses. Focal lighter areas throughout the tumor are composed of slightly larger cells and are considered "*reaction centers*" consisting of prolymphocytes with a higher level of cellular proliferation. In the smaller cell types, the tumor cells resemble cortical thymocytes without nucleoli, and mitoses are rarely found outside of the reaction centers (Fig. 2.33B). In the CLL/SLL of the larger cell type, the cells histologically have greater internal nuclear detail, but again appear round with slightly greater cytoplasmic volume and greater internal nuclear detail. Mitoses again are rare.

Chronic lymphocytic leukemia and small lymphocytic lymphomas in both humans and animals are characterized by hypogammaglobulinemia and rarely monoclonal gammopathy of IgM type. The immunological implications of that abnormal globulin production may take the form of *autoimmune disease* of which immune hemolytic anemia is the most commonly observed type in humans and presumably in animals as well. Animals with hypogammaglobulinemia appear to benefit from globulin administration in terms of prevention of infectious disease. *CLL/SLL need to be differentiated from peripheralizing lymphoma of larger lymphocytes and chronic lymphocytic leukemia of the LGL type which are distinguished by their cytoplasmic granules to be of T-cell origin. The major differential diagnosis is with prolymphocytic leukemia (PLL).* CLL must have less than 10% prolymphocytes whereas disorders with 10 to 50% prolymphocytes are considered CLL/PLL, and PLL when greater than 50% of prolymphocytes are present in the peripheral blood.

Nuclei are characteristically 2 red cells in diameter with large densely stained chromocenters separated by lighter areas of parachromatin clearing and joined by fine chromatin bands. Nucleoli are present and irregularly rimmed by chromatin. (Courtesy of RM Jacobs.)

B-cell prolymphocytic leukemia

B-cell prolymphocytic leukemia (PLL) has not been formally reported in animals. *It is certain, however, that the disease occurs and is unrecognized, because the illustrations of prolymphocytic leukemias in humans have a very characteristic cytomorphology which can confidently be said to occur in animals*, but has not been described as an entity as distinguished from chronic lymphocytic leukemia of smaller cell type. The disease was first described in humans in 1974, and while of much rarer occurrence than CLL, the disease has been well delineated. The characteristic presentation in humans is an elderly male who presents with marked splenomegaly and leukocytosis. Lymph node involvement at presentation is unusual, whereas bone marrow failure is much more advanced than is the usual case with CLL, in that *anemia, thrombocytopenia, and neutropenia are all common at initial diagnosis*. The cytomorphological characteristics of PLL may be found in both B- and T-cell leukemias, but it is *likely that 80% or more cases of human PLL are of the B-cell type.*

Both benign and malignant prolymphocytes have distinct morphology, with the neoplastic counterpart being an exaggerated form of the benign cells with more contrast between the chromocenters and parachromatin areas of the nucleus. In humans and animals, the cells in blood in PLL have abundant pale blue agranular cytoplasm that may be deeply indented by the surrounding cells. The chromatin in PLL is densely stained and has more definition of chromocenters than in the large-cell type of chronic lymphocytic leukemia, and much more chromatin aggregation than is present in lymphoblastic leukemia/lymphoma. The chromatin in PLL is distributed in 20 or more large dense chromocenters that are cross-linked with each other by chromatin bands bridging relatively lightly or unstained areas of parachromatin clearing. PLL cells are characterized by a single prominent nucleolus, usually relatively central, and by irregular "rimming" of chromatin that adds unusual definition to nucleolar size and shape (Fig. 2.34).

Animals with PLL usually are presented after some period of declining health, usually noticed by loss of weight, appetite and vigor. PLL in animals is seen most frequently in dogs and cattle and less frequently in cats, horses and other species. Anemia is present of moderate or greater degree with typically 50–80 g hemoglobin/L, and usually uncomplicated by recent enteric or thrombocytopenic hemorrhage. Anemia is normochromic with occasional poikilocytosis, and polychromatic red cells and rubricytes are typically absent. There is usually some degree of thrombocytopenia with the platelet count usually of 50–100 × 10^9/L, with leukocyte counts generally in the same range of magnitude. Unlike CLL, mitoses in peripheral blood leukocytes are not infrequent and are most profitably looked for at the feather tip of the blood smear. On aspiration, the bone marrow is hypercellular and usually greater than 80% occupied by tumor and residual hematopoietic cells with a few fat cells remaining. Erythropoiesis and thrombopoiesis are reduced and residual cells are without dysplastic changes. A coarse hemosiderin pattern may be present with increased marrow iron.

Morphologically, PLL in animals is like CLL/SLL with a more rapidly progressive pattern of growth. Tissues other than marrow that are usually involved include lymph nodes, spleen and liver. Unlike CLL, there may be extensive involvement of nodes that are not grossly enlarged. There is typically effacement of germinal centers and diffuse filling of the node cortex with abridgement of the peripheral sinus and some degree of involvement of perinodal structures. The nucleoli prominent on cytological preparations are also apparent histologically, with the tumor cells expanding in a concentric fashion around germinal centers providing an architectural picture similar to mantle cell lymphoma in tissues with early involvement. There is massive splenic involvement in PLL with a miliary pattern often visible grossly and, histologically, there is expansion of the white pulp and diffuse filling of the red pulp. Splenic involvement may be characteristic with the residual benign cells of germinal centers collapsing in small dense nodules within the areas of previous germinal centers surrounded by the larger tumor cells, giving an inverted pattern of germinal center formation. The liver has a sinusoidal pattern of involvement with less prominent portal cuffing than in CLL.

B-PLL must be differentiated from B-CLL by the greater proportion of prolymphocytes in the blood exceeding 50% of the total lymphocyte compliment. In animal pathology, the other differentials might include *acute lymphoid leukemia*, which can be ruled out because of the characteristic retention of large chromocenters in the nuclei of PLL cells.

Lymphoplasmacytic lymphoma (LPL)

Lymphoplasmacytic lymphoma is a neoplasm of plasmacytoid lymphocytes with small B lymphocytes and some plasma cells that involves the bone marrow, lymph nodes and spleen. The typical cells of LPL have round or oval nuclei, slightly larger than those of small lymphocytic lymphoma (SLL), which lack nucleoli and have a moderate amount of densely stained, eccentrically placed cytoplasm. *In animals, LPL is one of the more common small cell lymphomas and is more common than SLL or small cell lymphomas of T-cell type.* Histologically, the LPL neoplasms have diffuse architecture and are characterized by cortical expansion of lymph nodes with effacement of normal architecture and involution of germinal centers. The disease is slowly progressive and mitoses are rare, with characteristically one present in 4 or 5 fields at ×400 magnification.

In animals, LPL tends to be a neoplasm with a relatively monotonous population of plasmacytoid small lymphocytes, whereas in human neoplasms of this type, there are numerous small lymphocytes and some more well-differentiated plasma cells. The neoplastic cells in human LPL have rearranged Ig heavy and light chain genes and express surface and cytoplasmic Ig, frequently IgM, but characteristically lack CD5 and CD10. Most human patients have a monoclonal paraprotein in the serum, commonly IgM, which corresponds to the syndrome known as *Waldenstrom's macroglobulinemia*. This paraprotein is seen in a significant portion of human patients with LPL, some of which have hyperviscosity syndrome or symptoms associated with cold agglutinins. While this aspect of animal pathology appears not to have been well studied, it is unlikely that LPL, as it is seen in animals, is very frequently associated with a paraproteinemia since this aspect of the disease is seldom one of the major presenting signs. In terms of the ontogeny of B-cell differentiation, *the LPL cells appear to be derived from germinal center B cells* in that they are characterized by having somatic mutations of their rearranged Ig genes. This change suggests antigenic selection and origin of the LPL cells from post-germinal center cells that did not complete differentiation to class-switching from IgM to one of the other immunoglobulin types. LPL is seen in some human patients with chronic *Hepatitis C virus* infection, many of whom have a mixed cryoglobulinemia. LPL developing in these patients has gene differentiation suggesting derivation from a highly selective and antigen-driven B-cell subset.

LPL has cytogenetic specificity with a t(9;14) (p13;q32) translocations as seen in approximately one-half of human cases. This change links a PAX 5 gene encoding a B-cell-specific transcription factor (BSAP) to the Ig heavy gene locus. This translocation leads to enhanced transcription of an unmutated PAX 5 gene and increased BSAP production. By definition, LPL does not have genetic alterations in the *BCL* area characteristic of other small B-cell lymphomas.

These genetic changes result in LPL cells having variable cytoplasmic staining for IgM and expressing the B-cell associated markers CD19, CD20, CD22 and CD79a. As noted earlier, they lack expression for CD5, CD10, CD23, and variable expression of CD43. CD25 or CD11c have faint expression in some cases. In summary, the typical morphology with lack of expression of CD5 and CD23 with strong reaction for surface immunoglobulin and CD20 confirms the diagnosis in human LPL. *In animals, the typical histo- and cytomorphology that is negative for CD3 and positive for CD79 constitutes confirmation of LPL.*

In animals, LPL is seen most frequently in *dogs and cats* but is also seen in cattle and occasionally in horses. LPL is a *disease of mature animals* and is characterized by *slow progression or enlargement of multiple peripheral lymph nodes* and may arise in skin, particularly in cats (Fig. 2.35A). Moderate splenic enlargement and colonization of the spleen is based on expansion of cells surrounding the germinal centers, presenting a miliary appearance on cut surface. In human LPL, particularly those associated with macroglobulinemia, it is characteristic to see cells with *Dutcher bodies* (intranuclear invagination of immunoglobulin containing cytoplasm found in both benign and malignant conditions) as well as some *Mott or flame cells* with multiple dilated vacuoles containing immunoglobulin. These are generally lacking in animal LPL and *the major differential diagnosis of this disease is from other small cell lymphomas, primarily mantle cell lymphoma, with less concern for differentiation from frank plasmacytoma.* LPL was referred to as lymphoplasmacytoid in the revised European–American lymphoma (REAL) classification System, but the category has been renamed lymphoplasmacytic in the WHO proposal. In previous classifications, both terms were used, with lymphoplasmacytoid being the term reserved for those small-cell lymphomas of intermediate nuclear type (slightly larger than benign cortical thymocytes) and with a narrow ellipse of eccentric cytoplasm. Lymphoplasmacytic was the term used for a tumor population with more variation in nuclear size and a greater volume of eccentric cytoplasm. In reviewing the literature on these lesions, it is apparent that the term lymphoplasmacytic as adopted by WHO better fits the majority of tumors of this type seen in human pathology than does lymphoplasmacytoid. In contrast, in animals, most of the indolent

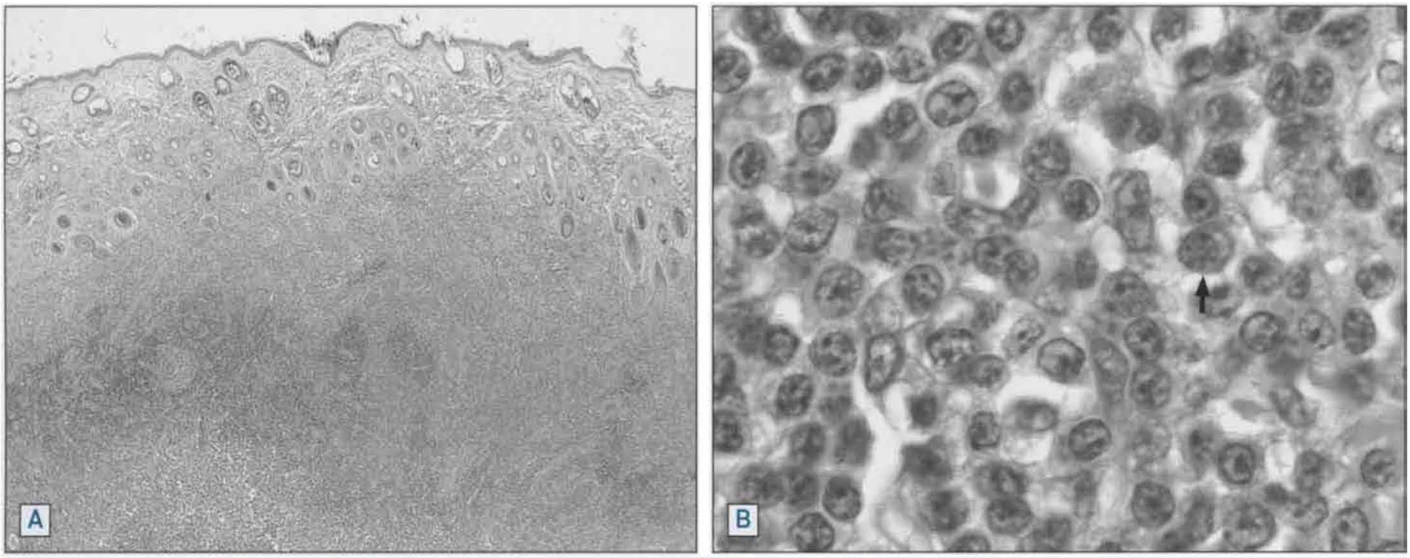

Figure 2.35 Lymphoplasmacytic lymphoma, skin, cat. **A.** There is relative sparing of the superficial dermis and adnexa with dense involvement of the panniculus. Small dark areas represent fading germinal centers, suggesting origin in benign lymphoid hyperplasia. **B.** Nuclei are slightly larger than red cells, vesiculated with peripheralized chromatin with nucleoli in larger cells. Cytoplasm is relatively abundant and deeply stained. Arrow indicates plasma cell differentiation.

small-cell lymphomas with plasmacytic differentiation have minimal cytoplasm and much better fit previous descriptions for lymphoplasmacytoid lymphoma (Fig. 2.35B).

Splenic marginal zone B-cell lymphoma (+/− villous lymphocytes)

Cells of the splenic marginal zone were described as having architectural and immunological specificity in the mid-1980s. *Marginal zone lymphoma has since become a recognized entity in lymph nodes as well as in spleen and in extranodal sites where it is associated with mucosal-associated lymphoid tissue (MALT) types of neoplasms.* Marginal zone lymphomas occur in cats and dogs (Fig. 2.36A–E) and likely other species, but have only become recognized as entities in animal pathology during the last decade. In human neoplasms, cells of splenic marginal zone lymphoma express a variety of B-cell markers including surface immunoglobulin, usually IgM and *BCL2*, but do not express CD5, CD10, CD23, CD11c, or CD43. In animals, marginal zone lymphoma cells mark with CD79α and are negative as would be expected for the T-cell marker CD3. Marginal zone lymphoma in the human context is characterized by cells with nuclei of intermediate size, that is a small-cell lymphoma slightly larger than benign cortical thymocytes and with a broad circumference of relatively water-clear cytoplasm. Nuclei are generally round to oval and, while they are described as having a "monocytoid" appearance, the cells resemble monocytes in the volume of cytoplasm and not in terms of nuclear shape.

In animals, marginal zone lymphomas appear to follow a pattern of development over time that *begins with a widening zone of marginal cells encircling the normal mantle cell layer of germinal centers* and visible on low power examination because of the lighter staining characteristics due to the increased amounts of cytoplasm. In hyperplasias and early stages of marginal zone lymphoma, the nuclei are of intermediate-cell type with relatively abundant lightly stained cytoplasm, and cellular boundaries are generally indistinct. In normal benign tissues, cells of the same type can be found individually and in small clusters in the marginal zone region and also lining the inner surface of the subcapsular sinus of lymph nodes. At this stage, the cells generally do not have nucleoli, and nuclei largely resemble those of small benign lymphocytes with increased intranuclear detail because of contrast between densely stained large chromocenters and intervening areas of parachromatin clearing.

The *distinction between marginal zone hyperplasia in node or spleen and marginal zone lymphoma* is largely on the basis on whether or not the expanding areas outside of the germinal centers are neoplastic and becoming confluent, or are benign and remaining as distinct bands, usually two to three times as thick as the normal mantle cell layer. With time, these lesions apparently become more aggressive and the cell type gradually becomes that of a small immunoblastic-type lymphoma with nuclei approximately 1.5 red cells in diameter in histological section, with marked parachromatin clearing and chromatin deposition on the nuclear membrane and with a prominent single central nucleolus (Fig. 2.36E). The remarkable aspect of this lesion is that these cells have a very low mitotic rate and, despite their aggressive appearance, they remain solidly "homed" to the perifollicular regions for up to a year before progression proceeds to a diffuse architecture with obliteration of residual germinal centers.

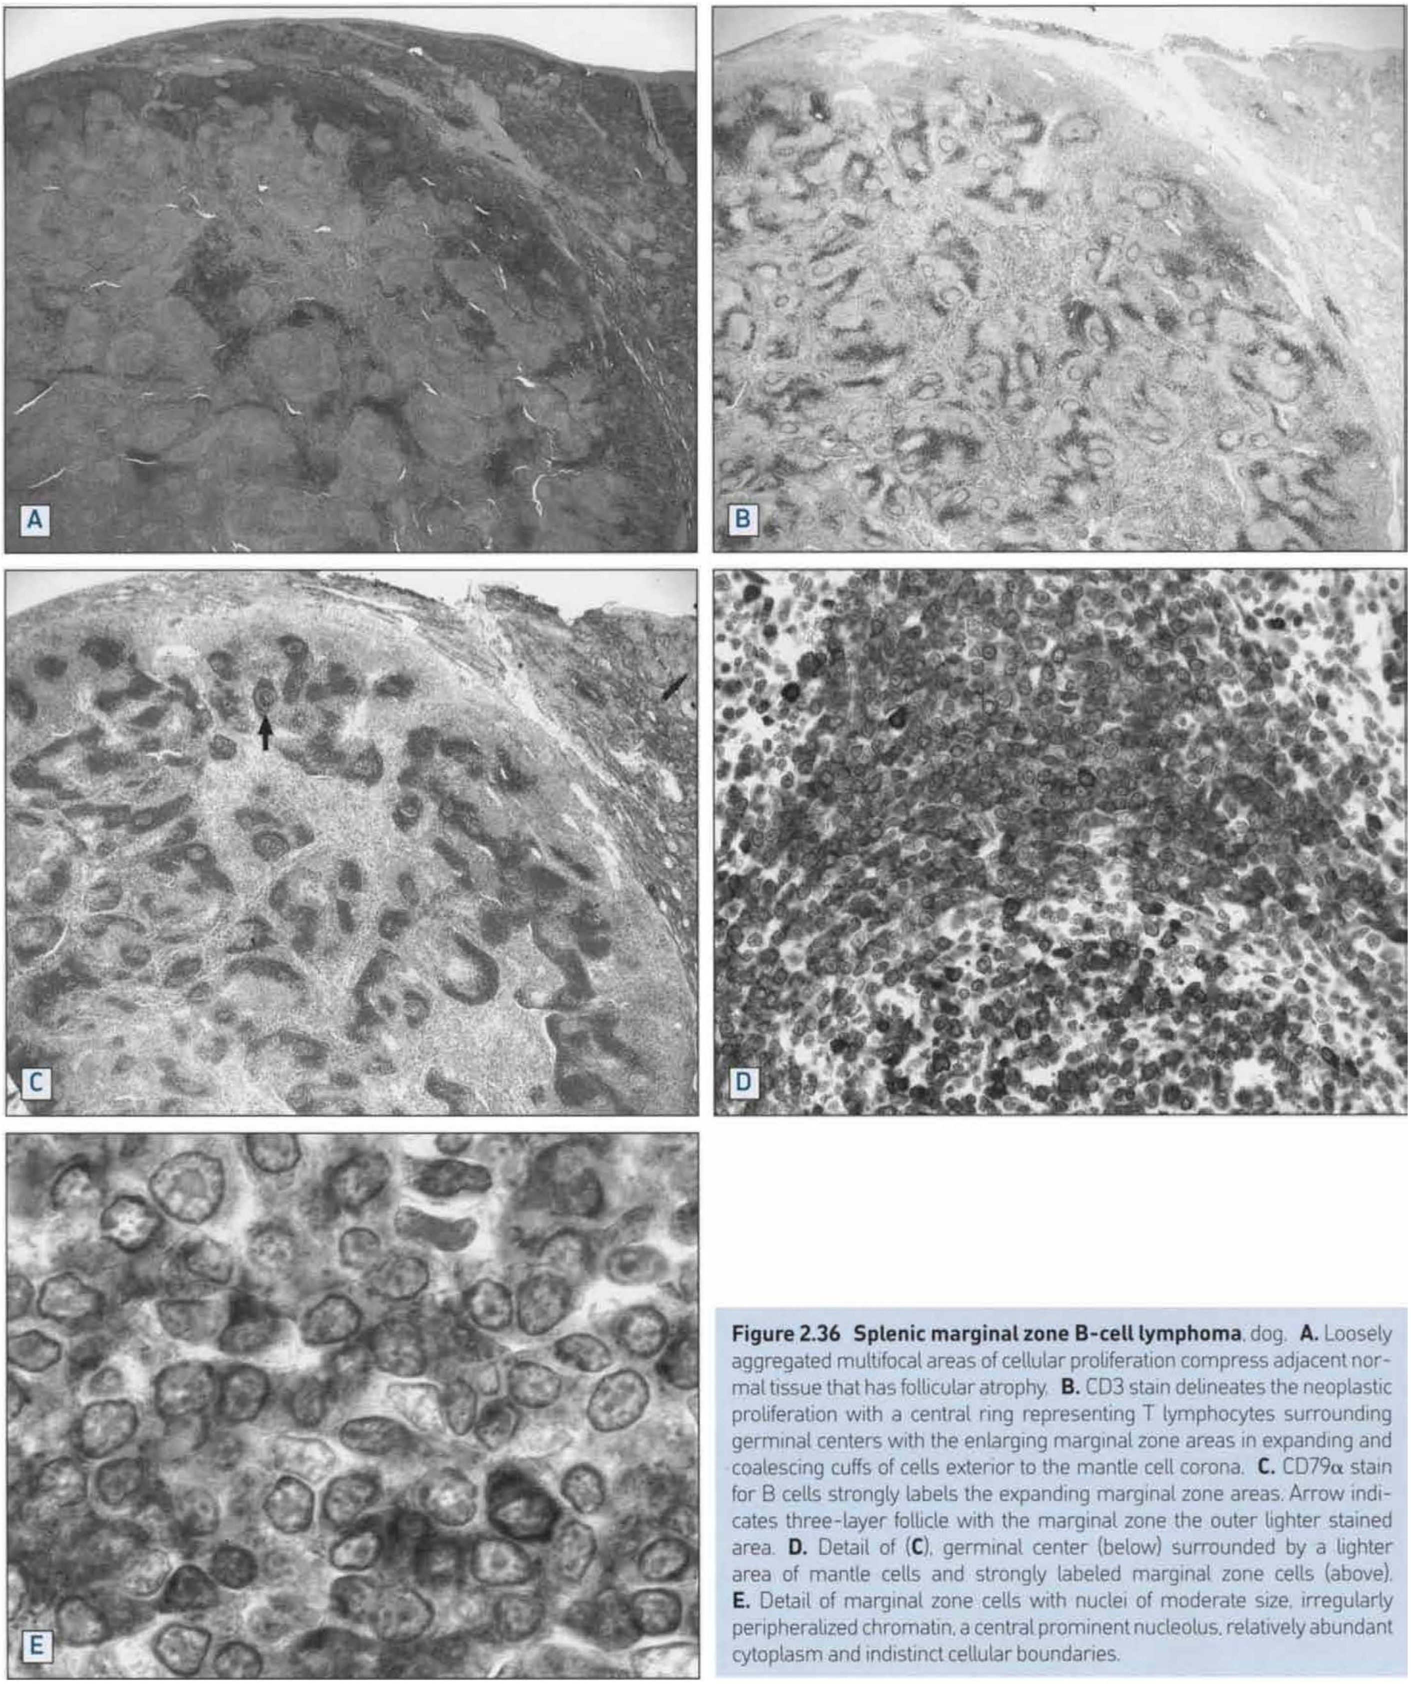

Figure 2.36 Splenic marginal zone B-cell lymphoma, dog. **A.** Loosely aggregated multifocal areas of cellular proliferation compress adjacent normal tissue that has follicular atrophy. **B.** CD3 stain delineates the neoplastic proliferation with a central ring representing T lymphocytes surrounding germinal centers with the enlarging marginal zone areas in expanding and coalescing cuffs of cells exterior to the mantle cell corona. **C.** CD79α stain for B cells strongly labels the expanding marginal zone areas. Arrow indicates three-layer follicle with the marginal zone the outer lighter stained area. **D.** Detail of (**C**), germinal center (below) surrounded by a lighter area of mantle cells and strongly labeled marginal zone cells (above). **E.** Detail of marginal zone cells with nuclei of moderate size, irregularly peripheralized chromatin, a central prominent nucleolus, relatively abundant cytoplasm and indistinct cellular boundaries.

Remarkably, the cells at the early stage of marginal cell lymphoma in spleen or node tend to mark much more lightly with CD79α than do more aggressive-appearing cells with the prominent single central nucleoli.

Marginal zone lymphoma is usually diagnosed in a peripheral node, but in those cases in which the disease appears to arise in the spleen, there is usually involvement of the liver and bone marrow and peripheral nodes at the time of diagnosis. Grossly, the spleen is dry on cut surface and shows miliary expansion of the follicular or white pulp areas. In the early stages of the disease in the spleen, there is a characteristic "bulls-eye" appearance to the splenic follicles due to hypocellularity of the germinal center, which is largely occupied by residual dendritic cells. At this stage, there is still a confluent cuff of small benign mantle cells surrounding the germinal center and inside the outer ring of lighter staining marginal zone cells. With progression, there is thinning and loss of the benign mantle cells with the rim of marginal zone cells remaining evenly centered on the involuting follicle. While it is difficult to determine in a particular case whether the lesion is splenic marginal zone hyperplasia or marginal zone lymphoma, some authors in the human literature confidently state that, if there are three zones in splenic follicles, the lesion is likely to be marginal zone lymphoma. On further progression of the lesion, particularly of lymph nodes, there is collapse of the residual mantle cells into the germinal center which then appears histologically as a focus of small dark cells at the center of an expanding circle of marginal zone cells that continue to be lighter staining because of their increased cytoplasmic volume.

In well-developed marginal zone lymphoma of spleen in the dog, the germinal centers are hypocellular and appear as epithelioid pale areas at the center of the expanding marginal zone. In the process of progressing from the three-ring "bulls-eye" appearance to the collapse of the germinal centers, the dendritic cell areas may become hyalinized or occupied by an amorphous proteinaceous insudation as evidence of progressing failure of the immune response and a kinetic absence of naive but competent B cells able to re-colonize the germinal follicles. The collapse and obliteration of the splenic germinal centers represents an important diagnostic finding that indicates the severity of impairment of the normal immune system and, thus, is less likely to be part of a hyperplastic marginal zone response than of marginal zone lymphoma. All of these changes may progress without marked enlargement of the spleen or impairment of sinus function, although there does appear to be some degree of increased phagocytic activity in splenic sinuses because of prominent hemosiderin-bearing macrophages in the red pulp or sinus areas and by progressive nonresponsive anemia.

In terms of **differential diagnosis**, marginal zone lymphoma of the spleen needs to be differentiated from *other B-cell lymphomas* that are centered on splenic white pulp. A major differential in human pathology is with villous lymphocytes or hairy cell leukemia that may not have a neoplastic counterpart in animals. Marginal zone lymphoma of the spleen is unlikely to be confused with lesions which, while causing lymphoid atrophy, are primarily centered on sinus areas such as the mast cell tumor of the spleen in cats.

Hairy cell leukemia

Hairy cell leukemia (HCL) is currently not recognized in animals. The term "leukemic reticuloendotheliosis" was first used in human medicine in 1958 to describe the entity now called "hairy cell leukemia." In 1964, *Gilmore and Jones described a leukemic disease of cats they termed* "**reticuloendotheliosis**." The disease they described consisted of severe refractory anemia with splenomegaly and the presence of neoplastic cells in the blood, bone marrow, spleen and sinusoids of liver and lymph nodes. The disease occurred in cats 1 to 9 years of age with a strong male predominance. The animals were presented with anorexia, listlessness and weight loss, with most of the animals debilitated and often febrile. Moderate-to-severe enlargement of the spleen was a constant finding. Hematologic changes consisted of severe nonresponsive or poorly responsive anemia with leukocyte counts in ten cats varying from 6–50 × 10^9/L. The cells were considered inconsistent with any lineage definition and were felt to be precursor cells of varying myeloid or even lymphoid lineage. Nuclei were described as large and round, and in illustrations can be determined to be 1.5 to 2 red cells in diameter. The chromatin was described as having a fine woven pattern and nuclei were characterized by a large single nucleolus often eccentric to the nuclear center. The cytoplasm was moderate in amount and eccentrically placed, with a lighter stained area adjacent to the nucleus. The latter finding is suggestive of lymphoid origin and the cells were described as having a variable number of fine azurophilic granules. In illustrations, the cytoplasm is smooth and entire and does not resemble the fine stellate projections characteristic of hairy cell leukemia in humans. Significant pathological findings were limited to the bone marrow, spleen, liver, and lymph nodes, with the spleen dry on cut surface, dark red and with a fine granular appearance that was felt to be indistinct enlargement of splenic follicles. The bone marrow was hypercellular and primarily occupied by invading cells which were not considered clearly neoplastic. Involvement of the spleen was primarily in sinus areas with irregular dilation of sinusoids and relative follicular atrophy. A characteristic feature of hepatic involvement was irregular dilation of hepatic sinusoids which were filled with the invading "reticulum cells." Invading cells also were found in the sinusoids of lymph nodes, and in some cases, were found to have effaced normal nodal architecture.

It is unlikely that these authors were describing a disease comparable to hairy cell leukemia but, with the mention of fine azurophilic granules in the tumor cells, *it is possible that the description is comparable to chronic leukemia of large granular lymphocyte type, or the much less common* $\gamma\delta$ *hepatosplenic T-cell lymphoma of humans and animals.*

A description of hairy cell leukemia as it occurs in humans is presented here in the event that this is a lesion present but as yet undefined in animals. The disease in humans is of young to mature individuals with a 4:1 male predominance. The presenting signs include fatigue and infectious phenomena, with the latter of importance because of the concurrence of neutropenia and immunosuppression. Splenomegaly is almost always present, with hepatomegaly in 40% of cases. Peripheral lymphadenopathy is much less common. Pancytopenia is present in more than one-half of the patients at the time of presentation, along with anemia and thrombocytopenia, often accompanied by bleeding. HCL in humans is almost always accompanied by *monocytopenia* which is considered a useful diagnostic finding. While most patients are leukopenic, 10–20% present with a leukemic picture generally in excess of 10×10^9 lymphocytes/L, of which more than half are hairy cells. The hairy cells may be identified in routinely stained blood films but are most dramatically identified in *phase contrast preparations* of wet mounts of living cells. *In humans, the hairy cells in blood have nuclei slightly larger than red cells with a moderate amount of eccentrically placed cytoplasm that has a villous or shaggy cytoplasmic border.* Significantly, cytoplasmic granules are reported to be occasionally present. Bone marrow is considered essential to the diagnosis and, because the disease is associated with reticulin sclerosis of marrow, a core biopsy is usually required. Most patients have hypercellular marrow with phthisis of normal elements. In sections, the hairy cells appear to have abundant cytoplasm similar to marginal zone cells that cause regular separation of nuclei and a lighter appearance of areas with solid tumor infiltration in histological preparations. The nuclei are described as oval, indented, or bilobed and nucleoli are usually inconspicuous or absent as are mitoses. The cytochemical reaction of hairy cell leukemia is the presence of a *positive cytoplasmic reaction to the tartrate-resistant acid phosphatase (TRAP) test.* Characteristic immunophenotypic features of human hairy cells include features of a middle- to late-stage B cell with little somatic mutation of rearranged immunoglobulin genes, suggesting that the cells have not undergone antigenic selection. Human HCL cells react positively with CD45, the common leukocyte antigen, as well as pan-B-cell antigens including CD19, CD20, CD22, and CD79α. The cells do not express the immunoglobulin-associated membrane antigens CD79b, CD10, and CD21.

The characteristic pathology of HCL is present in the spleen where there is extensive involvement of the red pulp with white pulp atrophy. Histologically, splenic involvement in HCL consists of sheets of cells with bland-appearing nuclei and abundant cytoplasm. In the liver, there is portal and sinusoidal infiltration by the hairy cells that may be associated with reticulin sclerosis. In liver, there is irregular dilation of sinusoids that are lined with the tumor cells, and sinusoidal involvement does not correlate with the level of circulating hairy cells. These irregular dilations of the sinuses mimic peliosis hepatis and are believed to arise because of tumor cell adherence to and subsequent injury to sinusoidal membranes.

Most human cases terminate in septicemia and pneumonia, often due to gram-negative organisms.

The normal counterpart of the hairy cell is unknown, but has been suggested to be the *marginal zone cells surrounding lymphoid follicles* to which they are morphologically similar and like hairy cells are positive for FMC-7 but unlike hairy cells are negative for CD11c. Other considerations are the so-called *monocytoid B cells* found in the sinuses of lymph nodes which, like hairy cells, are CD11c positive but unlike hairy cells do not express CD25. *Marginal zone cells and monocytoid B cells constitute the differential diagnostic considerations in the diagnosis of hairy cell leukemia in histologic sections. In blood, the thin stellate cytoplasmic projections are the major distinguishing feature of HCL.*

Plasma cell myeloma/plasmacytoma

Solitary plasmacytic tumors are largely diseases of the dog, and are rarely seen in the cat. In both species, they appear to be diseases of mature animals with most cases occurring in *animals over eight years of age. Plasmacytomas are considered monoclonal proliferations* in distinction to benign plasma cell hyperplasia, which may be characterized by gammopathy but of the polyclonal type. Benign plasma cell hyperplasias occur in diseases of chronic antigenemia and are seen in various tissues in equine infectious anemia and bovine trypanosomiasis. It is likely that the most marked example of benign plasma cell hyperplasia may occur in canine leishmaniasis, in which as much of 50% of bone marrow cells may be benign polyclonal plasma cells. Thus, *grading systems based on numbers and percentages of plasma cells are prone to error, and the distinction between monoclonal and polyclonal plasma cell proliferations is best based on a combination of cellular atypia and serum electrophoresis.*

Clonal plasmacytic tumors originate in soft tissues or bone and are referred to as **extramedullary plasmacytoma** *in soft tissues* and **solitary osseous plasmacytoma** *if occurring in bone.* The distinction is important, because *the osseous lesion may be expected to progress to a systemic multiple myeloma, whereas extramedullary plasmacytomas, particularly those of skin and the oral cavity, tend to be benign lesions that do not progress after simple excision.* In contrast, plasmacytomas of the esophagus, stomach, intestine and rectal area may be aggressive lesions that may become large locally and metastasize to regional nodes. Less commonly, plasmacytoma may occur in the spleen of the dog and the cat, with those in the dog tending to be focal or multifocal lesions that must be differentiated from nodular hyperplasia or lymphoma, while those in the cat may diffusely involve the sinus areas in a spleen of normal size and without surface irregularities (Fig. 2.37A).

The cytologic and histologic differentiation of benign and aggressive plasmacytoma and myeloma is not a clear-cut decision. In general, *plasmacytoma is characterized by a monotonous proliferation of cells that resemble plasma cells in any other location or site of aggregation* (Fig. 2.37B). Nuclei are round or oval, usually less than 1.5 red cells in diameter, and have densely stained chromatin with prominent chromocenters and lack nucleoli. Cytoplasm is usually abundant, eccentric and with an irregularly prominent Golgi zone. Binucleation of plasma cells occurs in benign plasmacytoma, but is relatively infrequent and mitoses are rare. In contrast, *in aggressive or anaplastic plasmacytoma there*

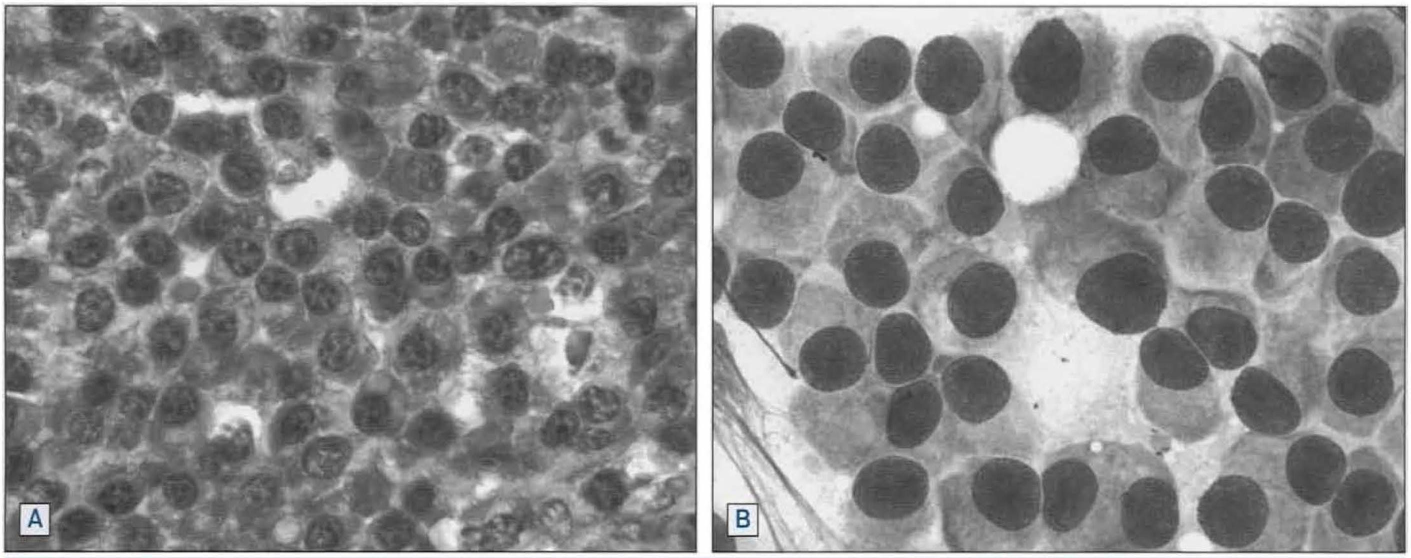

Figure 2.37 Plasmacytoma. A. Solid infiltrations of sinus areas with well-differentiated plasma cells in the spleen of a cat. **B.** Aspirate from subcutaneous mass near the elbow of a dog. Nuclei are round, regular with densely stained chromatin with cribriform pattern and small nucleoli. Cytoplasm is abundant, highly basophilic, and eccentrically placed. (Courtesy of RM Jacobs.)

is quite marked anisokaryosis, which in some cases, may be striking with scattered nuclei 4–5 red cells in diameter. Both aggressive plasmacytomas and myelomas differ from most other hematopoietic neoplasms and most carcinomas in that frankly malignant cells may maintain a lower than normal nuclear to cytoplasmic ratio than their benign counterparts. Thus, in aggressive plasmacytomas, cells with very large nuclei may have abundant cytoplasm. Besides marked anisokaryosis that may be expected to be present in aggressive plasmacytomas, the nuclei are hyperchromatic and characteristically have one or more prominent nucleoli. Binucleation is a frequent occurrence, and trinucleation or even multi-lobated nuclei may be present. In contrast to benign plasmacytoma, mitoses are of relatively frequent occurrence. In the dog, both the benign-appearing plasmacytomas of skin and the anaplastic-appearing lesions of the GI tract tend to be negative with CD79α, whereas plasma cell hyperplasias are strongly positive, a useful diagnostic distinction. All three lesions are strongly positive with vimentin.

Multiple myeloma is a disease of *mature and aged dogs* and is rare in the cat and other domestic species. *Myeloma is characterized by the production of monoclonal immunoglobulin, usually of the IgM type.* The immunoglobulin produced can represent a range of class of immunoglobulin or fragments of the molecule including both light and heavy chains of which the light chain is small enough to be passed through the glomerulus and represents a particular risk for renal failure (*myeloma kidney*). Small-cell lymphomas may also produce macroglobulinemia, known as Waldensdrom's macroglobulinemia in human pathology as noted in small-B-cell lymphomas. Thus, a variety of disorders may occur including dysproteinemia, paraproteinemia, and monoclonal gammopathy. *Plasma cell diseases have a risk of being followed by amyloidosis,* with deposition of a fibrillary protein that accumulates systemically and may cause fatal injury to the heart, liver and kidneys. Amyloidosis may be designated as *primary* when accompanying monoclonal plasma cell proliferation, and *secondary* when accompanying a chronic inflammatory or infectious process. Since monoclonal gammopathy may be present in the absence of localizing signs or focal lytic lesions of bone, the significance of monoclonal gammopathy may not always be clear. Human classifications of these conditions are given a working diagnosis of *monoclonal gammopathy of unknown significance* (MGUS).

The cause of myeloma is unknown. There is increased risk of developing this disease in humans with a background in cosmetology, farming, or employment in the petroleum, wood, leather or asbestos industries. This increased risk is related to exposure to agents such as *pesticides, petroleum products, asbestos, rubber, wood products, plastic, and high-dose gamma irradiation.* An association between myeloma and infection of *Human herpesvirus 8* has been suggested, with the pathogenesis being chronic infection of the marrow dendritic antigen-presenting cells which then over-produce IL-6 that drives plasma cell proliferation. *Long-standing or chronic infection with persistent antigenic stimulation has been considered a predisposing cause of myeloma in humans.* Most myeloma proteins are without specificity for a known antigen. Cases have been documented in which the M component in a canary breeder was related to canary droppings and to horse α-macroglobulin 30 years after passive therapy with equine anti-tetanus serum.

Dogs with myeloma are often presented with lameness, leading to detection of myeloma through aspiration of focal lytic lesions of bone identified radiographically (Fig. 2.38A). Hyperproteinemia in dogs may reach high levels of 80–140 g/L associated with high blood viscosity. These animals may also have a markedly enlarged spleen with focal areas of infarction and sepsis that makes these animals candidates for circulatory shock on even mild anesthesia for purposes of obtaining biopsy specimens. *Hyperviscosity syndrome* may be associated with bleeding tendencies due to inhibition of the large molecular weight clotting proteins by the M component produced by the myeloma cells.

The **diagnosis** *of myeloma is based on the identification of single or multiple foci of malignant cells associated with the production of the gammopathy* (Fig. 2.38B). In contrast to the aggressive plasmacytomas, *myelomas are usually characterized by homogeneity of cell type with the nuclei on histological examination characteristically 1.5 to 2 red cells in diameter.* The chromatin is densely stained with large chromatin aggregations and

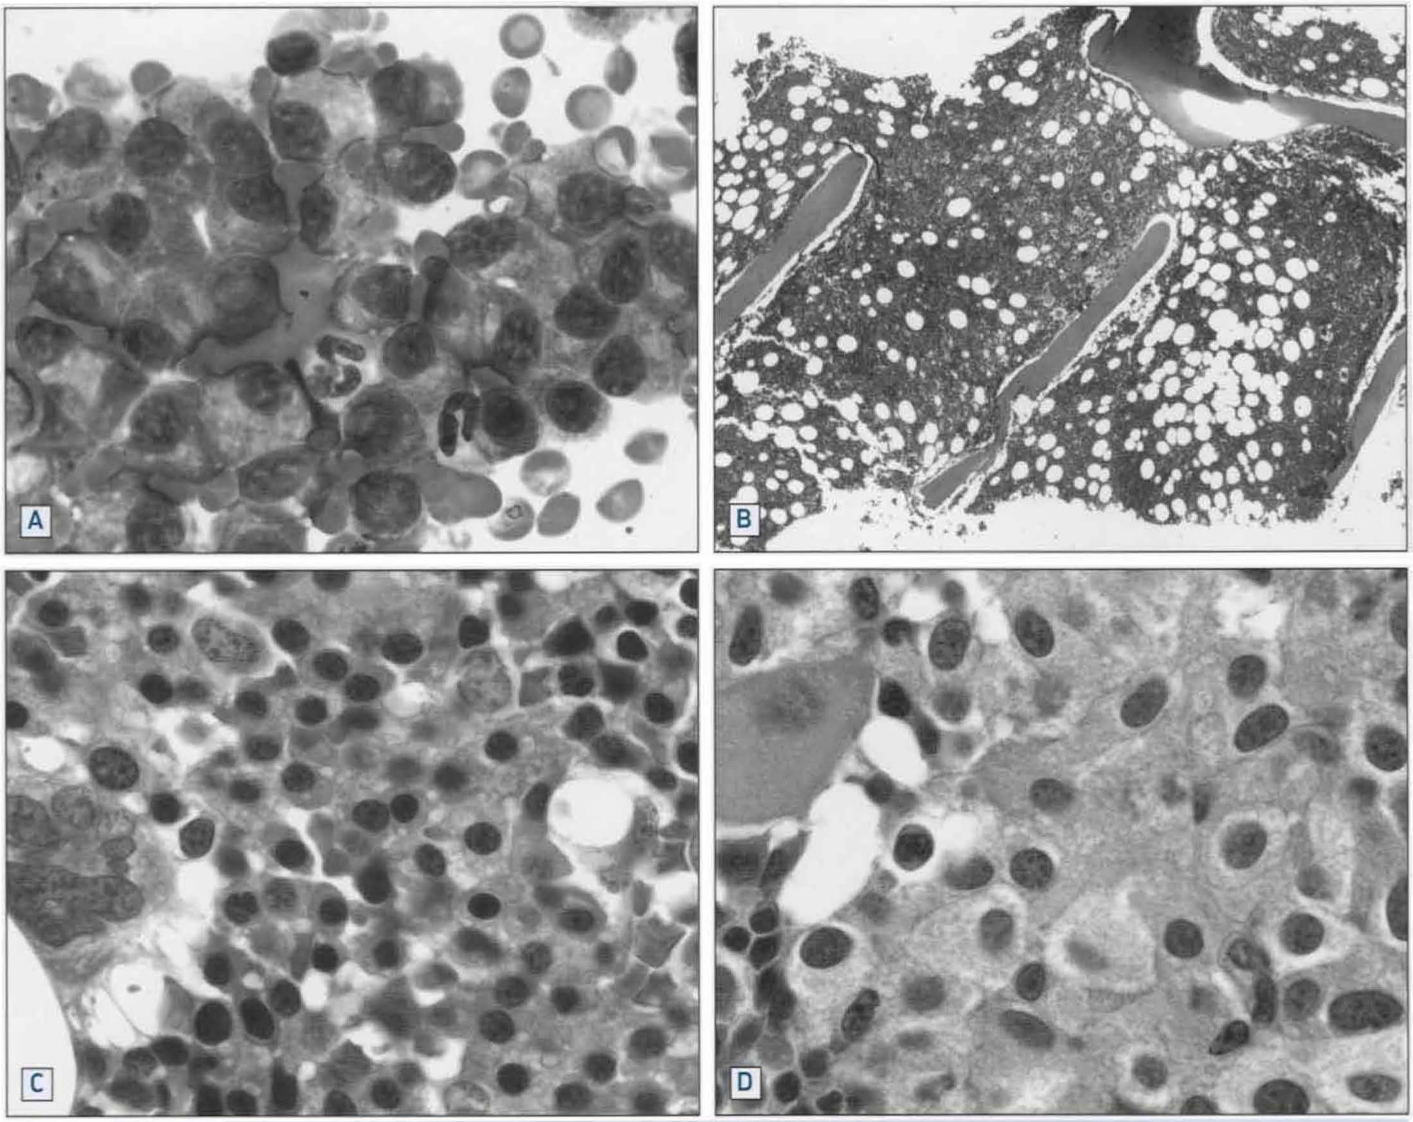

Figure 2.38 **Multiple myeloma**, bone marrow, dog. **A.** Aspirate. Note absence of mitoses in all illustrations.

irregular parachromatin clearing, with most cells having 1–3 relatively small nucleoli. The cytoplasm is usually abundant and stains uniformly pink with H&E (Fig. 2.38C, D); in cytologic preparations the cytoplasmic basophilia varies in intensity and in distribution (Fig 2.38A). Morphologically, foci of myeloma cells tend to grow in solid sheets displacing all normal bone marrow cells and causing lysis of bone that may be associated with *hypercalcemia*. Multiple foci are usually present. The most common sites for myeloma lesions are those areas that remain active in hematopoiesis in the adult animal, including spinal column, ribs, pelvis, calvaria and proximal long bones. Myeloma cells usually stain with strong cytoplasmic positivity for CD79α, and *the main differential is from benign plasmacytosis which usually has less cytoplasmic volume and absent nucleoli*. The mitotic rate of most myelomas is lower than that of normal bone marrow, and while mitoses may be found, they are not frequent. The low proliferative rate of myelomas needs to be considered in planning therapeutic management.

Extranodal marginal zone B-cell lymphoma of MALT type

Extranodal lymphomas are common neoplasms in both humans and animals. Lymphomas of extranodal tissue may be of B- or T-cell type and vary in cell size, proliferative rates and aggressiveness. *Extranodal lymphomas of the mucosal-associated lymphoid tissue (MALT) type are a specific type of extranodal tumor characterized by B-cell phenotype, unique cytomorphology, a unique histological pattern of glandular invasion known as the "lympho-epithelial lesion," and indolent progression as well as being relatively curable by surgery.* Lymphomas involving mucosal surfaces likely occur in all species of animals but are most frequently recognized in *mature cats and dogs*. In the dog, the tissues most commonly involved are the lining of the stomach and the colon. In cats, mucosa in the area of ileocecal junction is a recurring site of MALT-type lymphoma. Besides these sites, virtually every mucosal surface, including salivary glands, oral cavity, thyroid gland, lung, mammary gland and reproductive tissues including uterus, ovary, testes and prostate, may be involved. In many instances, lymphomas in these regions follow prolonged benign lymphoid hyperplasias.

In humans, autoimmune disease of the salivary glands resulting in Sjogren's disease and in the thyroid gland Hashimoto's thyroiditis are examples of autoimmune disease of prolonged duration that may result in MALT lymphoma. Most MALT lymphomas are characterized by a bi-phenotypic or what may appear to be a mixed type of lymphoid reaction as a result of the residuum of benign polymorphous follicular hyperplasia de-differentiating into a focal area of apparent marginal zone-type cell proliferation. The morphology of the marginal zone cells, described under splenic marginal zone B-cell lymphoma, have the same morphology wherever they are prone to occur. In human pathology, the extranodal proliferation of marginal zone cells has been referred to "*monocytoid B-cell lymphoma*." There appear to be some differences between the marginal zone cells of spleen and node and those of mucosal surfaces involved in MALT lymphomas. It is certain that the lymphomas of mucosal surfaces have more heterogeneity of cell type than is observed in the enlarging marginal zone areas around germinal centers in the spleen and lymph node. Cytologically, as previously described, the nuclei of marginal zone lymphomas of nodal sites tend to have round-to-oval nuclei and may have prominent nucleoli. In contrast, monocytoid cells of mucosal surfaces have smaller nuclei, which are frequently indented or folded, and deeply stained chromatin with little internal nuclear detail. The monocytoid cells lack nucleoli and, like the marginal zone B-cell lymphomas, are characterized by a periphery of relatively abundant clear cytoplasm. Non-MALT lymphomas of mucosal surfaces tend to surround the deep glandular structures and, while glands may be isolated by proliferating cells, the neoplastic lymphocytes tend not to bridge the epithelial basement membrane. In contrast, *in MALT lymphomas, the lympho-epithelial lesion is characterized by heavy invasion of neoplastic lymphocytes into the epithelial layer with glandular destruction* (Fig. 2.39A, B).

In animals, as in humans, *it appears that the neoplastic cells in MALT lymphoma are rather tightly "homed" to the site of lymphoma.* Thus, while there may be multifocal sites of neoplastic transformation, particularly in lymphomas of the intestinal tract, the neoplastic cells tend to proliferate in situ and may become large and bulky in situ without spreading beyond the adjacent mesenteric lymph nodes. *This homing characteristic is extremely important to surgical management* since, if the lesion can be identified as a MALT-type lymphoma, there is logic in treating the condition by surgical removal of the affected tissue with an expectation of prolonged postoperative survival. Remarkably, this may occur even with the tumor persisting at the margins of a resected mass at the ileocecal junction in cats.

MALT lymphomas must be distinguished from other enteric lymphomas of large B-cell type, including T-cell-rich B-cell lymphomas and enteric-associated T-cell lymphoma (EATL), which is characterized by heavy infiltration of the surface epithelium with small mature T cells. Phenotypically, the majority of cells in MALT lymphomas will mark with CD79α and, in particular, those cells involved in the lympho-epithelial lesion.

An unusual lesion of mucosal surfaces seen in humans is the *NK/T-cell lymphomas of the sinonasal region*. The disease is common in the East, particularly in China, where many cases are associated with Epstein-Barr viral infection. The growth pattern of the tumor is frequently angiocentric, particularly in T-cell tumors of the γδ type which also occur in this region. Neoplasms with the angiocentric growth pattern are prone to have multifocal areas of ischemic necrosis. A neoplasm with similar growth type and immunophenotype has not been identified in animals.

Nodal marginal zone B-cell lymphoma (+/– monocytoid B cells)

Marginal zone lymphoma (MZL) of lymph nodes is a slowly progressive proliferation of B cells with abundant relatively clear cytoplasm that accumulate in broad and uniform cuffs of cells outside the mantle cell layer of germinal centers. Marginal zone lymphoma is a relatively recently characterized entity in human lymphoma and has not yet been well described in animals. Marginal cell lymphoma in animals *is seen most frequently in mature dogs and cats* and likely occurs in other species. The benign counterpart of cells of marginal zone lymphoma were first described as immature sinus histiocytes which led to them being termed "monocytoid cells" and subsequently with phenotyping as "monocytoid B lymphocytes." In benign states in humans and animals, these cells can be found beneath the subcapsular sinus of nodes and lining the paratrabecular sinuses and occasionally in medullary sinuses in inflammatory states. They may proliferate in certain inflammatory processes in which the nodal architecture is relatively preserved with intact follicles and paracortical T-cell areas. Monocytoid B cells are found in relatively tight bands and clusters in human toxoplasmic lymphadenitis and in AIDS-associated lymphadenopathy. They are also prominent in lymph nodes in patients with infectious mononucleosis, cytomegaloviral lymphadenitis, as well as in nonspecific lymphoid hyperplasias and some granulomatous and purulent lymphadenopathies. Specific infectious disease association has not been defined in animals with a relatively pure proliferation of benign monocytoid B lymphocytes.

The morphology of nodal marginal zone lymphoma is similar to that described for splenic marginal zone lymphoma.

Phenotypically, the cells of human marginal zone lymphoma express B-cell markers with IgM more frequently than IgG. They are negative for IgD, CD5, CD23, CD10, and cyclin D-1, and they are positive for most B-cell markers. *Nodal marginal zone lymphoma is both an architectural and cytologic diagnosis with unique features on low power examination, with proliferation of cells in a continuous band surrounding the mantle cell layer of germinal centers.* Close association of marginal zone cells with reactive follicular hyperplasias suggests that they represent a stage of B-cell differentiation related to follicular proliferation. The follicular marginal zone is that area immediately external to the outside of the mantle cell corona of germinal centers. This area tends to be well developed and relatively easily identified in reactive B-cell areas whether spleen, Peyer's patches or lymph nodes. *In animals, the nodes most often reactive in benign states include those of the submandibular area and mesenteric sites as well as the popliteal lymph nodes of dogs.* In rats and mice, the splenic marginal zone is clearly delineated from the mantle cell corona by a marginal sinus. Within other species, the transition between mantle and marginal zone layers is less well defined.

In histologic section, the cells of *early* marginal cell lymphoma are small cells that resemble centrocytes, having round or oval nuclei or occasionally with shallow indentations and approximately 1.5 red cells in diameter. The chromatin pattern is like that of intermediate lymphomas of small cell type, with large chromocenters and irregular parachromatin clearing, and nucleoli are usually small or absent (Fig. 2.40A–E). Cells have abundant relatively water-clear cytoplasm with indistinct cellular boundaries. This volume of cytoplasm results in relatively even separation of the nuclei and a readily recognizable architectural region on low-power examination due to the lighter staining of the marginal zone cells. Marginal zone lymphomas in animals mark

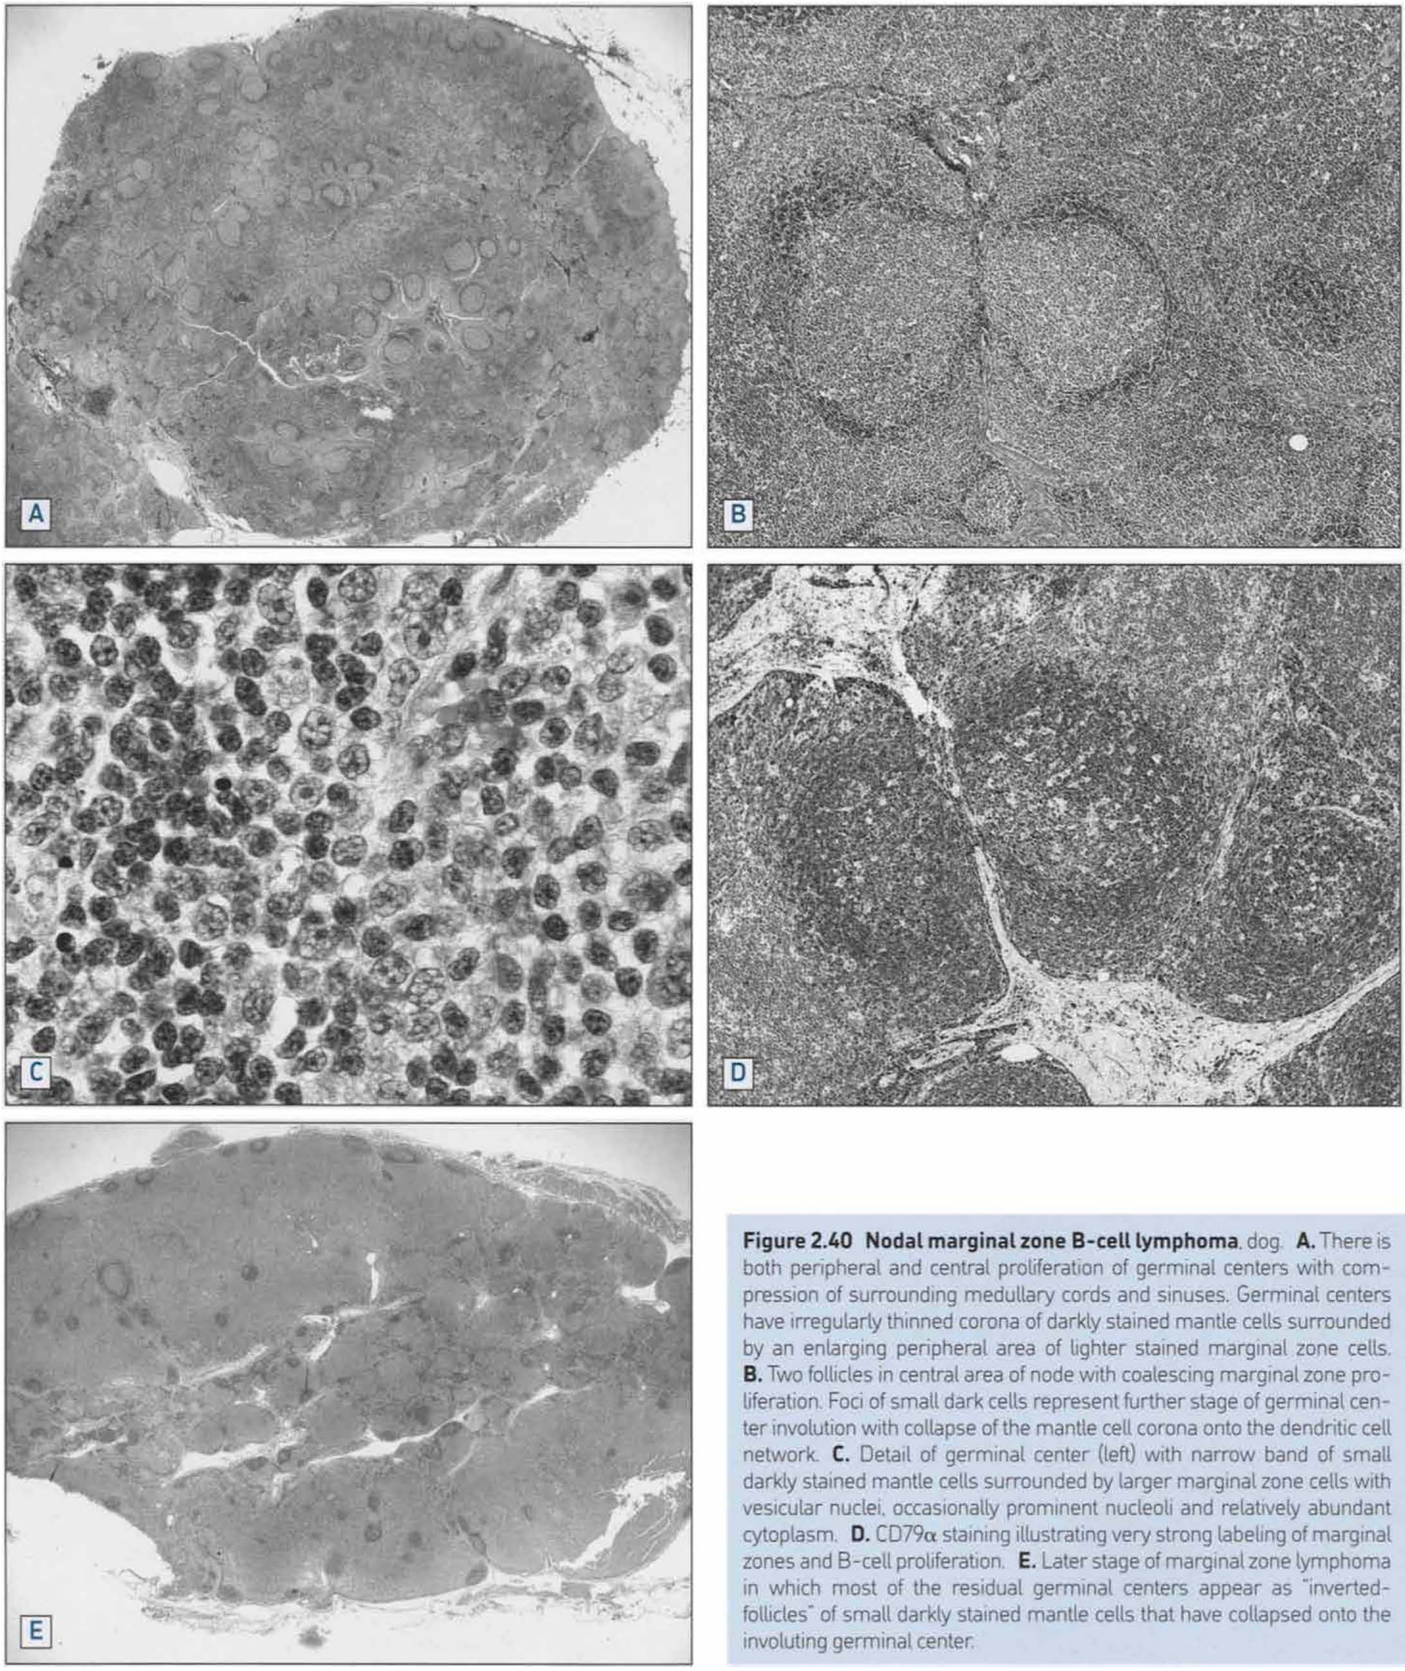

Figure 2.40 Nodal marginal zone B-cell lymphoma, dog. **A.** There is both peripheral and central proliferation of germinal centers with compression of surrounding medullary cords and sinuses. Germinal centers have irregularly thinned corona of darkly stained mantle cells surrounded by an enlarging peripheral area of lighter stained marginal zone cells. **B.** Two follicles in central area of node with coalescing marginal zone proliferation. Foci of small dark cells represent further stage of germinal center involution with collapse of the mantle cell corona onto the dendritic cell network. **C.** Detail of germinal center (left) with narrow band of small darkly stained mantle cells surrounded by larger marginal zone cells with vesicular nuclei, occasionally prominent nucleoli and relatively abundant cytoplasm. **D.** CD79α staining illustrating very strong labeling of marginal zones and B-cell proliferation. **E.** Later stage of marginal zone lymphoma in which most of the residual germinal centers appear as "inverted-follicles" of small darkly stained mantle cells that have collapsed onto the involuting germinal center.

strongly with CD79α and paradoxically, as the tumors become more aggressive, the cytoplasmic marking of the larger cell complement is more intense (Fig. 2.40D). *The differentiation between marginal zone hyperplasia and marginal zone lymphoma is not clear-cut.* In general, marginal zone hyperplasia is not associated with involution of the germinal centers nor diminution of cells of the mantle cell layer. Thus, marginal zone hyperplasia is generally seen with a florid follicular hyperplasia that may extend into the medullary areas of the node. At the level of the individual follicle in mantle cell hyperplasia, the germinal center is usually characterized by numerous tingible body macrophages, and the mantle cell layer is entire and of relatively uniform depth. Characteristically, the hyperplastic marginal zone layer will be 2–3 times the depth of the mantle cell layer, with irregularly sharp and intermingled definition with the surrounding paracortical areas. The postcapillary venules are always excluded from the marginal zone hyperplasias and marginal zone lymphoma. With progression, the marginal zones increase in depth and the mantle cell layers become thinned and discontinuous, whereas the germinal centers themselves show various stages of involution (Fig. 2.40B). With marginal zone lymphoma, the proliferating layers tend to become continuous between adjacent germinal centers and there is progressive involution of germinal centers in which the mantle cells have aggregated into the center of the follicle and appear as a cluster of small dark benign cells surrounded by the enlarging marginal zone lymphoma. This type of change is referred to as an "inverted follicle" (Fig. 2.40B, D). On the basis of very few cases, it appears to take about a year from the stage at which marginal zone lymphoma is apparent until there is a diffuse architecture with effacement of normal node structures and germinal centers are reduced to small clusters of residual mantle cells. Since most cases of nodal marginal zone lymphoma arise in a background of chronic follicular hyperplasia, *the transition from marginal zone hyperplasia to lymphoma is likely a year or more prior to evident neoplasia.* With further progression, there is increased presence of tingible body macrophages throughout the diffuse tumor area along with a shift in nuclear character to the vesicular nucleus that resembles small immunoblastic cells with peripheralized chromatin and a prominent single central nucleolus.

In dogs, marginal zone hyperplasia is characterized by a mixture of mantle cells and marginal zone cells of intermediate size with prominent central nucleoli. In early marginal zone lymphoma, marginal zone cells predominate and become more apparent due to peripheralized chromatin that makes the nucleoli appear more prominent. But in all cases, the mitotic rate of these cells is very low and, in early stages of the disease, marginal zone cells remain tightly homed to the periphery of the mantle cell cuffs. In marginal zone lymphoma in the dog, there is usually thickening of the capsule and the paratrabecular collagen bands, which suggests a prolonged period of reactive hyperplasia prior to the development of marginal zone lymphoma. The peripheral capsule remains intact until late in the involvement of the node when there is nearly complete effacement of normal node architecture, at which time there may be focal colonization of perinodal structures.

Marginal zone lymphoma needs to be differentiated from mantle cell lymphoma and follicular lymphoma.

- Marginal zone hyperplasia and early marginal zone lymphoma are characterized by germinal centers with 3 distinct cell layers including the germinal center, the mantle cell cuff, and the marginal zone layer.
- *Mantle cell lymphoma only has 2 cell layers,* with the germinal center and the mantle cell cuff, which is easily distinguishable from the surrounding heterogeneous cellular population of the paracortex.
- Mantle cell hyperplasia and lymphoma are characterized by proliferation of the mantle cell layer with gradual development of complete and diffuse encirclement of fading germinal centers.
- *Follicular lymphomas are characterized by closely facetted nodular proliferations surrounded by discontinuous residual mantle cell layers.*
- Marginal cell lymphoma in the dog may be confused with a type of *T-zone lymphoma* in which there is an architectural picture very similar to marginal zone lymphoma, but in which the perifollicular cells remain characteristically of small-cell type and mark strongly for CD3 and are CD79α negative.

Follicular lymphoma

Follicular lymphoma (FL) is very predominantly a neoplasm of lymph nodes. Extranodal lymphoid tissue including the spleen and oropharynx (Waldeyer's ring) may be involved as well as bone marrow and liver and, less commonly, nonlymphoid organs such as skin, the ocular adnexa, gastrointestinal tract and female genital tract, the latter particularly in the cow. *Follicular lymphoma is defined as a lymphoma of follicular center B cells (centrocytes and centroblasts) that has at least a partially follicular pattern; FL is a neoplasm of germinal center B cells in which the centrocytes fail to undergo apoptosis.* This failure is due to a chromosomal rearrangement which in humans is shown to be t(14;18) that involves the anti-apoptosis gene *BCL2* that prevents the normal inactivation of this gene.

In order to understand the development and evolution of follicular lymphoma, it is useful to *review the temporal and cellular events in the formation of benign follicles.* Germinal centers tend to form several days after initial immunological stimulation of managerial T cells in the lymph node outer cortex. Typically, the node has a florid diffuse paracortical hyperplasia for a week following antigenic stimulation until follicular centers are formed. This fact has led to confusion in the biopsy of enlarged axillary nodes of children without knowledge of recent vaccination. The *timing of germinal center formation following vaccination* has been studied serially in nonhuman primates following immunization and in dogs given vaccinations into the foot pad with serial biopsy of the popliteal nodes. Similar timing is found in both dogs and primates, with *diffuse hyperplasia for at least a week followed by the development of follicular hyperplasia*. The *secondary response to antigen is much faster* and may result in new follicle formation in about 3–4 days or about one-half the time required for a primary immune response. Each new germinal center is believed to be formed by as few as 3–10 naive B cells to ultimately contain 10 000–15 000 B cells within the ten generations required to form a visible germinal center.

Initial reaction takes place between naive B cells on encountering T-cell-directed antigen in the paracortex, which then proliferate as IgM+ B blast cells. These blast cells migrate to the center of a primary follicle and fill the follicular dendritic cell network 3–7 days after antigen stimulation, forming an enlarging germinal center. The initial proliferation differentiates into Ig-negative large noncleaved follicular center cells, which appear as early as 4 days and accumulate at the dark or deep zone of the germinal center. These centroblastic large cells with vesicular nuclei have 1–3 prominent nucleoli that typically are peripheral and impinge on the nuclear membrane, a feature that is retained in follicular lymphomas. At this stage, the **centroblasts** have only a narrow rim of basophilic cytoplasm. These cells lack surface immunoglobulin and switch off the gene that encodes the BCL2, which permits these cells and their progeny to enter programmed cell death through apoptosis. At this time, the centroblasts express activation-associated antigens involved with recognition and interaction with T cells, including CD23, CD71, CD40 and CD86 as well as CD11a/18 and CD29, which permit their continued adhesion to the follicular dendritic cells. An early event in germinal center formation is the expression of the BCL6 protein with a nuclear zinc-fingered transcription factor essential for germinal center formation, and expressed by centroblasts and their progeny the centrocytes but not by naive or memory B cells, mantle cells or plasma cells. Normal inactive B lymphocytes express high levels of BCL6 messenger RNA but do not transcribe the protein. Subsequently, the mutations of the immunoglobulin and *BCL6* genes serve as markers of cells that have passed through the germinal center. At this early stage of germinal center development, the centroblasts begin a process of somatic mutation of the immunoglobulin gene variable regions, which permits the selection of cells with increasingly avid antibody for the inciting antigen. At the stage of variable chain mutation, the enzyme terminal deoxynucleotidyl transferase (TdT) adds a variable number of nucleotides at the heavy chain joining region thus adding a further area of diversity in the final antigen receptor gene. Examination of individual centroblasts picked from the dark zone of developing germinal centers suggests that there are initially many clones (5–10) of centroblasts with mutation of the variable region of the immunoglobulin gene, which subsequently diminishes to as few as 3 with progressive selection of cells producing the best antibody "fit" and antigen binding.

These early centroblasts and their progeny mature to nondividing smaller cells with irregular nuclei and inconspicuous nucleoli with scant cytoplasm then called **centrocytes**. Morphologically, these are first large and then small-cleaved follicular center cells that then accumulate at the opposite pole or light zone of the germinal center, which is typically oriented toward the subcapsular sinus of lymph nodes or towards the epithelium and source of antigen in Peyer's patches and tonsilar tissue. This peripheral and outer area of the germinal center also contains the highest concentration of follicular dendritic cells. The centrocytes now re-express surface immunoglobulin which has the same variable-diversity-joining (VDJ) gene rearrangement as the parent naive B cell and the centroblasts of the dark zone, but now has an altered antibody-combining site because of the somatic mutations in the immunoglobulin variable region, and in addition the cells may have undergone heavy-chain class switching. This process of somatic mutation uses a high level of intraclonal diversity of antibody-combining sites in a large population of cells derived from only a few precursors. Those centrocytes whose immunoglobulin gene mutations have resulted in decreased rather than increased affinity for antigen are rapidly eliminated by apoptosis. They are evident in the prominent tingible body macrophages of germinal centers. Those centrocytes with the most avid antibody binding are then able to present antigen to T cells in the light zone of the germinal center, and this interaction is thought to activate the T cells to express the CD40 ligand permitting them to bind to the CD40 antigen on the surface of the B cells. This ligation of the B-cell antigen receptor by antigen plus ligation of the CD40 receptor to T cells constitutes a functional "rescue" from death by apoptosis of B cells producing the most efficient antibody. Further interaction between the centrocytes and CD23 expressed on the follicular dendritic cells induces heavy-chain class selection and directs centrocyte differentiation into plasma cells. Alternatively, T cells in the germinal center light zone bearing the ligand for CD40 on the B cells are active in inducing maturation to memory B cells. The combined antigen-receptor ligation and CD40/T-cell ligation switch off BCL6 messenger RNA production and BCL6 protein expression in the B-cell progeny.

With development of polarity in the germinal center into a **dark and light zone**, the mantle cell layer becomes better defined and eccentric with a broader proportion throughout the light zone of the germinal center, usually nearest the subcapsular sinus. Those antigen-specific B cells produced in the germinal center migrate from the follicle to the periphery of the mantle cell layer to form the marginal zone cells. Marginal zone cells retain the slight irregularities of nuclei characteristic of the centrocytes but now develop more abundant pale-staining cytoplasm which gives this area the characteristic lighter appearance on low magnification of conditions of marginal zone hyperplasia or lymphoma. *Marginal zone B cells are thought to be memory B cells, and on exposure to the same antigen in a secondary immune response, the splenic marginal zone B cells migrate to the light zone of the germinal center and become immunoglobulin-positive blast cells and subsequently antigen-specific plasma cells*. There is apparently migration of marginal zone B cells in the spleen and Peyer's patches, indicating that they are not clonally related to an adjacent germinal center. In lymph nodes, in contrast to the spleen and Peyer's patches, the monocytoid B cells in reactive nodes do not appear to have mutated immunoglobulin gene variable regions, suggesting that they have not been through the antigen selection process of the germinal center.

In the current WHO Classification of Follicular Lymphomas, *the term has been defined more precisely to apply only to lymphomas of follicular center cells with a follicular pattern and not to lymphomas of other cellular origin with a nodular or follicular growth pattern*. The current understanding is that follicular lymphoma does not derive from reactive follicular hyperplasia but rather from an altered clone of B cells that mimic the activity of their benign counterparts in forming neoplastic follicles by the same manner as well-differentiated adenocarcinoma forming neoplastic glands. Neoplastic lymphoid follicles are composed of centrocytes and centroblasts in various combinations forming germinal centers that are relatively uniform in size, closely packed, lacking a mantle zone layer and are usually evenly distributed throughout the node obliterating medullary structures and extending outside of the capsule. Variations on this appearance include changes in the size, shape and distribution of follicles with the presence or absence of mantle cell cuffs, involvement of the intrafollicular areas, residual areas of diffuse paracortex and the presence of sclerosis. Within most follicular lymphomas of animals and humans, the follicles tend to be relatively uniform in size and shape and are closely facetted but may have markedly irregular shapes. *In most follicular lymphomas, the follicles themselves appear lighter on low magnification examination than the intrafollicular regions because they are composed of larger more pale-staining lymphocytes than the residual small cells of the intrafollicular region* (Fig. 2.41A–D). In most follicular lymphomas, the follicles are closely packed with obliteration of the paracortical T-zone areas. The intrafollicular area will contain the compressed residual high endothelial venules. There is loss of the cellular heterogeneity of the normal T-zone paracortex with the presence of neoplastic centrocytes and centroblasts similar to those cells within the neoplastic follicles. Chronic benign lymphoid hyperplasia appears to be a risk factor for lymphoma, and lymphomas of both follicular and diffuse types frequently are found in lymph nodes with collagenous thickening of the capsule and medullary raphe. In most cases, sclerosis in nodes is limited to broad collagen bands that are an exaggeration of normal node architecture, but occasionally there may be sclerosis of reticulin fibers and even fine collagen bands that encircle small nodules of lymphocytes. Vascular invasion occurs in both diffuse and nodular lymphomas and is most frequently seen in the larger peripheral veins with marked dilation of the vessel wall and gradual filling of subendothelial space with gradual compression and obliteration of the vascular lumen.

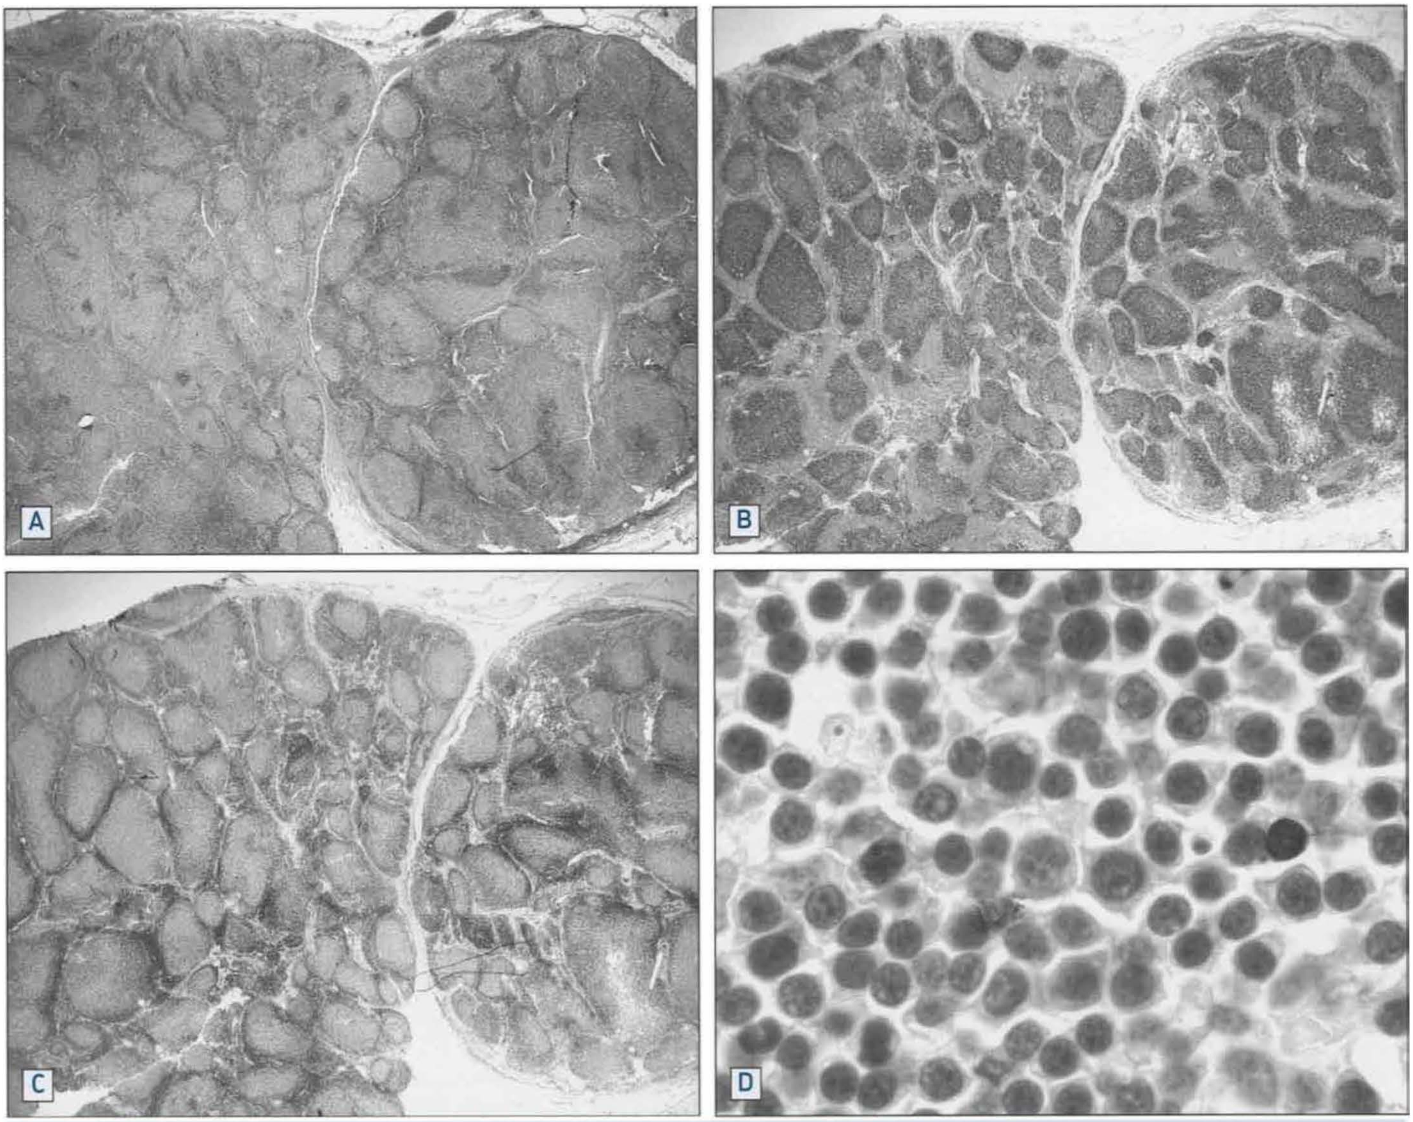

Figure 2.41 Follicular lymphoma, dog. **A.** The peripheral capsule is thin but intact, as is the peripheral sinus. The node is completely occupied by enlarging follicles of various sizes and shapes. Mantle cell coronas are absent from most follicles and of irregular thickness where present. **B.** CD79α stain distinctly marking the proliferative areas as of B-cell type. **C.** CD3 stain for T cells demonstrating marked involution of paracortex. **D.** CD3 stain of follicular center to demonstrate nuclear detail. Centroblasts (center) typically have 1 or more nucleoli impinging on nuclear membrane. Most cells present are centrocyte nuclei of intermediate small lymphocyte type with variation in depth of chromatin staining and absent nucleoli.

In terms of morphology, *the centrocytes and centroblasts of neoplastic follicles are similar or identical to those of benign germinal centers.* Unlike benign centrocytes, those of neoplastic follicles have a greater size variation and may be twice the size of the small-cleaved cells or centrocytes of benign follicles. The nuclei of centrocytes appear irregular or lobulated in histological sections and, while the term "cleaved" has been applied to these cells, the nuclear clefts are largely unseen. Chromatin of the centrocytes is less densely stained than that of benign small lymphocytes and relatively evenly dispersed, and 1 or 2 small nucleoli may be present. Centrocyte cytoplasm is scant, pale, and unobvious in H&E sections. Generally, the neoplastic centrocytes appear more monomorphous than those of normal follicles where there is a migration of cell types corresponding to the light and dark zones of a benign germinal center. The neoplastic centroblasts are much larger than small lymphocytes and may have nuclei 3–4 red cells in diameter. Centroblast nuclei are round or oval and may have shallow irregular indentations or obvious deep clefts. Nuclei are vesicular with peripheralization of chromatin and a clear center, often with some fine chromatin branching and 1–3 relatively prominent nucleoli usually near or impinging on the nuclear membrane (Fig. 2.41D). Centroblasts have a narrow rim of cytoplasm which is relatively inconspicuous on H&E preparations. In comparison to benign germinal centers, the mitotic activity is low within neoplastic nodules and a starry-sky pattern of tingible body macrophages normally seen within benign germinal centers is not present. In general, the number of mitoses in neoplastic follicles increases with the proportion of centroblasts to centrocytes.

In the classification of follicular lymphomas in the Working Formulation, *three types of follicular lymphomas were described based on cell type. These consisted of follicular lymphoma of small-cleaved cell type, follicular mixed small-cleaved and large-cell type, and follicular lymphoma of large-cell type.* The interpretation of survival data at that time was such that follicular small-cleaved and follicular mixed lymphomas were considered low-grade tumors, whereas follicular large cell lymphoma was included in the intermediate-grade neoplasms. Subsequent evaluations have indicated that follicular lymphomas have virtually the same survival pattern when given the same types of therapy. Thus, *follicular lymphomas are currently seen more as a continuum.* Variations in the proportions of centrocytes to centroblasts are their major distinguishing features. Currently, in the REAL and WHO classifications, follicular lymphoma is classed as Grade I if there are 6 or fewer centroblasts per neoplastic follicle, and Grade II if there are 6–15 centroblasts per follicle. Follicles with 15 or more centroblasts are classed as Grade III. These determinations are suggested to be made on the basis of counting centroblasts in 10 to 20 centers at ×400 magnification. Concerns expressed over the size of the field examined, whether using 10 × 18 mm diameter oculars or 10 × 22 mm diameter (wide-field) oculars, appear to require a level of precision in grading which is not borne out by subsequent survival data. *For purposes of diagnoses in animal lymphomas, it appears important to recognize follicular lymphoma as an entity with some indication of the proportions of centroblasts to centrocytes as an overall interpretation.*

Follicular lymphoma in humans express pan-B-cell antigens CD19, CD20, and CD22, as well as surface immunoglobulin with light-chain restriction. Follicular lymphomas in animals regularly mark with CD79α (Fig. 2.41B). CD3-positive T cells generally are restricted to residual cells in the mantle cell cuffs and focal areas of remaining paracortex (Fig. 2.41C). The use of CD79α and CD3 staining may be particularly useful in recognizing follicular lymphoma that is faintly nodular and largely composed of centrocytes or of centroblasts in the process of converting to a more aggressive, diffuse lymphoma. Follicular lymphomas in humans have rearranged immunoglobulin in heavy- and light-chain genes, demonstrable in southern blot analysis or polymerase chain reactions. In addition, like normal germinal center B cells, the follicular lymphomas have somatic mutations in the variable regions of immunoglobulin genes. The principle cytogenetic abnormalities in human follicular lymphoma are translocations involving the long arms of chromosomes 14 and 18, producing t(14;18) (q32;q21) in 75–90% of cases. This translocation between chromosomes 14 and 18 is not associated with a better or worse prognosis than those cases lacking this change. A study of the t(14;18) breakpoint revealed that a portion of DNA which is rearranged in most follicular lymphomas co-migrated with rearranged immunoglobulin genes in southern blots (of DNA). The gene encoded by that segment was given the name ***BCL2***. The protein product of the *BCL2* gene is expressed by resting B and T cells but not by normal germinal center cells, cortical thymocytes, or monocytoid B cells. Over-expression of the *BCL2* apparently provides a survival advantage to B cells by preventing apoptosis. Transgenic mice expressing the *BCL2* gene developed massive follicular lymphoid hyperplasia, with the persistence of a mature B-cell proliferation. Thus, follicular lymphomas are tumors of germinal center B cells in which the maturation from centroblasts to centrocytes fails to terminate in apoptosis because the t(14;18) translocation prevents inactivation of the anti-apoptosis gene *BCL2*.

Follicular lymphomas likely occur in all domestic species, but are most commonly recognized in the cat and cow and less commonly in the dog. Approximately 25–40% of human lymphomas are of follicular type, but fewer than 5% of animal lymphomas are considered follicular, assuming all of them are recognized. It is likely that these diseases are under recognized in animals because their lymphomas tend to be presented at an advanced stage when the architecture has become diffuse with melding of the follicles, and because immunophenotyping is not routinely done that tends to show the outline of the B-cell areas by residual T cells. Follicular lymphomas are indolent tumors that may reach quite large size in a single node in both the cat and dog. In about a third of human cases, follicular lymphoma will convert to a large-cell lymphoma of diffuse type with a more rapid subsequent clinical course that is usually refractory to treatment. Less information is available on the outcome of follicular lymphomas in animals, but it is likely that they are similar in becoming more aggressive with time. In humans, follicular lymphoma is a disease of adults generally older than 50 years. *In dogs, most cases of follicular lymphoma have the Grade III type*, with a high proportion of centroblasts, and the disease occurs in animals as young as 2 years but most occur in animals 10 years of age or older. In cats, the age distribution is much more variable with follicular lymphoma occurring in animals less than 2 years of age and as old as 22 years. Cats also appear to have more variability in grade, with the follicular mixed or Grade II lesion most common. In a large series of cat lymphomas derived from a number of contributing institutions, follicular lymphomas were less than 1% of the population, which suggests that follicular lymphoma was likely selected against, possibly because they were considered hyperplasia.

The main **differential diagnosis** *for follicular lymphoma is benign follicular hyperplasia.* Follicular hyperplasia usually has more variation in follicle size, with retention of the mantle cell cuff around each germinal center, and while the medullary structures may be compressed, there is not obliteration of the medullary cords and sinuses. *A major factor in differentiating follicular lymphoma from follicular hyperplasia is the presence of polarity in germinal centers of benign reactions and its absence in the neoplastic counterpart.* Polarity is best assessed near the peripheral capsule where orientation of the light and dark zones to the source of antigen can be more confidently assessed.

Mantle cell lymphoma

Mantle cell lymphoma (MCL) is an aggressive small-cell lymphoma of B-cell type. The normal cell counterpart of mantle cell lymphoma appears to be naive B lymphocytes that home to and reside within primary lymphoid follicles and the mantle cell layers of secondary follicles. Cytologically, the cells of mantle cell lymphoma are slightly larger than their benign counterparts of the mantle cell cuff normally found around germinal centers. The nuclei tend to be round with shallow indentations, or more irregular and deeply indented. The nuclei are of "intermediate" type, slighter larger than 1.5 times the diameter of a red cell, with densely stained chromatin, incomplete parachromatin clearing, and inconspicuous or absent nucleoli. They have minimal cytoplasm, which is pale staining in H&E preparations, but of sufficient volume so that nuclei tend to be narrowly separated from each other. The early stage of mantle cell lymphoma is characterized by a reduction in size of the germinal centers, which have reduced cellular density and often display a background of bare follicular dendritic cells. The surrounding mantle cell cuffs are irregularly thickened and advancing in a discontinuous pattern into the surrounding paracortex. With progression of the disease, there is fusion of the proliferative areas between adjacent germinal centers, and on low-power examination, the cortex of the node is filled with small dark-staining cells in which the residual germinal centers appears as much lighter hypocellular areas. Because the tumor cells grow out of the mantle cell layers, there is never a three-layer appearance, as is the case with retention of the mantle cell layer around the germinal center in an expanding marginal zone lesion. Mantle cell lymphomas have been described as having a "blastoid" variant where the enlarging cuffs of cells have more of a vesicular nucleus with the irregular presence of small nucleoli. This variant has a tendency to become leukemic and appears to have a counterpart in animals, particularly dogs.

Mantle cell lymphoma may occur in the spleen, particularly in dogs, as focal or multifocal lesions within an expanding nodule of 1–2 cm in diameter (Fig. 2.42A–E). The mantle cell proliferations appear eccentric to a small arteriole, which suggests they may have arisen around an obsolescent germinal center (Fig. 2.42D). These proliferations appear as small, darkly stained masses on low-power magnification, which are separated from lighter stained areas that are more like the paracortical area of lymph nodes rather than splenic sinuses, and which are completely displaced to the periphery of the enlarging mass (Fig. 2.42A–C). Bone marrow is usually not involved, but involvement of the spleen usually coincides with involvement of the liver.

In animals, the MCL mark with variable intensity with CD79α (Fig. 2.42B) and strongly with BLA-36. They are routinely negative for CD3, but the use of that stain helps to delineate the areas of mantle cell proliferation in both the spleen and node (Fig. 2.42C,D). In humans, mantle cell lymphomas have a monoclonal B-cell phenotype, usually bearing surface IgM, with most cases expressing monoclonal lambda light chain. In early stages of mantle cell lymphoma, the cells within the remaining germinal centers are polyclonal and benign. Neoplastic mantle cells in humans stain with pan-B-cell markers including CD19, CD2, CD22 and CD24 and the histocompatibility antigen HLA-DR. There are negative for CD23, but typically stain for the T-cell antigen CD5 and express bcl-2 and cyclin D1. The characteristic cytogenetic abnormality in human MCL is a reciprocal translocation t(11;14) (q13;q32).

Mantle cell lymphoma is a relatively rare tumor of dogs and is apparently even more unusual in cats. It would be expected to occur in the spectrum of B-cell lymphomas in other animals. In dogs, mantle cell lymphoma appears to occur primarily in animals 10 or more years of age, and may be more common in males than females. In humans, the median age of mantle cell lymphoma is approximately 60 years, with a male predominance. If mantle cell lymphoma is a tumor of maturity onset in animals, then logically it would likely only be recognized in cats, dogs, and horses and possibly some exotic species.

Mantle cell lymphoma must be differentiated from other small cell lymphomas of similar cell type. The **diagnosis** of mantle cell lymphoma is *very predominantly on pattern recognition* on low-power examination of a lesion in the early stages of development characterized by irregular thickening of the mantle cell layers around involuting germinal centers. Mantle cell hyperplasia does not appear to occur as a component of follicular hyperplasia and, therefore, the recognition of proliferation within the mantle cell layer in the node or spleen with follicular involution is the key to recognition of MCL.

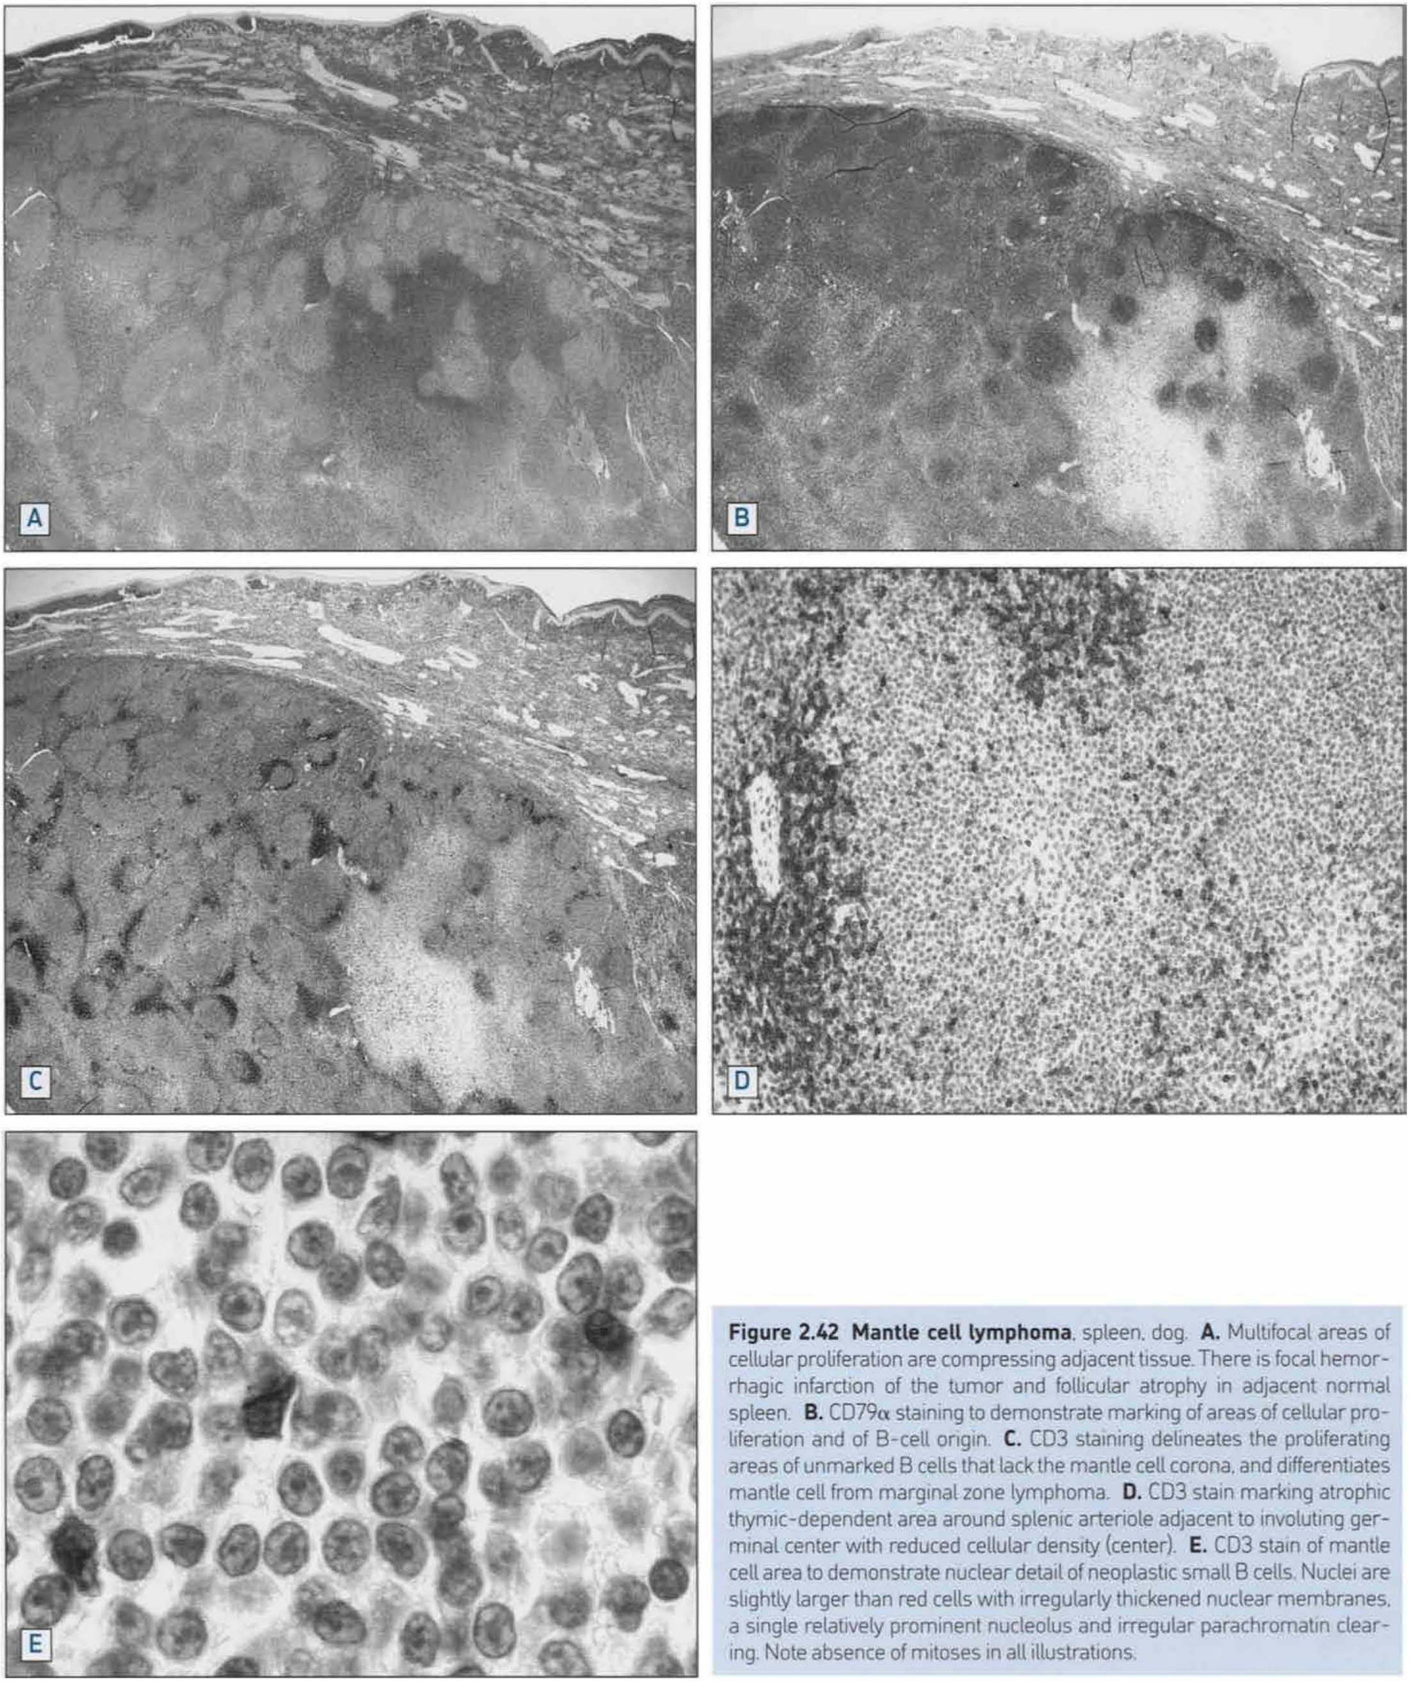

Figure 2.42 Mantle cell lymphoma, spleen, dog. **A.** Multifocal areas of cellular proliferation are compressing adjacent tissue. There is focal hemorrhagic infarction of the tumor and follicular atrophy in adjacent normal spleen. **B.** CD79α staining to demonstrate marking of areas of cellular proliferation and of B-cell origin. **C.** CD3 staining delineates the proliferating areas of unmarked B cells that lack the mantle cell corona, and differentiates mantle cell from marginal zone lymphoma. **D.** CD3 stain marking atrophic thymic-dependent area around splenic arteriole adjacent to involuting germinal center with reduced cellular density (center). **E.** CD3 stain of mantle cell area to demonstrate nuclear detail of neoplastic small B cells. Nuclei are slightly larger than red cells with irregularly thickened nuclear membranes, a single relatively prominent nucleolus and irregular parachromatin clearing. Note absence of mitoses in all illustrations.

Diffuse large B-cell lymphoma

Lymphomas of diffuse architecture composed of large B cells constitute a very broad spectrum of lesions in both humans and animals. *Large-cell lymphomas that are presumptively of B-cell type are the most commonly occurring tumors in the cow, cat, horse and pig.* Two-thirds of the lymphomas in cattle are of the large B-cell type, about half of which are associated with *Bovine leukemia virus* infection and tend to have more variation in nuclear shape, most commonly sharp nuclear folds which has been referred to as the *diffuse large cleaved-cell type*. Twenty percent or more of the lymphomas of the dog are of the diffuse large B-cell type, while in the cat, approximately half of the lymphoid tumors are the large diffuse types including centroblastic, immunoblastic and large cleaved-cell types. The horse is unique in having a frequent association between a large B-cell lymphoma of the T-cell/histiocyte-rich type and multiple subcutaneous neoplasms. Finally, approximately two-thirds of the lymphomas of pigs are of the diffuse large-cell type, which are presumed to be of B-cell lineage.

In humans, the diffuse large B-cell lymphomas (DLBCL) represent as many as 40% of non-Hodgkin lymphoma cases, which are characterized by an aggressive natural history but usually have a good response to therapy with a complete remission rate in the 70–80% range and long-term disease-free survival of nearly 50%. Human large B-cell lymphomas usually occur in lymph nodes or in extranodal sites, of which those most frequently involved include the bone, skin, thyroid, gastrointestinal tract, and lung. *The DLBCLs are morphologically heterogeneous*, which has complicated classification for both humans and animals. Since the reproducibility rate of subtyping these lymphomas in human studies has been low, the European/American lymphoma (REAL) and revised WHO classifications have grouped the large B-cell lymphomas into a single category with description of a number of morphological variants and major subtypes.

A number of molecular genetic and immunophenotypic markers are employed in the characterization of human large B-cell lymphoma. In contrast to the enormous diversity in immunoglobulin gene rearrangements present in reactive B lymphocytes, *each neoplastic cell in a B-cell lymphoma has identically rearranged immunoglobulin genes, is derived from a single transformed B cell, and constitutes a monoclonal B-cell population.* Under normal circumstances, the naive B lymphocytes leave the bone marrow following successful immunoglobulin gene rearrangement, and in the peripheral B-cell pool, on encounter with antigen, their antibody may be modified by somatic hypermutation and class-switch recombination to provide an antibody with more avid binding to a particular antigen. This process of somatic hypermutation is apparently restricted to B-cell proliferation within the specific micro-environment of a lymphoid germinal center. Thus, the presence in a B-cell clone of somatically mutated immunoglobulin gene variable region constitutes the hallmark of germinal center B cells and their subsequent progeny, which may become either long-lived memory cells or plasma cells. Examination of the rearranged variable region genes of B-cell lymphomas by sequence analysis has become a useful tool by which to define the maturational stage at which neoplastic transformation has occurred and thus to assign the neoplastic clone to a cell type corresponding to their normal benign counterparts. The conclusions of these studies are that *the DLBCLs are, as a group, derived from antigen-experienced B cells that have participated in a germinal center reaction.*

Cytogenetic studies of B-cell lymphomas have identified a number of translocations including t(3;14) (q27;q32) as well as t(14;18) and t(8;14). The chromosomal translocation involving 3q27 involves a region of the immunoglobulin heavy chain gene. Cloning of the DNA from a novel gene of this region identified the *BCL6 (B-cell leukemia lymphoma-6) gene* which has a product apparently active in DNA binding and transcriptional regulation. High levels of expression of this protein have been found in a number of lymphoma subtypes. In gene knock-out mice with biallelically disrupted *BCL6* genes, the animals display normal B- and T-cell lymphocyte counts but completely fail to form germinal centers on exposure to T-cell dependent antigens. The animals suffer a high incidence of infectious diseases and inflammatory processes. It is concluded that *BCL6* is required for germinal center formation and normal antigen-dependent immune responses.

The t(14;18) (q32;q21) translocation characteristically found in follicular lymphomas places the *BCL2* gene into juxtaposition with a joining segment for the immunoglobulin heavy chain gene. Despite the mature phenotypes of the follicular lymphomas bearing this translocation, the change appears to occur at an early pre-B-cell stage of immune-differentiation. The t(14;18) translocation involving the *BCL-2* gene leads to over-expression of the BCL2 protein product by placing the *BCL2* proto-oncogene under the constitutive activation of the immunoglobulin gene IgH promoter. The resulting BCL2 fusion protein is located in the mitochondrial inner membranes and functions as an anti-apoptotic protein inhibiting cellular programmed death. This BCL2 protein over-expression occurs in up to 80% of DLBCLs with the differences between the large B-cell lymphomas and the follicular lymphomas suggesting that other changes must be responsible for their differentiation. The third translocation, t(8;14) (q24;q32), identified in diffuse large B-cell lymphomas involves the *MYC* oncogene located on chromosome 8 at band q 24, which is located to the IgH locus at 14q32. This defect has been reported in the great majority of Burkitt type lymphomas and is recognized in that all proliferating tissues express one member of the *MYC* family which is then downregulated when the cells reach terminal differentiation, which in the case of lymphocytes constitutes becoming long-lived memory cells in permanent G_0 resting phase. Transfection studies have shown that constitutive expression of *MYC* impedes inducible differentiation, whereas inactivation of *MYC* by antisense constructs permits the induction of cell differentiation. Thus, the expression of the *MYC* gene appears closely linked to the check-point decision between further proliferation and differentiation in lymphoid tissues.

Morphologic variants of diffuse large B-cell lymphomas

Centroblastic variant

Diffuse large B-cell lymphomas of this type have morphologic features of the centroblast found in benign reactive germinal centers. These cells have medium-to-large, round-to-oval nuclei 1.5–2 red cells in diameter with vesicular nuclei, finely branched and peripheralized chromatin, and 2–4 nucleoli often impinging or bound to the nuclear membranes (Fig. 2.43). These cells are characterized by a very narrow boundary of moderately basophilic cytoplasm. Most of the cells in diffuse lymphomas of the centroblastic type have morphology as just described, but all have a certain proportion of cells with single central nucleolus known as *immunoblasts*. In addition, a third cell type may be present in which the nuclei are multi-lobated and polymorphic but retain the characteristic central nucleolus. Thus, as in the classification of large cell lymphomas by the Working Formulation, *the pathologist is faced with the decision of arbitrarily deciding which cell population is dominant among these various cell types.*

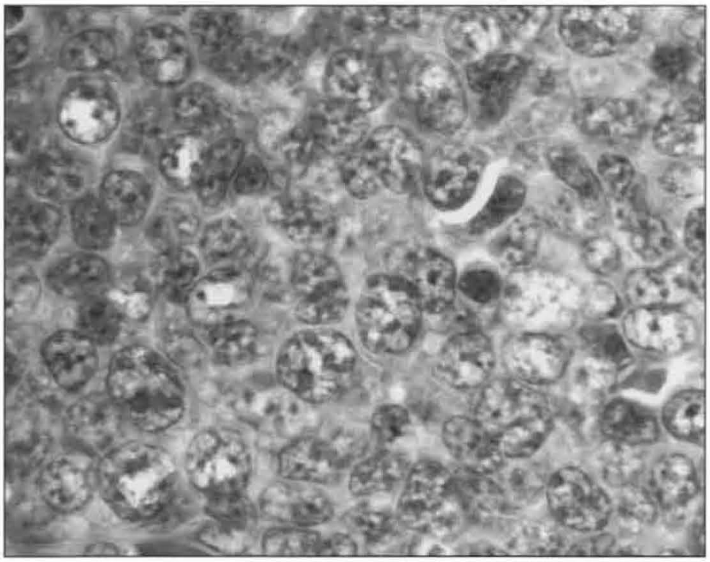

Figure 2.43 Diffuse large B-cell lymphoma, centroblastic variant, lymph node, dog. Nuclei are large (2 to 2.5 red cells in diameter) with small chromocenters, prominent parachromatin clearing and multiple small but prominent nucleoli usually adjacent to nuclear membranes. The neoplastic cells are caricatures of their counterpart in benign germinal centers.

Immunoblastic variant

By definition, more than 90% of the cells of this variant have a prominent single central nucleolus and, in contrast to the centroblastic large cell lymphomas, *the immunoblastic lymphomas may have more abundant cytoplasm with increased basophilia* (Fig. 2.44). Lymphomas of this type are felt to be relatively rare in human pathology but are *common in the dog and cat,* where a quarter to a third of lymphomas may be of this type, but are relatively rare in cattle, and constitute 5 to 10% of the lymphomas seen in the pig and horse. In animals, diffuse large B-cell lymphomas of the centroblastic and immunoblastic variants mark positively with CD79α and are negative for CD3. The human large B-cell lymphomas of this type mark with various pan-B-cell markers, including CD19, CD20, CD22, and CD79α, with surface immunoglobulins present in most cases with IgM followed by IgG and IgA in terms of frequency of immunoglobulin class types.

T-cell-rich/histiocyte-rich variant

One of the more intriguing variants of diffuse large B-cell lymphoma is the T-cell-rich variant in which *the malignant cells may constitute less than 25% of the tumor mass and may be as little as 5%.* Initial descriptions of the tumor credited the predominant T-cell component as a beneficial host response given the relatively indolent course of tumors of this type. The T-cell-rich/histiocyte-rich variant of B-cell lymphoma was known as the diffuse mixed cell lymphoma in the Working Formulation and was considered of intermediate grade in terms of its propensity for aggressive behavior. *It is currently felt that a*

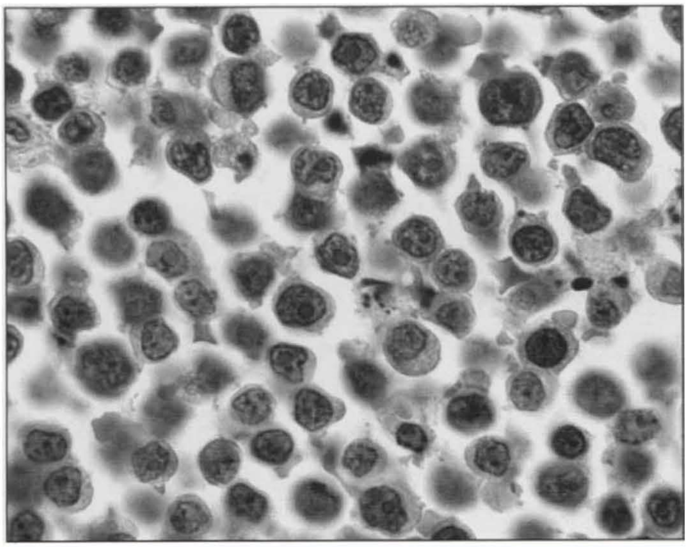

Figure 2.44 Diffuse large B-cell lymphoma, immunoblastic variant, lymph node, dog. The nuclei of immunoblastic lymphoma may be smaller or larger than those of the centroblastic variant and typically are round-to-oval with irregular thickening of nuclear membranes, irregular parachromatin clearing and prominent, usually single, central nucleoli. Cytoplasm is usually moderate-to-abundant and deeply stained.

number of entities may be present within the current definition of the T-cell-rich/histiocyte-rich variant of large B-cell lymphoma. The general criteria proposed for diagnosis of this lesion in humans include the following:

1. A diffuse growth pattern throughout the entire specimen on H&E-stained preparations.
2. Large neoplastic B cells with a highly variant morphology occurring singly constitute less than 10% of the total cell population and may occasionally show nodular grouping.
3. Other cells in the lesion are primarily benign T cells and histiocytes.
4. The clonality of the neoplastic B cells can be demonstrated by immunohistologic and molecular analyses.
5. While sharing features with lymphocyte-predominant Hodgkin lymphoma, the T-cell-rich B-cell lymphoma is usually associated with advanced clinical stage at presentation, and indolent behavior.

These criteria apply equally well to these neoplasms as they occur in animals, with the addition that in animals the lesions are characterized by fine reticulin sclerosis that is a highly consistent finding in all species. This characteristic of the T-cell-rich B-cell lymphomas is immediately apparent on low magnification examination of lymphomas of this type because they are completely cohesive and lack any architectural breaks in the tissue that are frequently seen in other lymphomas with a more friable architecture. Despite their apparent frequency, fibroblasts within these neoplasms are inconspicuous on histological examination, with the oval vesicular nuclei of moderate size relatively unapparent in the mixture of lymphocyte types. On specific staining with antibody against collagen type III or silver stain for reticulin, the background connective tissue is immediately apparent. Lymphomas of the T-cell-rich/histiocyte-rich large B-cell lymphoma are the characteristic type of subcutaneous lymphoma of the horse (Fig. 2.45A–D), which may be presented with literally of hundreds of small subcutaneous discoid masses 1–2 cm in diameter and up to 2 cm in depth. These proliferations are entirely subcutaneous and do not involve the skin or underlying musculature until they become very large, which may occasionally occur with single tumors weighing 4–6 kg. Tumors of this type are infrequently seen in the cow and dog, but constitute about 7% of lymphomas seen in the cat, and more than a third of cases in the horse.

In animals, T-cell-rich/histiocyte-rich B-cell lymphomas have a normal reaction for the benign T cells with CD3 and variable but consistent marking of the atypical large B cells with CD79α (Fig. 2.45D). The histiocyte population of these tumors has not been a matter of recognition in veterinary pathology, and specific staining to demonstrate their relative frequency has yet to be carried out. In human lesions, the T cells are predominantly CD4-positive while CD8-positive cells are present. The large atypical cells in human tissues mark for CD20 and CD45a as well as CD79α and other B-cell markers. An unusual lymphoma of cats of T-cell rich large B-cell type (Fig. 2.46A–E) has similarities to, and is described with, human Hodgkin lymphoma.

Lymphomatoid granulomatosis variant

Lymphomatoid granulomatosis (LYG) is principally a disease of humans and dogs. A form of the disease may rarely occur in cats but has not been identified as part of this morphologic variant. *LYG was defined in humans as an angiocentric and angioinvasive lymphoproliferative disease that principally occurred in lung, but also occurred in other sites including skin, kidney, liver, and central nervous system.* The diagnosis of LYG in humans was based on recognition of *characteristic histologic findings of polymorphic lymphoid masses composed of small lymphocytes, plasma cells,*

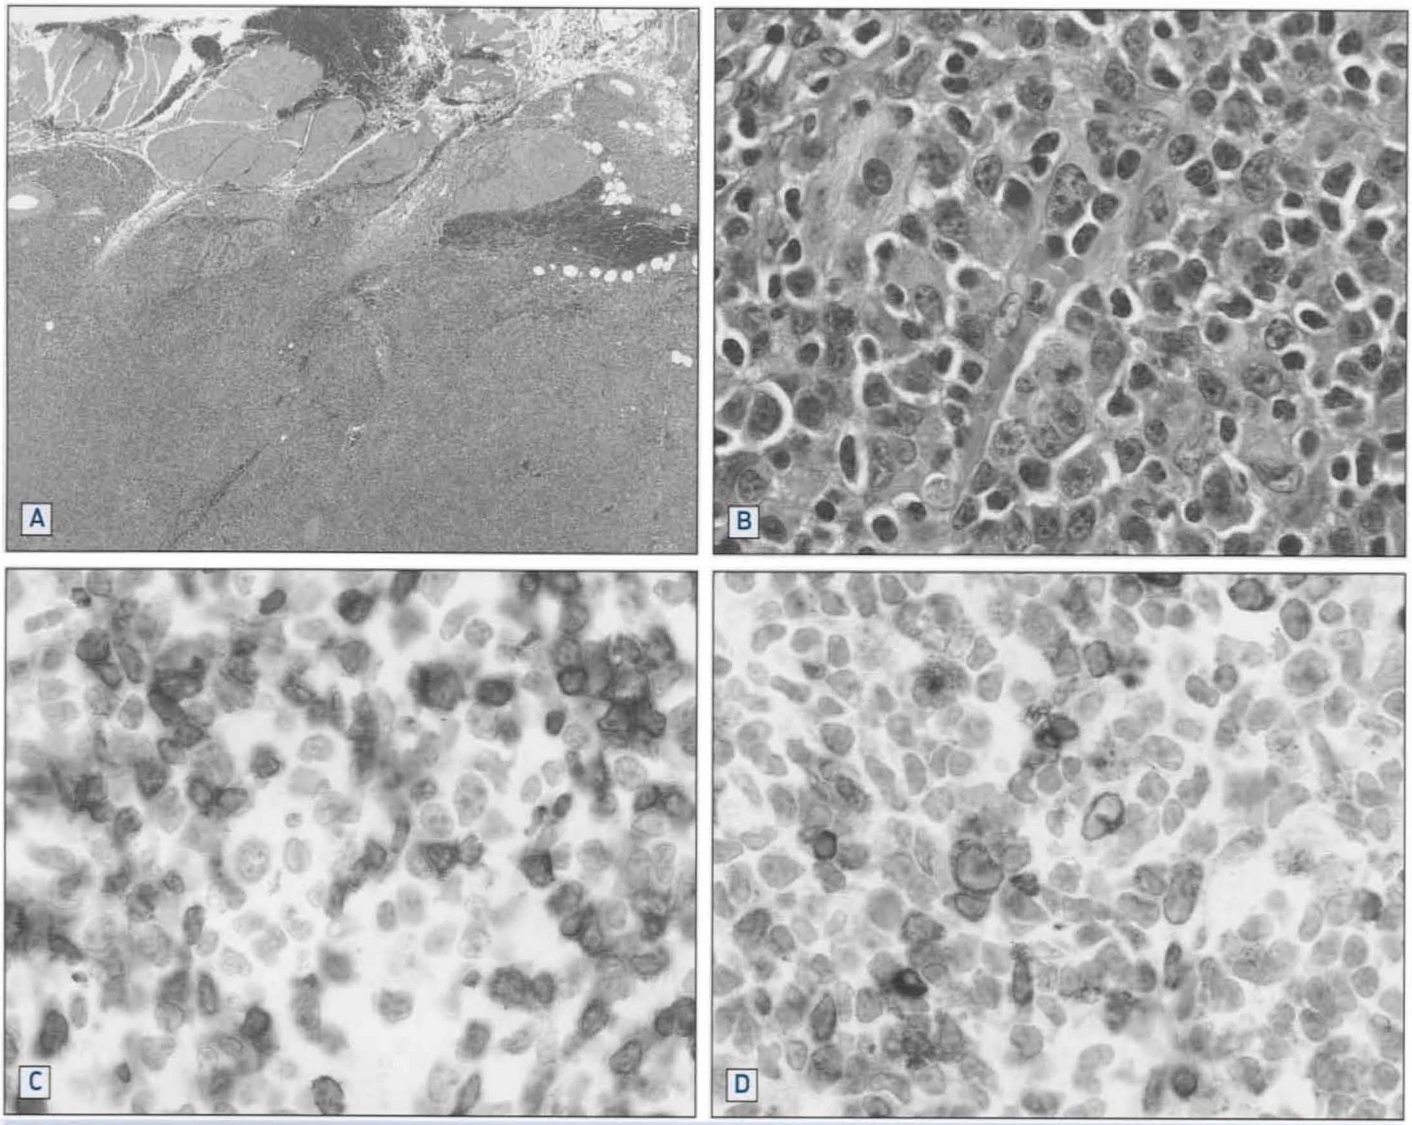

Figure 2.45 Diffuse large B-cell lymphoma, T-cell-rich/histiocyte-rich variant, subcutaneous mass, equine. **A.** The tumor has a solid appearance due to the presence of fine sclerosis and is invading subcutaneous muscle on an irregular broad front pattern. **B.** The lesion consists of a relatively even intermixing of a predominant population of benign small darkly stained T lymphocytes and large neoplastic B lymphocytes with atypical nuclei, multiple nucleoli and usually abundant cytoplasm. **C.** CD3 staining marks a high proportion of the small background lymphocytes with the larger atypical cells (center) negative. **D.** CD79α staining to demonstrate marking of the large atypical cells with most of the smaller background lymphocytes unmarked.

with scattered large atypical lymphocytes, and a lesion characterized by angiotropic transmural destruction of the walls of arteries and veins and the irregular occurrence of necrosis. It became apparent that the large atypical cells in human LYG were lymphoid cells with evidence of Epstein-Barr virus (EBV) infection of a phenotypic B cell. *The view has subsequently developed that most cases of human LYG are a form of T-cell-rich EBV-associated B-cell lymphoma.*

The disease in dogs is more variable and the lesion is less angiotropic and not angiodestructive, but focal ischemic necrosis does occur. In dogs, the predominant cells are small, apparently benign, T lymphocytes, with larger cells of irregular phenotype resembling centrocytes, and scattered large atypical cells with very large nuclei and nucleoli, plus the irregular aggregation of huge giant cells with many nuclei and abundant, often eccentrically placed, cytoplasm (Fig. 2.47A–D). LYG in the dog is characterized by *irregular fibrosis and multifocal areas of ischemic necrosis.* The cellular infiltrates surround and collapse the major airways and tend not to destroy bronchiolar walls or the epithelium. Phenotypically, LYG in the dog does not always make a convincing case for being a subtype of T-cell-rich/histiocyte-rich B-cell lymphoma. The small cells in the lesion regularly mark for CD3; whereas, the intermediate-sized cells have variable markings for both CD3 and CD79α and very large atypical cells, which appear to be the major or only neoplastic cells in the reaction, irregularly mark for CD79α (Fig. 2.47C, D). Macrophages are present but appear to be principally related to areas of necrosis. The giant cells are negative for lysozyme and a histochemical stain for myeloid and histiocyte cell peroxidases. One of the most typical characteristics of LYG in the dog is the topographical presentation with *the lesion characteristically forming a large mass in the upper caudal area of one lung lobe.* These lesions may become very large (10 cm or more in diameter) and ultimately involve mediastinal tissues.

In conclusion, the **diagnosis** of LYG in the dog is based on the location of the lesion in the mature animal, and is characterized by dense and irregular lymphoid cell infiltration with atypical large

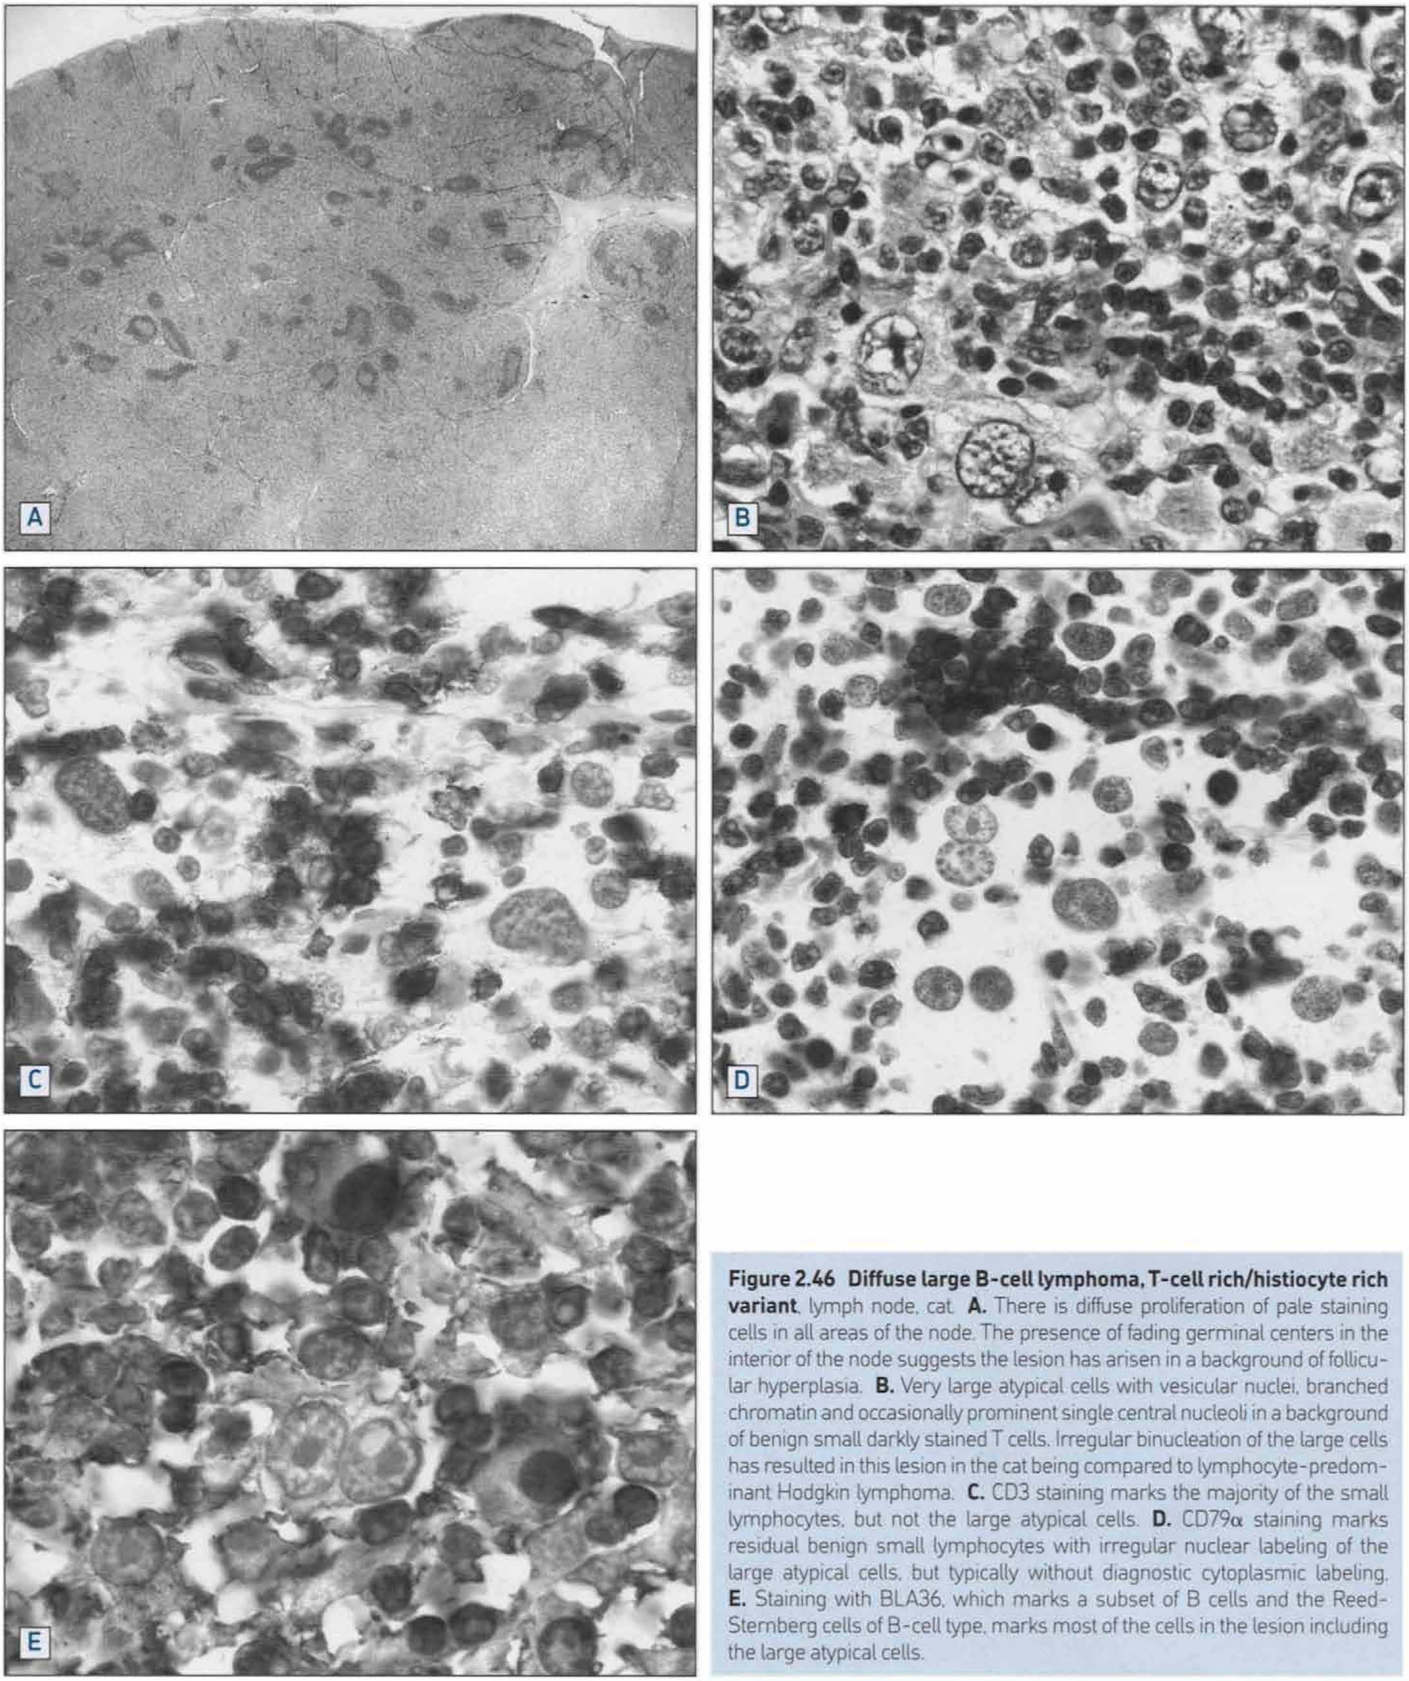

Figure 2.46 Diffuse large B-cell lymphoma, T-cell rich/histiocyte rich variant, lymph node, cat. **A.** There is diffuse proliferation of pale staining cells in all areas of the node. The presence of fading germinal centers in the interior of the node suggests the lesion has arisen in a background of follicular hyperplasia. **B.** Very large atypical cells with vesicular nuclei, branched chromatin and occasionally prominent single central nucleoli in a background of benign small darkly stained T cells. Irregular binucleation of the large cells has resulted in this lesion in the cat being compared to lymphocyte-predominant Hodgkin lymphoma. **C.** CD3 staining marks the majority of the small lymphocytes, but not the large atypical cells. **D.** CD79α staining marks residual benign small lymphocytes with irregular nuclear labeling of the large atypical cells, but typically without diagnostic cytoplasmic labeling. **E.** Staining with BLA36, which marks a subset of B cells and the Reed-Sternberg cells of B-cell type, marks most of the cells in the lesion including the large atypical cells.

cells and giant cells, multifocal areas of necrosis, and variable markings of the atypical cells for CD79α. Recent ability to stain with CD18 suggests that histiocytic sarcoma needs to be ruled out in the diagnosis of LYG.

Anaplastic large B-cell variant

Anaplastic large-cell lymphoma (ALCL) occurs as both a B- and T-cell lesion in humans and animals. In the early 1980s, an antibody was developed that marked Reed-Sternberg cells with the discovery of

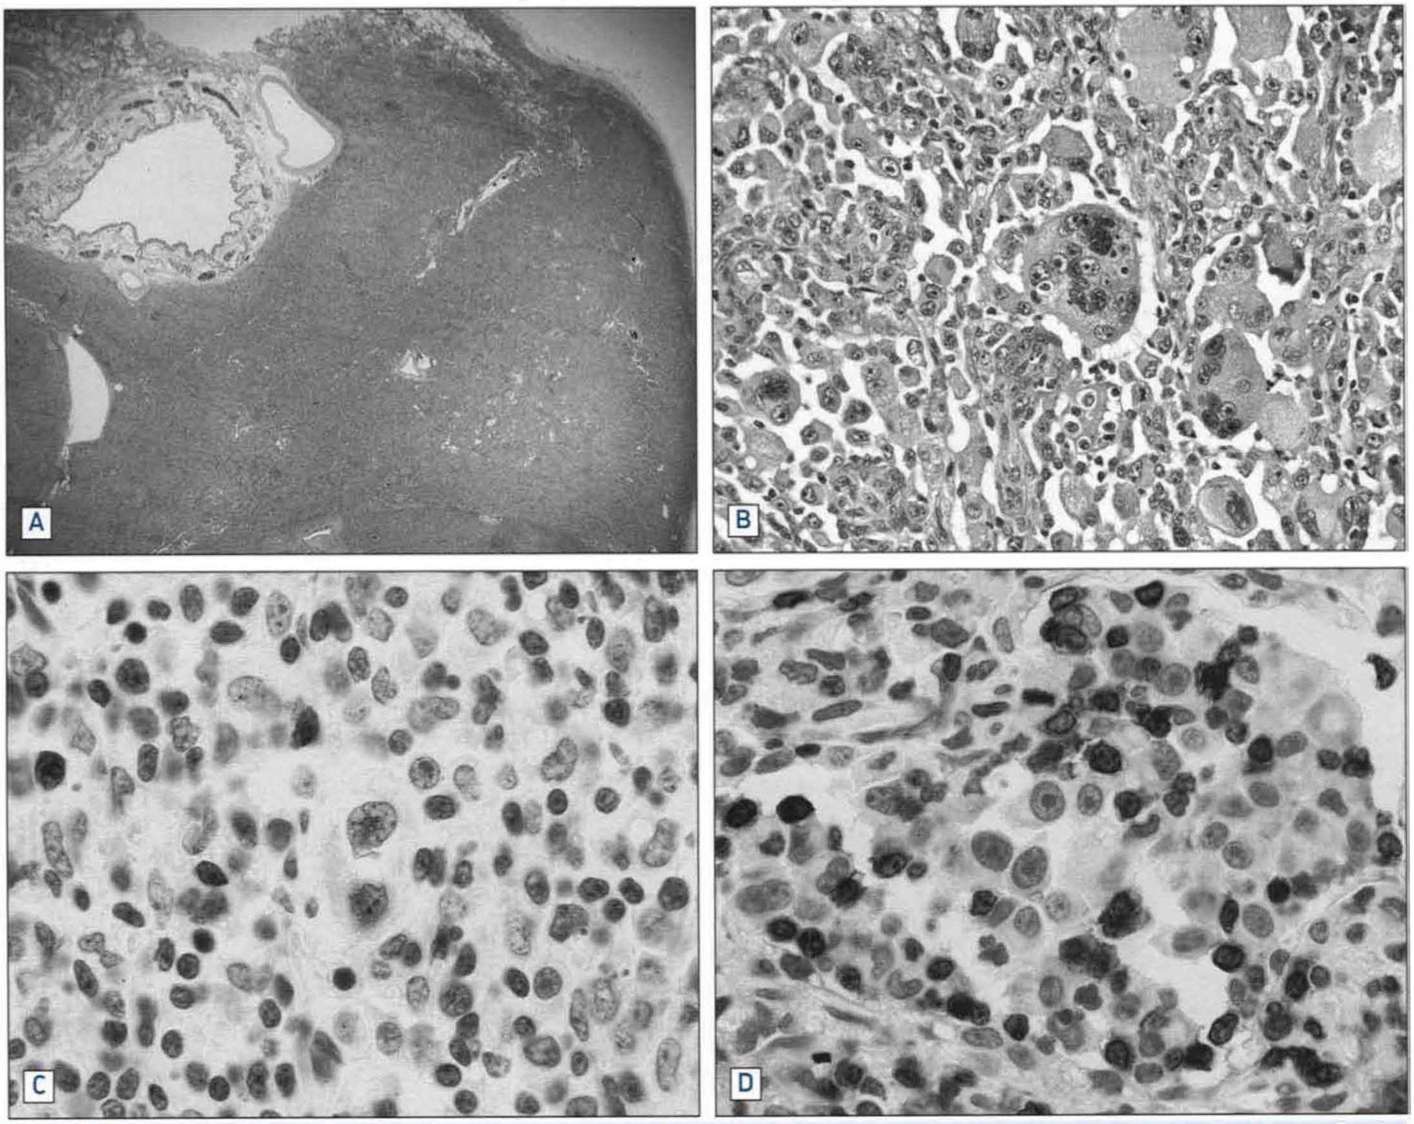

Figure 2.47 Diffuse large B-cell lymphoma, lymphomatoid granulomatosis variant, lung, dog. **A.** There is diffuse infiltration of pulmonary parenchyma with compression of vessels and smaller airways. **B.** Area with highly variable cell type including small and large lymphocytes and giant cells with marked anisokaryosis. Note giant cell undergoing necrosis. **C.** CD79α staining marks the nuclei but not the cytoplasm of the larger atypical cells and an occasional plasmacytic cell. **D.** Staining with CD3 marks many of the small lymphocytes as T cells but not the cytoplasm of the large atypical cells. Lymphomatoid granulomatosis in humans has been suggested to be a variant of the T-cell-rich B-cell lymphoma.

an antigen called "Ki-1" and subsequently clustered and recognized as CD30. Use of this antibody led to the identification of a heterogeneous group of human large cell neoplasms that marked with the CD30 reagent plus lymphoid markers, which were called "Ki-1 positive anaplastic large cell lymphoma." Recent classifications have recognized CD30-positive lymphomas of B-cell type and a T/null-cell phenotype usually bearing a chromosome 2 and 5 translocation. The disease is not well characterized in dogs and it appears that anaplastic large cell lymphoma tends to arise in body surfaces, i.e., skin, lung and gastrointestinal tract, with rapid spread to adjacent lymph nodes. Both B- and T-cell types of anaplastic large cell lymphoma have a similar morphology with nuclei that are 3–4 red cells in diameter and often indented or irregularly folded with peripheralized chromatin, marked parachromatin clearing, and 1 or 2 large central nucleoli (Fig. 2.48). Cytoplasm is moderately abundant and may be markedly basophilic. There is a high mitotic rate. The B-cell ALCLs tend to arise in the deep dermis and extend into the panniculus with multifocal areas of necrosis. The B-cell ALCL tend to have solid masses of atypical but clonal tumor, whereas the ALCL of the T-cell type tend to have a more pluricellular appearance with accompaniment of a mixture of small benign lymphocytes, mainly T cell.

Plasmablastic variant

The plasmablastic variant (PV) of diffuse large B-cell lymphoma appears to be a neoplasm that is intermediate in differentiation between clearly malignant B immunoblastic lymphoma and a plasmacytoma. This tumor in humans is found frequently but not exclusively in HIV-positive individuals and tends to arise in the oral cavity. *The disease is not described in dogs*, but may occur as a subset of those

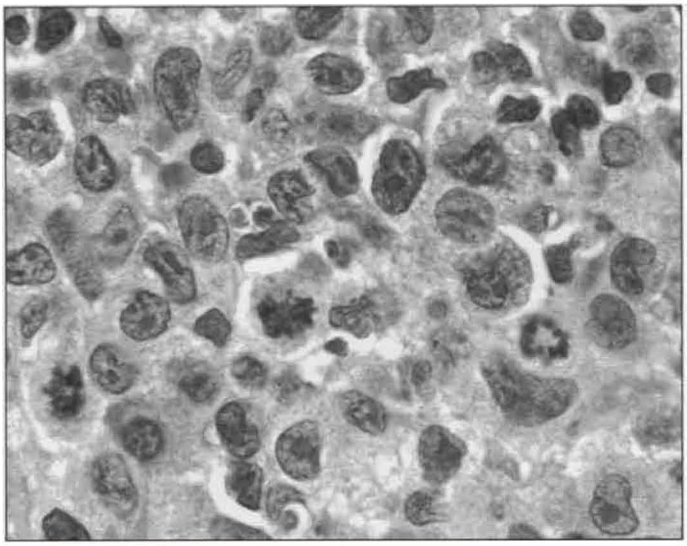

Figure 2.48 Diffuse large B-cell lymphoma, anaplastic large B-cell variant. lymph node, dog. Nuclei are generally large and irregularly folded and clefted with irregular thickening of nuclear membranes and 1 to 2 prominent nucleoli irregularly rimmed by small chromocenters. There are numerous mitoses and apoptotic bodies.

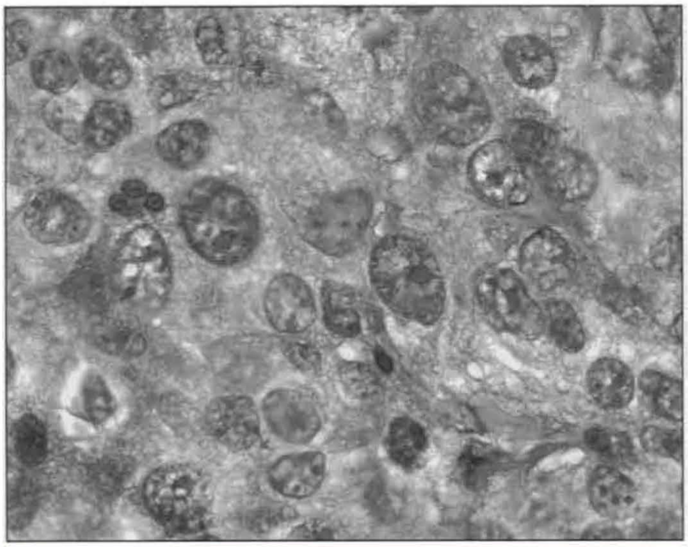

Figure 2.49 Diffuse large B-cell lymphoma, plasmablastic variant. lymph node, dog. Nuclei are 2 to 3 red cells in diameter with 1 to 2 prominent nucleoli and abundant moderately basophilic cytoplasm often eccentrically placed. There are frequent mitoses.

plasmacytomas found to be malignant (Fig. 2.49). The cytology of the disease in humans is of *relatively monomorphic plasmacytomas that have large and eccentric nuclei and single or several prominent nucleoli.* Cytoplasm is abundant and basophilic and there are numerous mitotic and apoptotic figures and frequent single cell necrosis. The phenotype of the human plasmablastic variant marks with strong expression of CD79α in half of the cases and strong consistent positivity with VS-38C. There are variable or weak reactions for CD45 and CD20. A similar disease in animals would likely be called an *anaplastic or atypical plasmacytoma.*

Topographic variants of diffuse large B-cell lymphoma

Mediastinal (thymic) large B-cell lymphoma

Primary mediastinal (thymic) large B-cell lymphoma in humans is an unusual neoplasm of young women that is characterized as a mediastinal mass of at least 5 cm in maximal dimension with no other lesion larger than that in the mediastinum. Characterization of the human lesion is demonstrated to be a lymphoma apparently arising within the thymus and of B-cell type. The human lesion is characterized by sclerosis with a predominance of large centroblast-like cells predominating. All cases have a B-cell phenotype and are positive for CD19, CD20, CD22, and CD79α, and negative for CD3.

In animals, the disease largely or primarily occurs in dogs and is only rarely encountered. These neoplasms in the dog *were called a multi-lobated B-cell lymphoma* and had a striking appearance in cytologic preparations derived from fine-needle aspiration and characterized by large and very large nuclei with multiple deep nuclear clefts and multiple prominent nucleoli (Fig. 2.50A, B). Older cases were found to be positive for IgM, and more recent cases mark strongly for CD79α. Histologically, the neoplastic cells have relatively abundant, lightly or clear-staining cytoplasm, and the sclerosis does not appear to be as prominent a factor in dogs as in the human disease. Very large cells with quite abundant cytoplasm are occasionally seen, which may suggest an epithelial cell arising in a thymoma, but these cells are negative for cytokeratin and weakly or strongly positive for CD79α. Mitotic rate is relatively low, but the lesions are aggressive and invade the lung and mediastinal tissues. The presentation is usually related to problems with cough, swallowing and exercise intolerance. *Mediastinal lymphomas in the cat are of a much more homogeneous cell type*, and usually composed of aggressive small B-cell lymphoma, more typical of the Burkitt-like lymphoma or small noncleaved cell of the Working Formulation.

Not all areas of tumor have this degree of pleomorphism.

Primary effusion lymphoma

Effusion lymphoma, also known as *body cavity lymphoma*, is a *rare neoplasm of large B cells* that in humans presents as a lymphomatous effusion in the absence of an adjacent lymphomatous mass. The disease is most frequently seen in immunodeficient patients with fairly consistent association with *Human herpesvirus 8* (HHV-8) infection. Effusion lymphoma apparently has a heterogeneous mutation profile of rearranged heavy chain genes that suggests that HHV-8 may transform B cells at various stages of maturation. Human effusion lymphoma lacks surface immunoglobulin and is positive for CD45, CD30, and CD38, but generally negative for CD19, CD20, and CD22.

Lymphoma is relatively frequently diagnosed in the cat and dog on the basis of the presence of neoplastic cells in body cavity fluids. The presence of neoplastic lymphocytes in aspirates of cerebrospinal fluid is the most common type of effusion lymphoma seen in animals. Neoplastic lymphocytes are generally more commonly found in thoracic than abdominal aspirates and, in both cases, the malignant cells in the effusion appear to be derived from exfoliation of lymphomatous masses that represent spread from a common type of large-cell lymphoma. No particular infectious agent is associated with lymphomatous effusions in animals, and the cytologic cell type is usually typical of immunoblastic or centroblastic lymphoma.

Intravascular large B-cell lymphoma

Intravascular large B-cell lymphoma has gone through a series of name changes beginning as *angioendotheliomatosis* some 40 years ago on the presumption that the tumor arose from the endothelial cells. With recognition that the tumor was of lymphoid origin and B-cell type, the current terminology has been adopted. Intravascular lymphoma in humans marks with CD19, CD20, CD22, and CD79α. The predilection of the tumor for vascular channels is unexplained. Neoplasms of this type in humans lack the leukocyte adhesion molecule CD11a/CD18, which may explain the inability of these cells to extravasate to perivascular tissues. There appears to be no specific immunoglobulin gene rearrangements associated with intravascular lymphoma in humans, but infection with *Human herpesvirus 8* appears to be a condition for a diagnosis of this neoplasm in humans. The disease has a rapid clinical course in humans, and most cases are diagnosed at necropsy.

In animals, intravascular lymphoma of large B-cell type is a rare disease that is seen in the dog, and may rarely occur in other species. As in humans, most cases are diagnosed at necropsy after animals have been presented with sudden collapse that seems to involve failure of the cardiovascular or pulmonary systems. One case presented with paraplegia that rapidly progressed to cardiac failure. Necropsy demonstrated tumor emboli in the atria, myocardium and spinal cord (Fig. 2.51A). On necropsy of other animals, these large B-cell tumor emboli have been found in dilated vessels in the meninges (Fig. 2.51B) and in the choroid plexus of the central nervous system. Cytologically, the neoplastic cells are of immunoblastic and centroblastic type with multinucleation and a moderate amount of quite highly basophilic cytoplasm. *Involved vessels are almost always quite markedly dilated and the tumor cells appear to be coherent to each other but not particularly adherent to vascular endothelium.* Prior to CD immunochemistry, the neoplastic cells were found to mark with anti-canine IgM, and are strongly positive with CD79α. Cases of lymphoma of similar cytologic type and topographical distribution that are CD3-positive and that appear to begin in the nasal turbinates occur occasionally in animals.

Burkitt lymphoma/Burkitt cell leukemia

The revised WHO classification divides the category of Burkitt lymphoma into **morphological variants** and **subtypes**. The variants include *classical Burkitt lymphoma* characterized by a genotype of *MYC* but not *BCL2* rearrangements, with a B-cell phenotype and highly consistent uniformity of cell size, and features associated with a starry-sky pattern on low-power examination. The *Burkitt-like lymphoma* cannot be distinguished from the classical type on cytogenetic or phenotypic characteristics but only on morphology, with the Burkitt-like variant having moderate anisokaryosis and anisocytosis. It has been suggested that, in humans, the Burkitt-like variant is characteristically found in an older age group than the classical Burkitt lymphoma, and is more common in HIV-positive immunocompromised individuals.

In animal pathology, high-grade lymphomas with intermediate-size nuclei, vesicular chromatin pattern, and prominent nucleoli with a B-cell phenotype and starry-sky pattern were called *Burkitt-like lymphoma/leukemia*. In contrast, the category now termed Burkitt-like in the REAL and WHO classifications constitutes that category formerly known as *small-noncleaved cell lymphoma* in the Working Formulation. Further minor distinctions in identification of Burkitt lymphoma variants include cases with a plasmacytoid differentiation, usually associated with HIV-positive individuals, and subtypes based on geographic localization as endemic (African) and sporadic (European–American) cases.

The identification of Burkitt and Burkitt-like lymphomas in animals requires a careful consideration of their characteristics from a number of standpoints. In terms of *nuclear size*, tumors of Burkitt cell type are larger than those of the intermediate lymphomas of plasmacytic type and smaller than those of diffuse large-cell lymphoma, and are generally comparable in size to those of lymphoblastic lymphoma of both B- and T-cell type. In further consideration of nuclear size, the *Burkitt-type lymphoma can be identified in animals on the basis of the remarkable similarity and homogeneity of cell type, similar to disease in humans* (Fig. 2.52A, B). In contrast, the entity now known as Burkitt-like, and formerly known as small-noncleaved cell, characterized by greater variation in nuclear size, cannot be distinguished in morphometric studies as an entity separate from diffuse large-cell lymphoma. Thus, there has always been difficulty in assigning animal lymphomas with vesicular nuclei and multiple nucleoli to categories of either large-cell lymphoma or small-noncleaved cell lymphoma based largely on the subjective decision as to whether the nuclei were on the whole more appropriate in the large-cell or small-cell category. These difficulties have in no way been resolved by the newer tumor classification systems. Other minor distinctions between large-cell lymphoma and Burkitt-like lymphoma are that the large-cell type tends to have fewer and larger *nucleoli*, of which some characteristically impinge on the nuclear membrane as described for centroblastic neoplasms. Burkitt-like lymphomas may have 3–5 small nucleoli generally detached from the nuclear membranes, and as their previous name implied, the Burkitt-like lymphomas tend to have a round or oval nuclear shape without indentation or cleavage, whereas large-cell lymphomas may be of either type or mixed. Further, the Burkitt-like lymphomas tend to have a higher *mitotic rate* than large B-cell lymphomas and are more likely to have a starry-sky pattern on low-power magnification, but both of these distinctions are relatively arbitrary. Finally, the definition

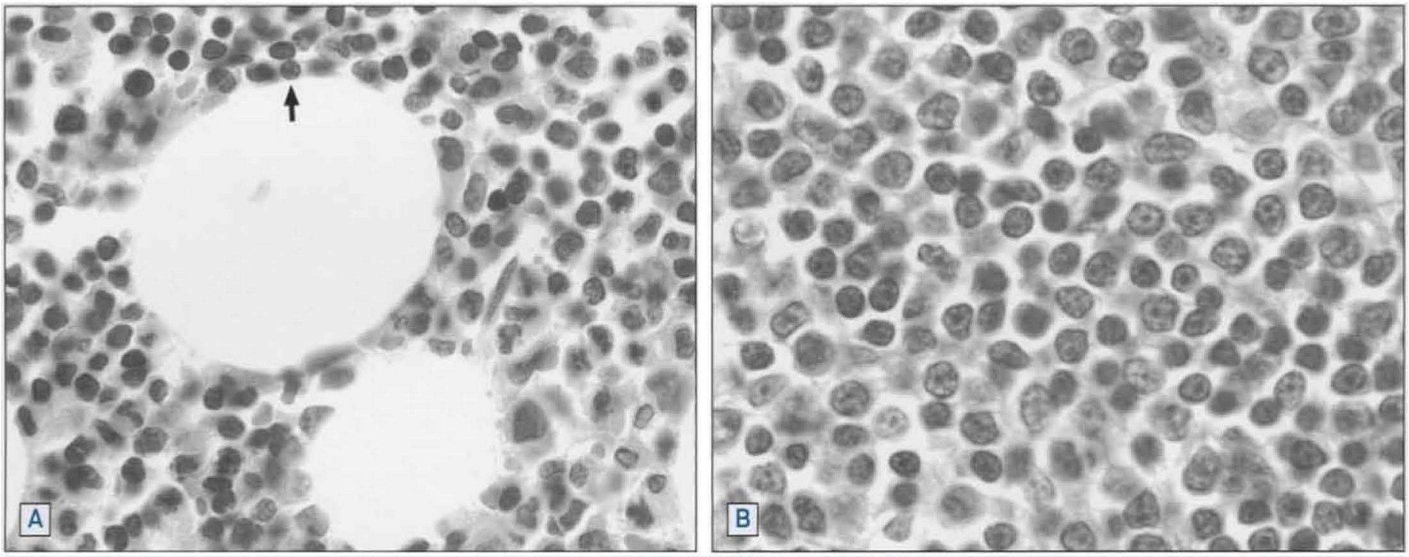

Figure 2.52 Burkitt-type lymphoma/leukemia, pig. **A.** Bone marrow. The small dark cells (arrow) represent focal interstitial colonization of bone marrow. **B.** Lymph node. Note homogeneity of cell size and nuclear type. Nuclei are generally densely stained with thickening of the nuclear membranes, irregular parachromatin clearing and occasional small prominent nucleolus. (Courtesy of T Dukes.)

of *chromatin distribution* in the Burkitt and Burkitt-like lymphomas is important to distinguish them from lymphoblastic lymphomas that have nuclei of the same or similar size. Lymphoblastic lymphomas are characterized by relatively dense and uniform chromatin distribution with absent or obscured nucleoli. In contrast, the nuclei of Burkitt and Burkitt-like lymphomas have a vesicular appearance due to peripheralization of chromatin, with thickening of the nuclear membranes and irregular well-defined parachromatin clearing that adds prominence to multiple and small nucleoli. Both lymphoblastic lymphomas and Burkitt-type lymphomas have high mitotic rates and may have a starry-sky appearance on low magnification examination. Further, subtle distinction exists between these two groups in that, like the internal nuclear detail that is poorly defined in lymphoblastic lymphomas, the metaphases in this category of neoplasm are also less densely stained and sharply defined than those of all other lymphoid neoplasms, and must be carefully looked for at a ×1000 magnification to be confident of an accurate assessment of their number.

It is suggested that eponyms such as Burkitt and Hodgkin diseases not be used directly to designate the counterpart neoplasms in animals, but rather that they be termed Burkitt or Hodgkin type. The Burkitt-like (formerly small-noncleaved cell) should have direct, comparable use in animals. *True Burkitt-type lymphomas are rare occurrences in animals*, occurring occasionally in the cow, dog, and horse. In contrast, *the Burkitt-like category constitutes approximately 20% of cases of lymphoma in the cow, 25% in the dog, 13–15% in the cat, 2% in the horse, 24% in the pig, and approximately 5% in humans*. In animals, as in humans, these two categories of lymphoma tend to reach complete remission with aggressive treatment that is more durable than that obtained with the T-cell counterparts.

T-cell and NK-cell neoplasms

Precursor T-cell neoplasms

Precursor T-lymphoblastic lymphoma/leukemia

Precursor T-lymphoblastic lymphoma/leukemia (T-LBL/ALL) is a neoplasm of T-cell lineage composed of small to medium-sized blast cells, with scant cytoplasm, finely condensed chromatin, and indistinct nucleoli. There is variable involvement of bone marrow, as well as of thymus and lymph nodes. In humans, precursor T-cell neoplasms occur most frequently in late childhood to young adulthood with male predominance. These tumors comprise 15% of childhood and 25% of adult *acute lymphoblastic leukemias* with the prognosis typically worse than that for precursor B-cell neoplasms. Patients with T-LBL/ALL typically have elevated leukocyte counts at presentation, often over 50×10^9/L and are more likely to have irregular adenopathy and organomegaly. A cranial mediastinal mass is a highly specific predictor for T-cell phenotype in patients with ALL. In terms of staging, patients are defined as having *lymphoma* if there is a mediastinal or other mass and less than 25% blasts in the bone marrow, and as having *leukemia* if there are more than 25% bone marrow blasts with or without mediastinal or other masses.

Rearrangement of antigen-receptor genes is variable in human lymphoblastic neoplasms, and precursor T-cell neoplasms may have rearrangement of either or both TCR beta or gamma chain and

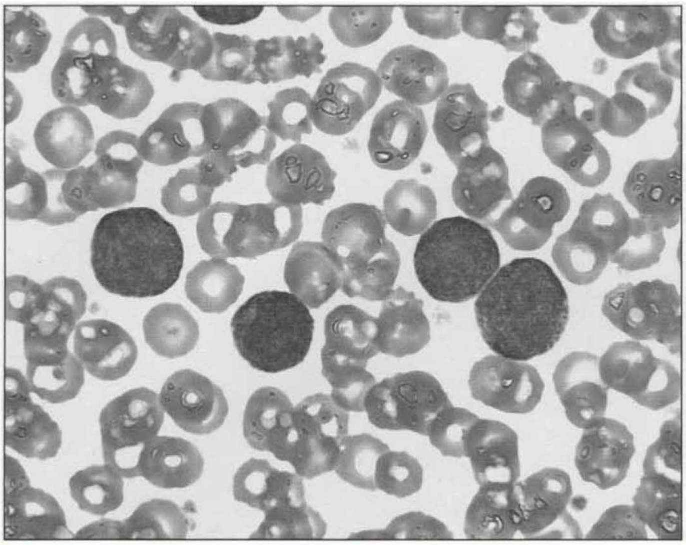

Figure 2.53 Precursor T-lymphoblastic lymphoma/leukemia, blood, dog. The blasts are usually of the L1 type. The blasts are typically small cells with nuclei 1.5 red cells in diameter and a very narrow rim of highly basophilic cytoplasm. The chromatin is densely stained with a coarsely cribriform pattern and nucleoli are present but relatively inconspicuous. (Courtesy of RM Jacobs.)

even the immunoglobulin heavy chain. Phenotypically, precursor T lymphoblasts are typically TdT positive and have variable expression for CD2, CD7, CD3, CD5, CD1a, CD4, and CD8, of which only CD3 is considered lineage specific.

Precursor T-cell neoplasms occur widely in animals but are seen most often in the cat, dog, calf and horse. The association with a thymic lesion probably occurs most often in the cat, although the relationship of this finding to T-cell phenotype is not generally considered. The small type of lymphoblast typical of the L1 FAB classification with a hyperchromatic cribriform chromatin pattern with inapparent nucleoli, nuclei about 1.5 red cells in diameter (10 μm) and scant cytoplasm is a relatively rare presentation in animals (Fig. 2.53). Approximately two-thirds of animal LBL/ALL are of the L2 type, with nuclei approximately twice the diameter of a red cell and nearly twice the diameter of a normal small lymphocyte. The chromatin pattern is fine granular to uniform with few or no large chromocenters and more obvious nucleoli. The cells have relatively abundant cytoplasm that is relatively pale staining with lighter perinuclear halo and increasing density toward the cellular margins. L1 and L2 types of neoplasms do not specify lineage and can be of B- or T-cell type, but most in animals appear to be T-type neoplasms. In contrast, the L3 type of ALL has relatively uniform round nuclei which are 1.5 times the diameter of L1, approximately the same size or slightly smaller than L2, and more uniform in size and shape. The chromatin is a more expanded version of L1, with hyperchromatic cribriform chromatin distribution with small, but relatively distinct, nucleoli and a moderate amount of highly basophilic cytoplasm that is frequently vacuolated. The L3 neoplasms tend to be characterized by numerous mitoses and apoptotic bodies and are the characteristic cytologic presentation of a Burkitt-type lymphoma and are usually of B-cell type. *T-type LBL/ALL in animals is characterized by rapid progression with anemia, thrombocytopenia with progressive marrow involvement, marrow failure and hepatosplenomegly.* T-cell LBL/ALL is not associated with a specific viral infection in animals. Cells of T-LBL/ALL regularly mark in high proportion in both cytoplasmic and histologic preparations with CD3.

Mature (peripheral) T-cell neoplasms

T-cell prolymphocytic leukemia

T-cell prolymphocytic leukemia (T-PLL) is an aggressive T-cell neoplasm characterized by proliferation of medium-sized prolymphocytes with a mature T-cell phenotype. Prolymphocytic leukemia is a relatively infrequent disease in animals and probably occurs in all species. In terms of morphology, the leukemic T cells of T-PLL are larger than the blasts of L1 and approximately the same size of those of L3. Prolymphocytic leukemia cells are round and can be occasionally clefted with a narrow ellipse of moderately basophilic cytoplasm that is without vacuolation or granulation. *The characteristic feature of prolymphocytic leukemia is in the chromatin distribution, which characteristically consists of large densely stained chromocenters separated by branched areas of chromatin with parachromatin clearing providing a striking pattern of large chromocenters delineated by surrounding lightly stained zones.* T-cell PLL has prominent nucleoli and there may occasionally be broad-based cytoplasmic protrusions similar to the blasts of AML M7 (Fig. 2.54). There is usually extensive bone marrow involvement at presentation, and the peripheral lymphocyte count is typically high and in the 50–100 × 10^9/L range. The spleen and liver are involved, and lymph nodes tend to be involved in a paracortical T-zone manner with some sparing of follicles and medullary structures until late in the disease. T-PLL marks with CD3 in histological preparations, and while there is inadequate experience with immunophenotyping of cytological preparations, there is reason to expect that these would react positively to CD3 as well.

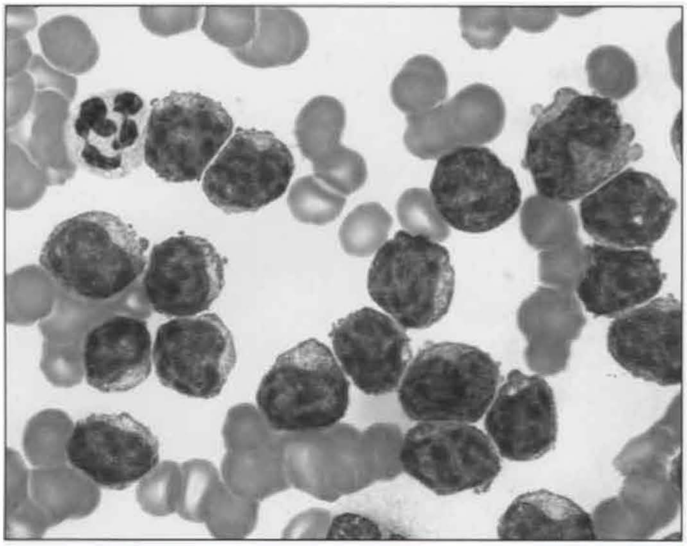

Figure 2.54 T-cell prolymphocytic leukemia, blood, dog. The characteristic feature of prolymphocytic leukemia is due to the retention of large chromocenters with irregular areas of parachromatin clearing. Nuclei may be round and occasionally cleft, unlike the more regular appearance of B-cell leukemias. Nucleoli are present but not prominent, and the cytoplasmic protrusions are characteristic of this neoplasm. (Courtesy of RM Jacobs.)

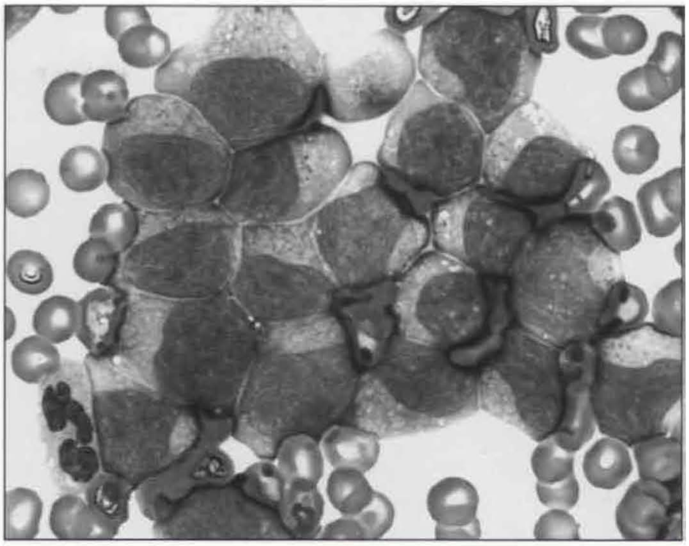

Figure 2.55 T-cell granular lymphocytic leukemia, blood, dog. The nuclei are 1.5 to 2 red cells in diameter and often irregularly indented. The chromatin pattern tends to be more homogeneous than that of prolymphocytic leukemia with retention of few large chromocenters and irregularly prominent nucleoli. The cytoplasm is abundant and irregularly basophilic, and small azurophilic granules are irregularly present.

T-cell granular lymphocytic leukemia

T-cell large granular lymphocyte leukemia (T-LGL) is defined as a neoplasm of mature CD8+ T lymphocytes characterized by cytoplasmic granulation with primary bone marrow involvement, and typically associated with neutropenia in humans but not apparently in animals. The human disease is characterized by adult onset with moderate lymphocytosis in the range of 5–20 × 10^9/L. Anemia and neutropenia are commonly found, usually with significant splenomegaly, but without major involvement of bone marrow, liver or lymph nodes. The course of the disease tends to be indolent, following a pattern of chronic lymphocytic leukemia. In the human disease, the T-LGL cells express CD2, CD3 and usually CD8 as well as the NK cell associated antigen CD16 and CD57, and genetically the T-cell receptor genes are clonally rearranged.

Neoplasms of LGL type occur in the dog, cat, horse, and rarely in the cow and have only been adequately described for the dog. Benign lymphocytosis of large granular lymphocytes may occur in most species, and is a typical response to inflammation in the cow. The disease in dogs is characterized by mature onset (>5 years of age) and there is persistent lymphocytosis with subgroups consisting of acute leukemia or chronic lymphocytic leukemia, with or without anemia. There is immunophenotypic variation between these groups in the dogs, but within a single individual, the neoplastic cells are of homogeneous immunophenotype. Dogs with T-LGL tend to be presented with high leukocyte counts in the 50–200 × 10^9/L range and two-thirds of the cases had splenomegaly on presentation. Most cases have T-cell receptor profiles of αβ type but TCR γδ was found in one-third of the cases. Both types of canine T-LGL mark with CD3 and those that have similar morphology with cytoplasmic granulation and are CD3-negative are considered likely NK-cell leukemias. The β2 integrin expression is distinctive in canine T-LGL, with CD11a consistently expressed, CD11B absent, and CD11c weakly expressed in two-thirds of the cases. The leukointegrin α subgroup D β2 is expressed in over 90% of cases.

Hematologically, T-LGL in the dog is characterized by peripheral blood cells that have nuclei 1.5 to 2 red cells in diameter and round-to-oval nuclei with a chromatin pattern irregularly similar to that of prolymphocytic leukemia, but with much more abundant and lightly basophilic cytoplasm with multiple (2–20) small azurophilic granules (Fig. 2.55). Like most cases of chronic lymphocytic leukemia, nucleoli are usually not present in animals with stable disease, and greater immaturity is present in the blood of animals that have rapidly progressive LGL more comparable to T-ALL. Histologically, there is relatively solid and uniform infiltration of sinus areas of the spleen with mildly atrophic, but not obliterated, follicles. While T-LGL in dogs is not associated with neutropenia as in the disease in humans, there does appear to be selective depression of erythropoiesis, which may be a characteristic of this neoplasm in the dog. A retroviral agent has been isolated from a clone of canine LGL leukemia in long-term culture.

Aggressive NK-cell leukemia

Aggressive natural killer-cell leukemia (NKL) is defined in humans as a neoplasm of immature NK cells with peripheral blood lymphocytosis and a rapidly progressive clinical course. In humans, the cells in blood are described as larger than benign granular lymphocytes, and have irregularly indented and clefted hyperchromatic nuclei with distinct nucleoli. Lymph nodes and spleen have diffuse infiltration similar to other acute leukemias and appear to be involved prior to infiltration of the bone marrow. Phenotypically, in humans NKL express CD2 and CD56, but not CD3, and stain variably for CD11b. CD57 is usually not expressed and CD16 is positive in some cases. Genetically, the T-cell receptor genes are typically germline, and most human cases of NKL are associated with the clonal presence of Epstein-Barr virus (EBV) genomes. Clinical presentation is usually in the young adult with fever, hepatosplenomegaly, lymphadenopathy and leukemic lymphocytosis.

The most common example of aggressive NK-cell leukemia in animals is that found in Fischer 344 rats, in which 10–30% or more of animals over 18 months of age develop a spontaneous neoplasm arising in the spleen. The disease is rapidly progressive with peripheral leukocyte counts that may range from near normal to over 300 × 10^9/L. Leukemic rats consistently have immune-mediated hemolytic anemia, thrombocytopenia and coagulopathy suggestive of disseminated intravascular coagulation. Terminally, the animals are icteric with increased hepatocyte-specific enzymes. Peripheral blood is characterized by anemia with anisocytosis, spherocytosis, and moderately responsive anemia. The neoplastic cells are similar to those in other species with nuclei 2–2.5 red cells in diameter with densely stained large chromocenters and irregular parachromatin clear areas typical of prolymphocytic leukemia in other species (Fig. 2.56). Prominent nucleoli are present and often multiple with quite abundant, usually eccentric, cytoplasm with moderate basophilia and a small number of quite large azurophilic granules. Histologically, there is diffuse infiltration and expansion of the splenic red pulp by tumor, with depletion of the follicles and some degree of erythrophagocytosis believed to be by neoplastic cells. The liver has prominent sinusoidal infiltration, focal portal infiltration, and centrilobular ischemic necrosis. Mildly involved lymph nodes have tumor cells in the peripheral and medullary sinuses, which progresses to architectural obliteration by neoplastic cells. Bone marrow is involved in less than half of animals which develop the disease, and is characterized by myeloid hyperplasia and progressive osteosclerosis. The neoplastic LGL cells in the rat stain positively with beta-glucuronidase and acid phosphatase.

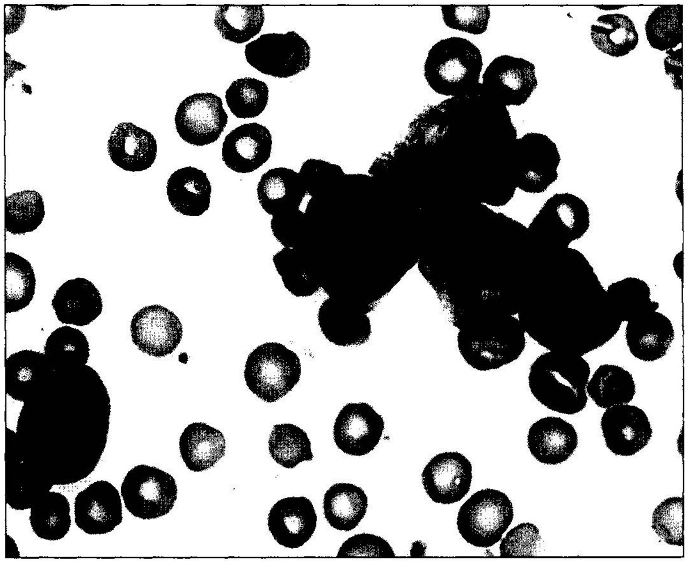

Figure 2.56 Aggressive NK-cell leukemia, blood, Fischer rat. Nuclei are generally 2 red cells in diameter with retention of some larger chromocenters in a finely woven chromatin pattern. Nucleoli are irregularly prominent. Cytoplasm is abundant, highly basophilic and contains numerous azurophilic granules. (Courtesy of RM Jacobs.)

It is likely that NK-cell leukemia occurs in both dogs and cats. The diseases are, as yet, undefined in those species. Cases of rapidly progressive leukemia with large granular lymphocytes in the dog and cat that are presented with splenomegaly and neoplastic cells in blood with the CD3-negative phenotype should be given more complete phenotypic and T-cell receptor analyses to further define this disease entity.

Adult T-cell lymphoma/leukemia

Adult T-cell lymphoma/leukemia is a peripheral T-cell neoplasm in humans with a causal association with the human T-cell lymphotropic virus type-1 (HTLV-1). The FeLV-associated T-cell leukemia/lymphoma in the cat may be a counterpart for this disease in humans, and while *the lymphoma/leukemia associated with Bovine leukemia virus is of the B-cell type*, there may be pathogenetic as well as morphologic similarities in terms of induction by exogenous retrovirus. The human disease has a regional distribution based on endemic infection with the HTLV-1 virus, with a relatively high incidence of neoplastic transformation occurring in people in the south island of Japan and in the Caribbean basin. There are interesting morphologic similarities between the

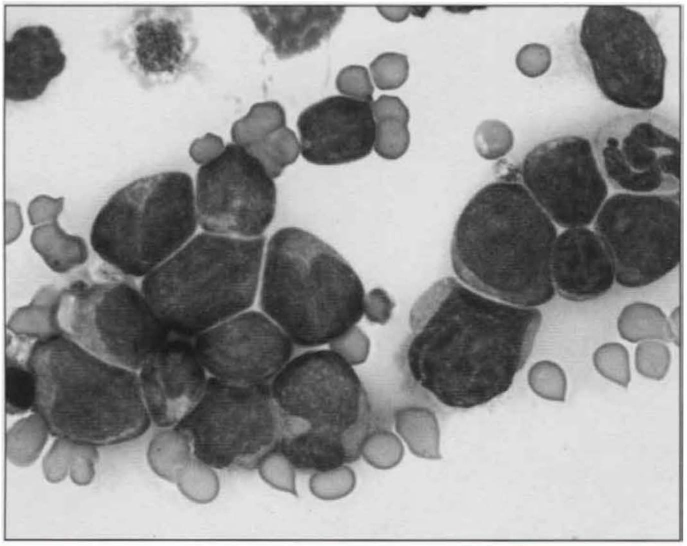

Figure 2.57 Adult T-cell lymphoma/leukemia, blood, cat, FeLV-positive. Nucleoli are present and irregularly apparent. Nuclei are 2 to 3 red cells in diameter and irregularly clefted, indented, or binucleated. Cytoplasm is moderate in volume and basophilia.

neoplastic cells in the human disease and those in animals with a retroviral-associated neoplasm. In humans, hyperlobated nuclei are frequently seen in cases of HTLV-1-associated lymphoma/leukemia known as the *floral variant, or flower cells*, and cells of this type are also seen in peripheral blood of BLV-associated lymphoma/leukemia in cattle and in FeLV-associated leukemia of cats (Fig. 2.57). In the human disease, there is always extensive lymph node enlargement, and bone marrow infiltrates tend to be patchy. Tumor cells express T-associated antigens CD2, CD3, and CD5, but usually lack CD7. Most cases are CD4-positive and CD8-negative; other combinations occur, but the disease is predominantly of helper-T-cell type. Genetic studies demonstrate clonally integrated HTLV-1 genes in all patients with this disease, and in all cases the T-cell receptor genes are clonally rearranged. Some human cases are lymphomatous and smoldering diseases with a relatively chronic progression, whereas the acute type, which is most common, presents with neoplastic cells in the blood, generalized lymphadenopathy with hepatosplenomegaly and often hypercalcemia.

Extranodal NK/T-cell lymphoma, nasal type

The NK/T-cell lymphoma of nasal type was formerly called angiocentric lymphoma, and is a human disease having an NK-cell phenotype and expressing Epstein-Barr virus (EBV). There is a broad spectrum of cell types present, *with frequent necrosis and angioinvasion.* The presenting areas are most commonly in mid-facial region but also occur in other extranodal areas. The disease has been compared to lymphomatoid granulomatosis because of the angiocentric/angiodestructive features causing widespread necrosis, and very variable cellular population including neoplastic and reactive cells. The disease was *formerly known as lethal mid-line granuloma.* Polymorphic reticulosis and mid-line malignant reticulosis are the same or closely related lesions. Cells in the human lesion are CD2-positive but CD3-negative, and T-cell receptor arrangement is always absent. In paraffin sections, the neoplastic cells are usually positive for CD43 and CD56, but are negative for CD57 and CD11. The lesions are always positive for EBV genome.

It is not apparent that a counterpart to this disease occurs in animals, although lymphomas of the nasopharynx are a relatively frequent occurrence in both cats (Fig. 2.58A, B) and dogs. The disease in humans tends to present with mid-facial skin eruption that appears to be a progression of the lesion from the nasal sinuses. This form of presentation is unusual in animals, with lymphoid tumors of the nasopharynx tending to obstruct the airways and frontal sinuses with invasion of the cribriform plate. They may even involve tissues surrounding either eye, but tend not to be presented with a destructive lesion of the skin on the bridge of the nose.

Enteropathy-type T-cell lymphoma

Enteropathy-type T-cell lymphoma in animals is *primarily a disease of dogs and cats* but likely occurs in other species. It is a disease of mature animals, which are presented with intermittent inappetence and diarrhea usually associated with some degree of weight loss. *The disease tends to involve the upper small intestine in both humans and animals and must be distinguished from inflammatory bowel disease of the lymphocytic–plasmacytic type, which it closely resembles.* In contrast to inflammatory bowel disease of the lymphocytic–plasmacytic type, there is usually much less lymphocytic proliferation in the submucosa, but there is prominent filling of the villi, and *the major distinction from inflammatory bowel disease of the lymphocytic–plasmacytic type is that there is a heavy but often segmental infiltration of the epithelium with small lymphocytes.* In histological sections, the neoplastic cells are found above the basal nuclei of the epithelial cells and apparently lie between adjacent epithelial cells and are characteristically surrounded by a clear

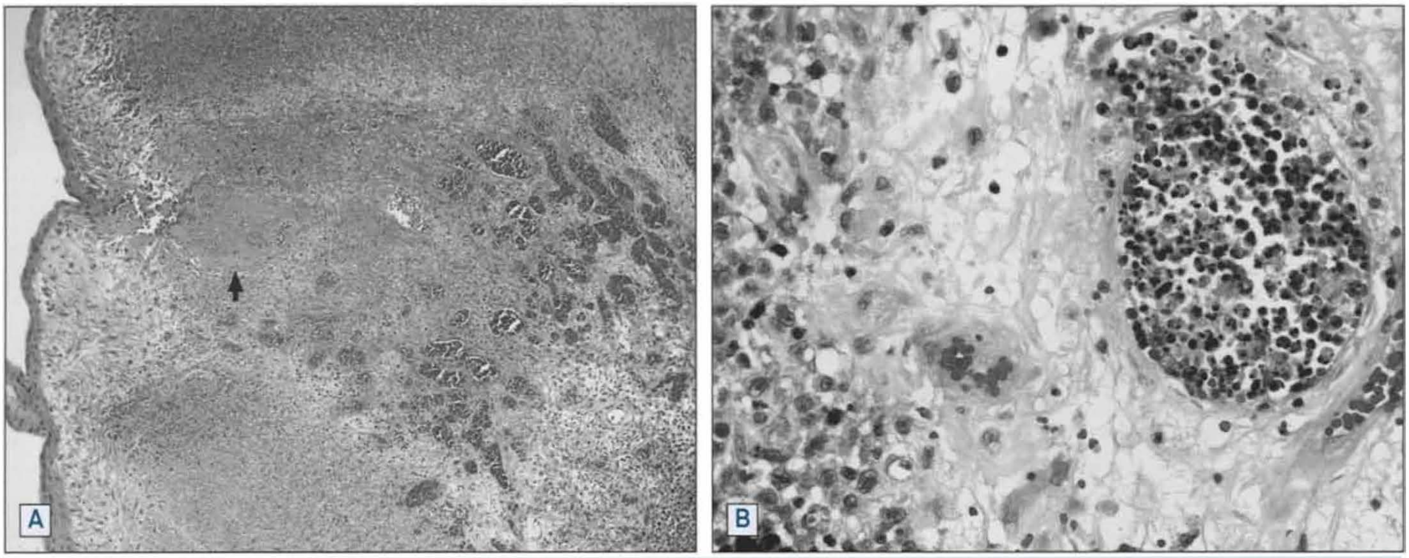

Figure 2.58 Extranodal lymphoma nasal type, nasal mucosa, cat. **A.** There is irregular dilation and thrombosis of mucosal vessels (arrow) and associated hemorrhage and infarction. **B.** Ischemic infarction of submucosa with extensive colonization and dilation of vein by tumor cells. The lesion was not phenotyped.

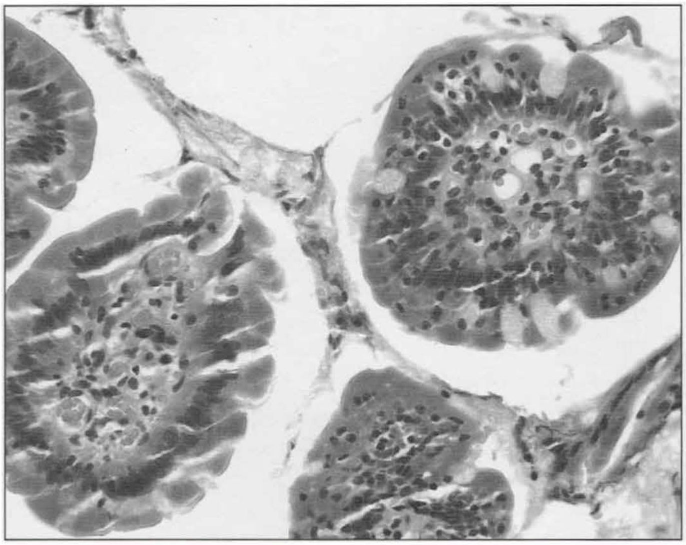

Figure 2.59 Enteropathy-type T-cell lymphoma, small intestine, cat. Early lesion characterized by irregular but extensive involvement of some villi with almost complete sparing of the epithelium of those immediately adjacent. Neoplastic nuclei are small, irregularly indented and deeply stained. Lamina propria and epithelial nuclei cells are CD3-positive. (Courtesy of FM Moore.)

halo, suggesting relatively abundant water-clear cytoplasm. In advanced cases, there is a blunting of villi and focal loss of epithelium, with much less heterogeneity of invading cells than is present in the lymphocytic–plasmacytic benign reactions. It has been suggested that *the key to early diagnosis of this disease is the presence of heavily involved villi with extensive epithelial invasion adjacent to others which have minimal or no involvement* (Fig. 2.59). This is in contrast to the benign lymphoid reactions of inflammatory bowel disease in which there tends to be relatively uniform involvement of all villi within the affected region of the small bowel.

In animals, the cells mark strongly with CD3, and in humans, the invading cells are CD3 and CD7 positive and usually CD8 positive and CD4 negative. Some cases of the human disease express cytotoxic T-cell-associated proteins granzym-B, TIA-1 and perforin.

Hepatosplenic $\gamma\delta$ T-cell lymphoma

Hepatosplenic $\gamma\delta$ T-cell lymphoma is a neoplasm of mature, nonactivated, cytotoxic T cells, with prominent sinusoidal infiltrations of the spleen, liver, and bone marrow. The disease occurs rarely in humans and is *recently defined in animals*. It has been found that over one-third of the benign T cells in the splenic sinus areas are of the α_D β_2 positive $\gamma\delta$ T-cell type. *It has been suggested that the LGL lymphocytosis occurring in dogs may arise*

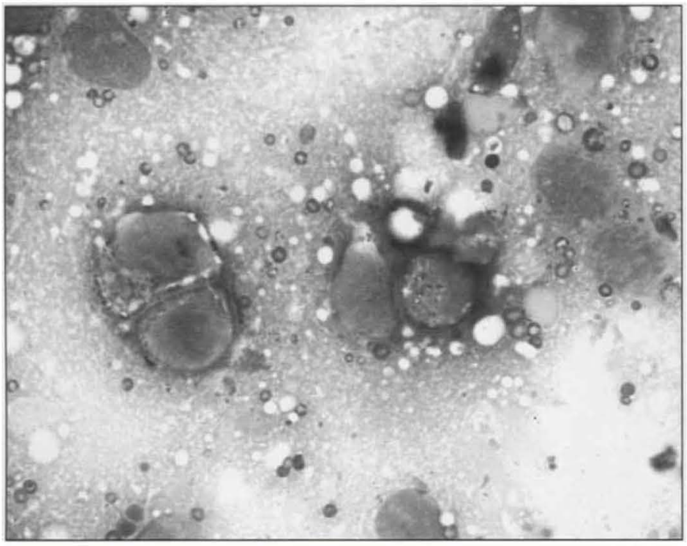

Figure 2.60 Hepatosplenic T-cell lymphoma, imprint of hepatic Tru-cut biopsy, cat. The nuclei are large and 2 to 3 red cells in diameter with relatively abundant cytoplasm and heavily granulated with large deeply azurophilic granules. The chromatin is coarsely granular with multiple small nucleoli. (Courtesy of RM Jacobs.)

from the large population of $\alpha_D\beta_2$ lymphocytes normally resident in the splenic red pulp.

In hepatosplenic γδ T-cell lymphoma of humans, the immunophenotype is generally positive for CD2, CD3, and CD16, negative for CD4, CD5, and CD8, with CD56 giving variable reactions. The neoplastic cells lack the αβ TCR protein and express the γδ complex. Typically, there is expression of the cytotoxic granule protein T1A-1, but granzyme-B and perforin are usually absent.

Clinically, the disease has only recently been characterized in humans and its occurrence in animals is still undefined. It is believed that previously cases occurring in humans were classified as T-cell CLL, with prolymphocytic leukemia or peripheral T-cell lymphoma of unspecified type. Most cases occur in young adult males who present with marked hepatosplenomegaly. There is usually minimal marrow involvement on presentation but neoplastic cells are present in the blood. The disease has been reported in patients receiving immunosuppressive drugs for solid organ transplants. Despite the relatively small size of the tumor cells, with relatively mature chromatin and low mitotic rate, the disease follows an aggressive pattern, often with prominent erythrophagocytosis by tumor cells in the spleen and liver. *A rare and highly aggressive hepatosplenic lymphoma occurs in cats and dogs in the absence of lymphadenopathy*; the disease in the cat is characterized by very large cytoplasmic granules (Fig. 2.60).

Subcutaneous panniculitis-like T-cell lymphoma

Subcutaneous panniculitis-like T-cell lymphoma is defined in humans as a T-cell lymphoma that preferentially infiltrates subcutaneous tissue with variably sized neoplastic cells and characterized by prominent necrosis, karyorrhexis and accompanying benign inflammatory reaction. It is not clear that there is a well-defined counterpart of this tumor in animals. The characteristic non-epitheliotropic (i.e., not mycosis fungoides type) neoplasm in animals is a relatively "high-up" lesion that usually has a narrow Grenz zone or sparing of tissues in the superficial papillary dermis, with encirclement but not penetration of the adnexa and extension through the deep dermis into the subcutaneous tissues. These lymphomas are characterized by relatively small densely stained cells surrounded by a characteristically water-clear halo with relatively few mitotic figures. These lymphomas in animals mark strongly for CD3. They usually occur as single lesions, and appear to be the primary site of neoplastic transformation and not extensions from lymphoma in other sites. Alternatively, T-cell lymphoma may occur in animals, particularly in dogs, with multiple plaque-like areas of skin involvement and characterized by a very anaplastic neoplastic population described below as anaplastic large cell lymphoma T/null cell primary cutaneous type.

The panniculitis type of lesion in humans outwardly resembles a focus of fat necrosis and cases apparently may go through multiple biopsies before the diagnosis is changed from chronic panniculitis to T-cell lymphoma, assisted by increasing anaplasia in the neoplastic cells with disease progression. The neoplastic cells of human panniculitis like T-cell lymphoma express most T-cell antigens and they are usually CD8 positive but may be CD4 positive and express cytotoxic granule proteins TIA-1 and perforin. Most human cases express the αβ TCR rearrangement of occasional cells derived from γδ T cells. Remarkably, there is a high proportion of human cases of panniculitis that progress to a fatal hemophagocytic syndrome. The latter form of the disease progression does not appear to have a counterpart recognized in animals.

Mycosis fungoides/Sézary syndrome

Mycosis fungoides occurs in humans and animals, where it is seen most frequently in dogs, but also occurs in cats and rarely in other domestic animals. *One of the more common presentations in animals is in the cutaneous type of T-cell lymphoma characteristic of 2-year-old cattle*

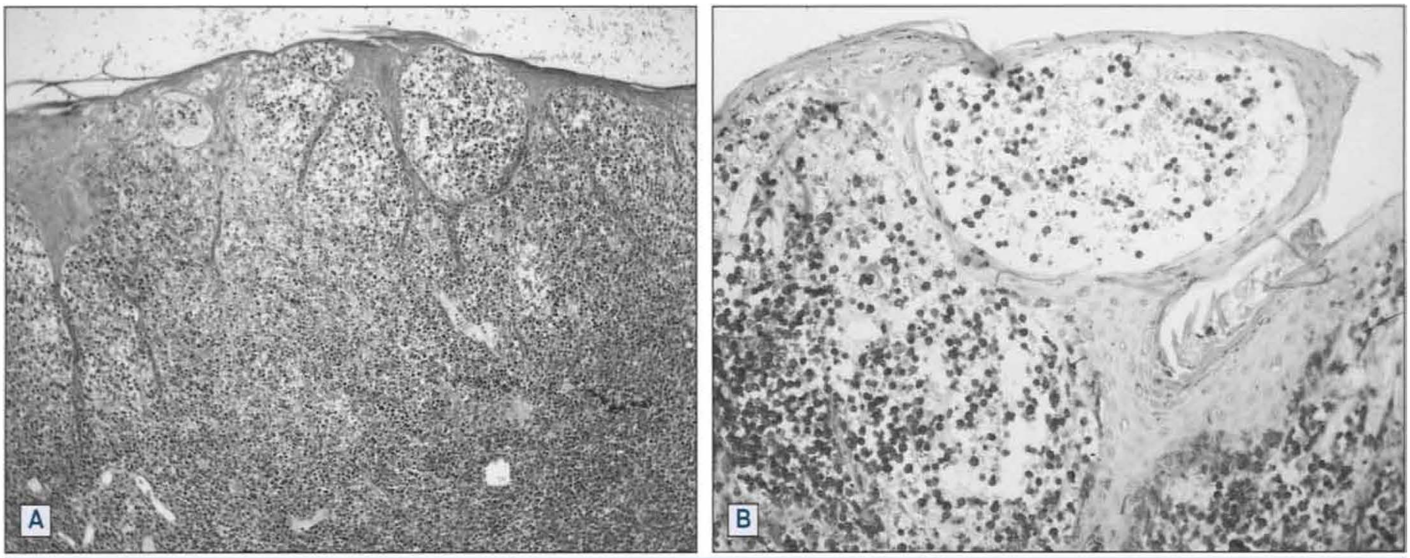

Figure 2.61 Mycosis fungoides/Sézary syndrome, skin, cat. **A.** There is marked cellular invasion of the reticular and superficial dermis with irregular cavitation of the epidermis and colonization of neoplastic cells. **B.** CD3 staining demonstrates T-cell phenotype of cells in superficial dermis and intraepithelial cysts (Pautrier's microabscess).

where the disease is not associated with Bovine leukemia virus. In the cow, the disease occurs as multiple plaque-like lesions with depilation and often ulceration, apparently due to irritation and rubbing on the part of the host. There may be systemic progression of the disease in dogs and cats, as is characteristic for cattle. These lesions wax and wane over a period of time and may become quite large, up to 10 cm or more in diameter, and because of the tendency of the lesions to be circular, they have been mistaken for ringworm infestations. The disease progresses relatively slowly, but over a period of a year, the lesions become systemic with involvement of the liver, spleen, lymph nodes, and bone marrow with the appearance of relatively characteristic **Sézary cells**, with convoluted nuclei in the peripheral blood.

Mycosis fungoides in other animals is a characteristic presentation of **epidermotropic lymphoma**, with proliferation of neoplastic cells immediately adjacent to the epidermal basement membrane and the formation of *tumor cell cysts (Pautrier's microabscesses)* in the epidermis, which is characteristically thickened over areas of tumor formation (Fig. 2.61A, B). There is generally some degree of sclerosis of the papillary dermis in areas of tumor formation and the disease regularly progresses to epidermal ulceration. From the deeper surface, the lesions progress through the reticular dermis, but tend not to invade deeply into the underlying structures. In both the dog and cat, the epidermotropic type of cutaneous T-cell lymphoma is a *disease of mature animals* with a mean age of onset in both species of about 10 years. The subtype of epidermotropic lymphoma in which the neoplastic cells primarily colonize the hyperplastic epidermis, known as *pagetoid reticulosis* or *Woringer-Kolopp disease*, is a very rare occurrence in the dog, and may occur in other species (Fig. 2.62A, B). The disease is indolent, but apparently has the potential to progress to systemic lymphoma.

The cytologic features of epidermotropic lymphomas in animals are similar to those in humans with tumor cells of intermediate to medium size and nuclei with moderate irregularity in nuclear shape. Ultrastructurally, it has been shown that the cells of mycosis fungoides in animals, and particularly the cow, have *cerebriform or deeply enfolded nuclear membranes*, like the counterpart in humans, and retain these characteristics on progression to the leukemic form, with Sézary-type cells in the peripheral blood. The chromatin has a granular or large chromocenter distribution without parachromatin clearing, and nucleoli are usually not evident in histological preparations. The neoplastic cells in animals regularly mark with CD3 and in humans the tumor cells are typically CD2, CD3, CD5 positive, with variable expression of CD7, and most cases express the β type of T-cell receptor. Most human cases are CD4 positive and it might be expected that the same situation prevails in animals, which would explain the tendency for animals to rub or injure the sites of tumor formation, however in dogs at least, most cases are of CD8 type.

Anaplastic large-cell lymphoma, T/null cell, primary cutaneous type

Anaplastic large-cell lymphoma (ALCL) is defined as a neoplasm presenting in the skin without pre-existing lymphoproliferative disease and no current evidence of extracutaneous involvement at the time of diagnosis. ALCL, as it is described in humans, occurs in *mature dogs and cats*, and possibly in other species. In animals, ALCL appears to begin with involvement of the vessels of the papillary dermis and progresses to deep involvement of the dermis with irregular extension into subcutaneous structures. Cytologically, the tumors are characterized by remarkable irregularity of nuclear form with folded, indented and multinucleated shapes all present. Cytologically, the neoplastic cells have peripheralized chromatin, with irregular parachromatin clearing, and prominent but not large nucleoli (Fig. 2.63A–C). The neoplastic cells have relatively abundant cytoplasm, and cell boundaries are generally indistinct. ALCL of the primary cutaneous type in animals is accompanied by quite heavy infiltration of smaller benign cells of both B- and T-cell type. The tumor cells are highly variable on immunohistochemistry, and while they are negative for CD79α, they may also be negative for CD3, but in any particular lesion, some cells with highly atypical and presumed neoplastic nuclei are associated with positive CD3 cytoplasmic staining (Fig. 2.63C). Clinically, the disease may appear as a solitary plaque or as an erythematous nodule. The progression of the disease is not defined and, in some cases, extra patience may be curative.

In the human counterpart, the neoplastic cells mark for T-cell antigens and are usually CD4 and CD30 positive. In humans, the cutaneous form of ALCL is distinguished from the systemic form by the cells not expressing the ALK or epithelial membrane antigen.

Anaplastic large-cell lymphoma, T/null cell, primary systemic type

The primary systemic form of anaplastic large T- or null-cell lymphoma (ALCL) is defined as the neoplasm of large lymphoid cells with pleomorphic, often multi-lobated nuclei, abundant moderately basophilic cytoplasm, and a cohesive pattern of tumor expansion. The disease as it occurs in animals is rare, and is typically seen in a large breed dog of 1 year or less of age. The neoplastic cells in a particular case mark uniformly and strongly with CD3. The animals have a rapid onset of disease associated with edematous swelling of the limbs, with multiple areas of eryrthematous skin plaque oozing serum and lymphadenopathy. Cytologically, the tumor cells have the same anaplastic appearance as the primary cutaneous type with folded and multi-lobated neoplastic cells with peripheralized chromatin and prominent, often multiple, nucleoli with a moderate amount of cytoplasm. The lesions in the skin are characterized by deep involvement of the subcutaneous tissues and larger vessels, which are frequently invaded and obstructed by the neoplastic cells. There does not appear to be a particular angiotropism, but rather the tumor moving in a solid progression and tends to invade vessels, causing widespread necrosis and karyorrhexis. Lymph nodes have effacement of normal architecture with diffuse involvement of the glands and irregular bridging of the peripheral sinus with extranodal involvement (Fig. 2.64A–C). Animals are apparently not leukemic, but there is a tendency to involve the liver, spleen and gastrointestinal tract. In humans, the neoplastic cells are positive for CD30 and usually CD25 and ALK or epithelial membrane antigen. About 2/3 of human cases express CD3 and CD43. In the majority of human cases, the TCR genes are rearranged and 1/4 or more cases have no rearrangement of T-cell receptor or immunoglobulin genes. A t(2;5) translocation is present in up to 1/2 of human cases, which results in fusion of the nucleophosmin gene on chromosome 5 with a tyrosine kinase gene on chromosome 2 called *ALK* (anaplastic lymphoma kinase). In humans, the disease in both children and adults, while aggressive, seems to be potentially curable.

Peripheral T-cell lymphoma, not otherwise characterized

The category of peripheral T-cell lymphoma (PTCL) includes a spectrum of diseases in humans with the disease generally occurring in a lymph node or other lymphoid tissue, including spleen or Waldeyer's ring. *A variety of morphologic subtypes have been described with no consistent immunophenotypic, genetic or clinical features associated with them.* In humans, PTCL is typically composed of a mixture of small and large atypical cells which could be classified as diffuse, small-cleaved, mixed small and large, large cell or immunoblastic types, as used in the Working Formulation classification. The presence of an inflammatory background, including eosinophils and epithelioid macrophages, is common in some types of the tumors, with a subtype of these lesions characterized by focal clusters of histiocytes known as *lymphoepitheloid cells or Lennert's lymphoma.* Phenotypically, the neoplastic cells in humans are variable in antigen expression as in morphology, and mark variably for CD3, CD2, CD5, and CD7. CD4 is present more often than CD8, and the tumors may be double negative for CD4n and CD8. A more consistent finding is that B-cell associated antigens are always lacking. No specific cytogenetic or oncogene abnormality is identified with the variant subtypes of PTCL in humans.

PTCL in animals is equally lacking in definition, but several characteristic disease types occur. In the **dog**, the diagnosis of peripheral T-cell lymphoma is most often applied to a neoplasm of lymph nodes characterized by lesions with diffuse effacement of node architecture and the occasional occurrence of isolated, very large nuclei of 10 or more red cells in diameter (Fig. 2.65A–C). The lesions mark variably with CD3 and are negative for CD79. A much less common occurrence in the dogs is a subcutaneous lesion that resembles T-cell lymphoma of the panniculitis type, except that there is actual granuloma formation, and fat necrosis is a feature only at the periphery of these lesions. These neoplasms are remarkably pluricellular, with plasma cells, eosinophils, macrophages and fibroblasts. These lesions are usually subjected to multiple stains for identification of infectious agents or foreign bodies before neoplasm is suspected. The lesions are characterized by fine vessel proliferation and prominence with generalized sclerosis. The malignant T cells tend to cluster near the vessels and have relatively abundant cytoplasm. The nuclei are round, oval or indented with peripheralized chromatin, quite marked

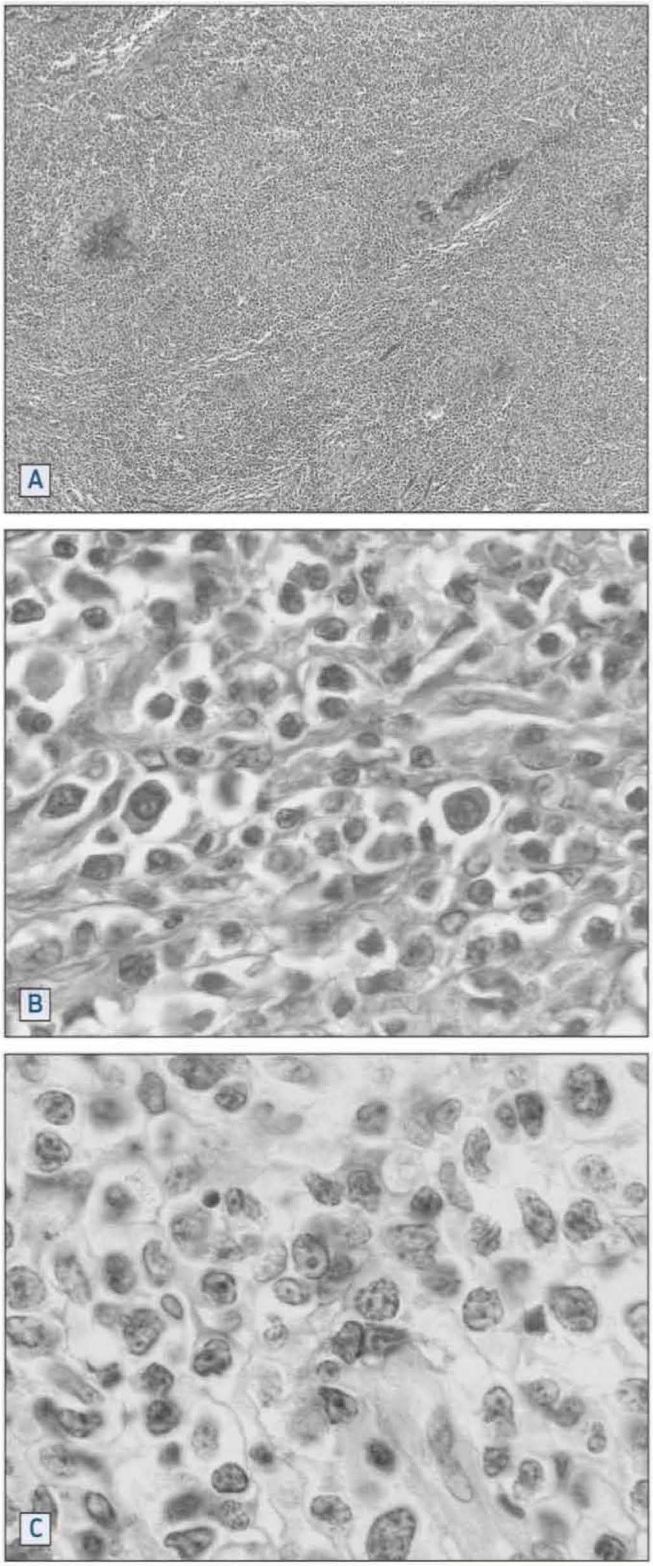

Figure 2.65 Peripheral T-cell lymphoma, not otherwise characterized, subcutaneous mass, abdomen, dog. **A.** The lesion has diffuse architecture with focal areas of necrosis surrounded by fibroblasts and large macrophages resembling an infectious granuloma. **B.** There is vibrant reticular sclerosis, mixed inflammatory cell type, including small, medium and large lymphocytes, eosinophils and plasma cells. Large cells with prominent nucleoli and relatively abundant basophilic cytoplasm occur singly, often near small vessels. **C.** CD3 staining demonstrating positive marking of a subset of large cells with atypical nuclei.

parachromatin clearing and a single prominent nucleolus that defines them as the only atypical-appearing cells in the lesion (Fig. 2.65B). Remarkably, these cells may constitute 5% or less of the lesion and appear to be a T-cell counterpart of the T-cell/histiocyte-rich B-cell lymphoma, where the neoplastic B cells are at the basis of the reaction but may be a small minority of the cells present. The neoplastic T cells mark irregularly with CD3, and the benign cells mark as would be expected for their lineage (Fig. 2.65C).

In the **cat**, peripheral T-cell lymphoma may take on a variety of histological subtypes, but characteristically is present in a cervical lymph node. These may become remarkably enlarged, and 4 cm or more in longest dimension, constituting discoid lesions lying on or beneath the jugular vein. Cases have been observed where the lesion may recur in the same site a year or more after the initial excisional biopsy, in a pattern of spread to contiguous lymphoid tissues not unlike that occurring in Hodgkin lymphoma in humans. The affected nodes have focal areas of benign follicular hyperplasia, but the major expansion is due to proliferation of medium-sized lymphocytes that resemble centroblasts with the scattered appearance of very large cells with nuclei 5 to 10 red cells in diameter and nucleoli as large as red cells. These atypical cells have abundant cytoplasm and are frequently undergoing single cell necrosis, with the cytoplasm becoming increasingly eosinophilic and retracting from surrounding cells. The nuclei are densely stained and pyknotic and progress to karyorrhexis but not apoptosis. There are scattered small lymphocytes and plasma cells throughout these lesions that mark strongly for CD79α, but the majority of the cells mark weakly for CD3 with the very large atypical cells often negative for both B- and T-cell reagents. These diseases in cats are remarkably indolent and tend to recur at the same site over a period of years. Neoplasms of this type in the cat have been called T-cell-rich/histiocyte-rich B-cell lymphoma, and it is likely that lesions of this type have promoted the feeling that a counterpart of Hodgkin lymphoma in humans may occur in the cat.

Angioimmunoblastic T-cell lymphoma

An initial description of human angioimmunoblastic T-cell lymphoma was termed "*angioimmunoblastic lymphadenopathy*" because the disease was not felt to be uniformly a malignant neoplasm. The initial definition was a lymphoproliferative disorder associated with systemic signs, generalized lymphadenopathy, hepatosplenomegaly, immunologic dysfunction, and polyclonal hypergammaglobulinemia. A latter finding of dysproteinemia prompted the use of the acronym **AILD** indicating *angioimmunoblastic lymphadenopathy with dysproteinemia*. Subsequently, the term "*peripheral (now mature) T-cell lymphoma*" was suggested to include neoplasms with mature T-cell proliferations with broader presentation than that defined for AILD. The similarities between peripheral T-cell lymphoma (PTCL) and AILD included diffuse architectural effacement of nodes, a pleomorphic lymphoid proliferation, and prominent postcapillary venules. PTCL was felt to lack the inflammatory component of plasma cells and eosinophils seen in AILD; however, it became apparent that neither description was sufficiently specific and overlap between the two conditions occurred. For economy of terms of understanding, *it has been suggested that AILD is a particular form of peripheral or mature T-cell lymphoma*. AILD in humans is characterized by a number of unique features that suggest it needs to be considered a separate disease entity. These include frequent concurrence with immunodeficiency, polyclonal hypergammaglobulinemia and occasionally the coincident appearance of clonal B-cell proliferation verified by immunoglobulin gene rearrangements. Since some cases considered to be AILD lack both clonal T- and B-cell receptor gene rearrangements, these may constitute a *benign form of AILD* that might progress to clonal proliferations.

The characteristic histologic features in humans are effacement of nodal architecture with peripheral sinuses open and occasionally dilated, but with focal tumor involvement of perinodal tissues. Likely, the most characteristic feature of AILD that appears to occur in animals as well as humans is the *prominent proliferation of high endothelial venules*, many of which have thickened or hyalinized walls and appear more eosinophilic than normal with H&E staining. There are focal aggregates of dendritic cells surrounding the small vessel proliferation that may suggest the presence of an obsolescent follicle. The lymphoid complement is variable and consists of small-cleaved cells, others resembling the larger type of centrocytes and centroblasts, plus plasma cells, and finally large immunoblasts. The latter have a vesicular appearance with peripheralized chromatin, irregular thickening of the nuclear membranes and finely branched chromatin extending from a large central nucleolus to the nuclear membrane. Cytoplasm is usually abundant and pale staining.

AILD cells in humans mark with T-cell-associated antigens and usually CD4, but many CD8 positive cells can be present and may be benign. The follicular dendritic cells mark with CD21, and identification of the FDCs adjacent to fine vascular proliferation is an important diagnostic feature. Genetic changes include rearrangement of T-cell receptor genes in 3/4 of the patients, and an immunoglobulin heavy chain in 10% of cases, with Epstein-Barr virus (EBV) genomes apparently frequently detected and may be found in either T or B cells.

The clinical presentation in humans includes generalized lymphadenopathy, fever, weight loss, recurrent skin rashes, polyclonal hypergammaglobulinemia, and a history of recurrent infections. The course tends to be aggressive.

AILD in animals is most often seen as the disease of lymph nodes in dogs. The most characteristic changes are diffuse effacement of nodal architecture with atrophy of germinal centers and prominent arborization of small vessels with thickened endothelial walls (Fig. 2.66A–C). Numerous cells are marked with both CD79α and CD3 reagents, but the immunoblastic-appearing cells with the prominent single central nucleolus typically mark convincingly with CD3. Dogs with AILD tend to have a history of recent loss of weight and appetite, but the presence of dysproteinemia and unusual susceptibility to infections has not been recognized.

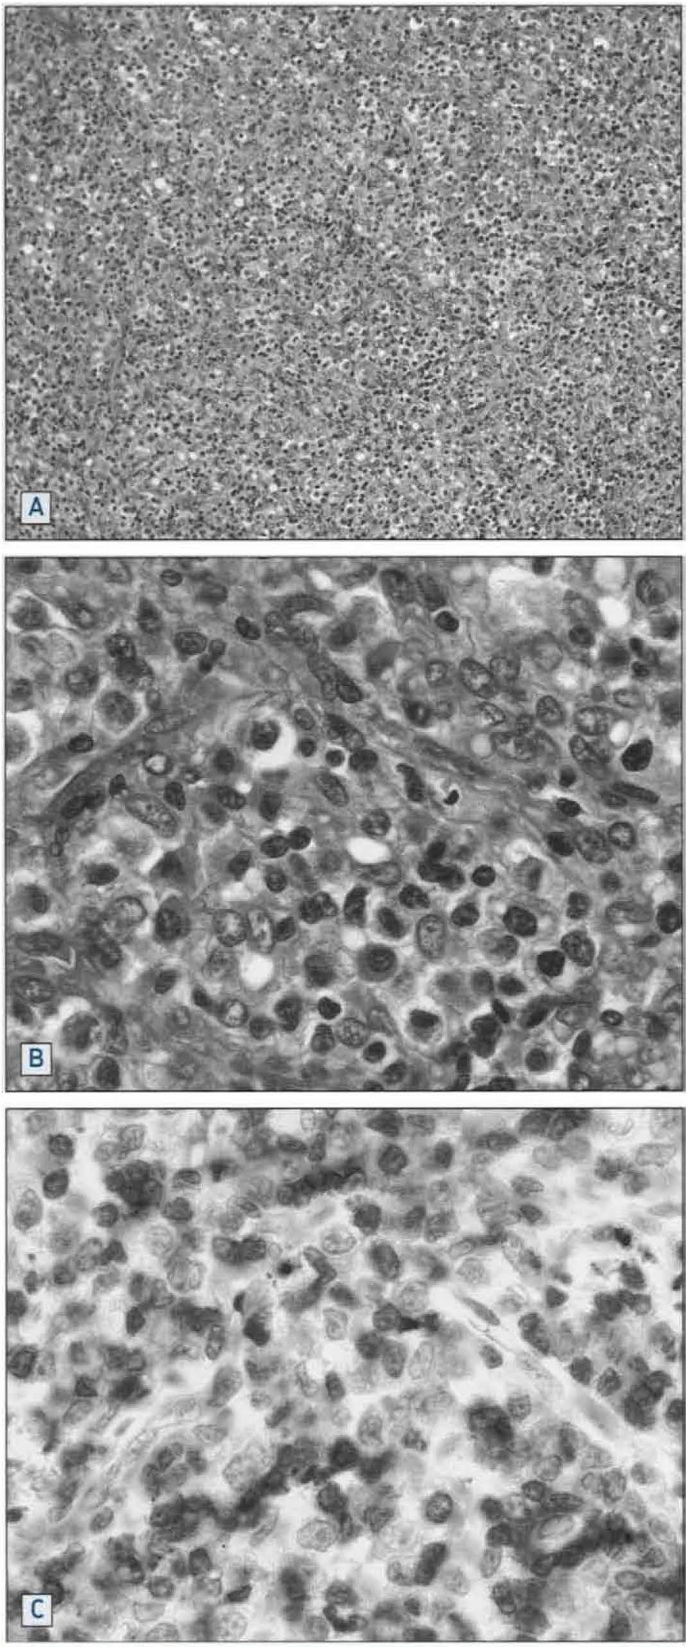

Figure 2.66 Angioimmunoblastic T-cell lymphoma, node, dog. **A.** There is obliteration of normal node architecture with a very prominent pattern of small vessel proliferation. **B.** The cellular infiltration is variable, including small, medium and large lymphocytes, plasma cells, fibroblasts and endothelial cells. **C.** CD3 stain demonstrating marking of small, medium and large cells as phenotypically T-cell derived. On staining with CD79α, only cells with plasmacytic appearance were marked.

Hodgkin lymphoma

Recent technology permitting analysis of genes in single cells using polymerase chain reaction provided new information on the origin of **Reed-Sternberg (RS) cells** in Hodgkin lymphoma. Current classifications of Hodgkin lymphoma include the *three subtype categories – nodular sclerosis, mixed cellularity, and lymphocyte depletion* – in the single designation of *classic Hodgkin disease*. This grouping is to draw attention to the close histologic similarities among these subtypes of Hodgkin lymphoma and their distinction from the lymphocyte-predominant subtype. *There is ongoing concern with the definition of the lymphoid-predominant type of Hodgkin lymphoma because of the close similarity between this disease and some cases of T-cell-rich B-cell lymphoma.* It is in the possibility for confusion between these latter two diagnoses that consideration of Hodgkin lymphoma is of concern to animal pathology. The possibility for a variant form of Hodgkin lymphoma in animals is plausible, since *while Hodgkin lymphoma is generally not considered to occur in animals, the T-cell-rich B-cell lymphoma is recognized in most domestic species.*

An unusual lymphoma occurs in **cats** that has a unique presentation, morphology and biology. Animals 10 or more years of age are presented with an enlarged cervical node that may be >4 cm in length, discoid in shape and unilateral. They are encapsulated and relatively mobile, but excision may be followed in months or a year or more by regrowth apparently in another node in the same or contiguous area. Histologically, they resemble the T-cell/histiocyte-rich variant of large B-cell lymphoma in having a background of sclerosis with small and medium T cells, but scattered huge cells with nuclei 10 or more red cells in diameter and relatively abundant cytoplasm. These cells are variable in size and shape and may occur in binucleated forms with large nucleoli suggesting similarity to Reed-Sternberg cells of human Hodgkin lymphoma (Fig. 2.46B). The nuclei of these large cells mark with CD79α, but their cytoplasm does not or only rarely. They are positive with BLA36 and are frequently undergoing single-cell necrosis, like the RS cells of Hodgkin lymphoma. Like the situation in human pathology with the T-cell-rich/histiocyte-rich B-cell lymphoma, *this disease in cats is not well characterized.*

Single-cell studies from the classic grouping of Hodgkin lymphoma point to the *origin of the RS cell from a postgerminal center B-lymphocyte that has undergone immunoglobulin gene hypermutations.* In contrast, single-cell studies on RS cells from lymphocyte-predominant Hodgkin lymphoma have shown that these appear to be derived from B cells undergoing continued mutations within clonal immunoglobulin gene rearrangements. *This suggests that somatic hypermutation of immunoglobulin genes in RS cells appears to be an ongoing* *process in lymphocyte-predominant Hodgkin lymphoma.* Since the RS cells of classic Hodgkin disease are not characterized by ongoing mutations and appear to be derived from postgerminal center memory B-cells, there appears to be major differences in these genotypic subsets.

Others have suggested that the RS cells of Hodgkin lymphoma might be derived from follicular dendritic cells. This approach is prompted by the finding that both follicular dendritic cells and the RS cells of Hodgkin lymphoma mark with CD21 antibody. In one review, a subgroup of Hodgkin lymphoma had RS cells that expressed CD21 without any other B-cell marker. Further, in this subgroup of patients, none had RS cells with rearrangements of either the immunoglobulin heavy chain gene or the T-cell receptor genes. Other studies have suggested that the RS cells have clonal T-cell receptor gene rearrangements and expression of T-cell antigens. It has been further demonstrated that in some cases, RS cells have the presence of cytotoxic molecules including granzym-B, perforin and TIA-1 that are normally found in cytotoxic T lymphocytes and natural killer cells. Since these RS cells did not express other markers of natural killer cells, but did express T-cell antigens, *these RS cells appear to be derived from cytotoxic T lymphocytes.* It was concluded that the derivation of RS cells from T lymphocytes and in particular cytotoxic T-cell lymphocytes appears to occur in a small percentage of cases of classic Hodgkin lymphoma.

These findings demonstrate that *Hodgkin lymphoma represents a spectrum of diseases in which it is becoming clear that subtypes identified by immunophenotypic analysis have strong prognostic importance.* There is, therefore, an effort to redefine Hodgkin lymphoma with the incorporation of immunologic criteria in order to differentiate Hodgkin lymphoma and the RS cell from cases of non-Hodgkin lymphoma that are histologically similar and in some cases morphologically indistinguishable. The succinct definition of Hodgkin disease that unifies the different histologic subtypes is the *identification of diagnostic Reed-Sternberg cells in the appropriate cellular environment.* To assist this definition, the *immunological criteria for identifying RS cells in classic Hodgkin lymphoma include*: CD15-positive, CD30-positive, vimentin-positive, fascin-positive, CD40-positive, CD45-negative, CD20-plus/minus, CD3-negative, EMA-negative, and ALK-negative. The appropriate cellular environment is described as a surrounding population of T cell, predominantly CD4-positive and TIA-1-positive. *Veterinary pathologists will need to be aware of these criteria in proposing that lymphoproliferative diseases in animals may be a counterpart of human Hodgkin lymphoma* (Fig. 2.67A–C).

Lymphoma in animals

The general pathology and classification of lymphoma are discussed in the preceding sections. The following sections deal with the epidemiologic and topographical aspects of lymphoma in several domestic species.

Bovine lymphoma

Lymphoma in adult cattle is very largely the **enzootic bovine leukosis form** *associated with retroviral infection* that is transmitted horizontally by direct contact, including natural breeding and accidental transmission by contaminated needles, ear-tagging and dehorning equipment and by the use of whole-blood vaccines. Infection, once established, is lifelong and is characterized by the development of circulating antibody, which is also present throughout life. Antibody levels tend to increase with the number of viral antigens recognized, as the animal passes from an asymptomatic carrier, to lymphocytosis, and to tumorous state (should malignant disease develop). *Bovine leukemia virus (BLV)* is highly cell-associated, and viremia does not occur unless in the period immediately following infection and before antibody is formed. The virus survives in proviral state in bone marrow-derived lymphocytes and monocyte/macrophages, which may be induced to release the C type retrovirus on short-term in vitro culture in the absence of antibody.

The dynamics of infection in a particular animal and the spread of virus within a herd are highly dependent on genetic factors in both the virus and cattle. Progression of infection in an individual animal to persistent lymphocytosis is under control of the bovine major histocompatibility complex mapping adjacent to *BoLA* class II genes. Resistance factors in some animals control the rate of progression and result in reduced numbers of viral-infected cells and lower cell counts, both of which would tend to reduce the likelihood that resistant animals would transmit the infection. Transmembrane motifs are required for both infectivity and for viral propagation within an infected animal. Five of 10 animals' BLV-induced lymphomas were found to have mutations in the P-53 tumor suppressor gene. This information fits the observed phenomena that *only a very small percentage of BLV-infected cattle go on to develop lymphoma*, suggesting that dysregulation of both P-53 alleles must occur for malignant transformation of bovine B lymphocytes. The interaction of other agents in inactivation of the P-53 genes needs to be considered, including bovine papilloma and herpesviruses as well as pesticide exposure, which would correlate with the higher incidence of lymphoma seen in dairy cattle. The demonstration of concurrent infections with *Bovine immunodeficiency virus* and *Bovine syncytial virus* indicates further factors that may be involved in the progression of the BVDV infection in an individual animal.

The transformed phenotype of bovine lymphoma suggests that most cells are naive B cells with rearranged immunoglobulin genes, but have not undergone hypermutation or antigen-driven germinal center mutations. There appears to be some increase in transmission during the summer months, suggesting that biting insects might be vectors. It is, however, possible to maintain infected and noninfected herds on the same premises for prolonged periods with reasonable isolation procedures, which *suggests that direct contact is the primary mode of transmission*. Some herds tend to have a very high level of infection, whereas others have a low level of infection, and the proportions of infected animals tend to remain relatively stable over long periods. There is likely a genetic basis for this phenomenon.

Less than 3% of infected animals develop malignant disease, and then only if allowed to survive to the age of peak incidence at 6–8 years. Since viral transmission occurs primarily in closely confined dairy herds, and currently the rate of culling in dairy herds in North America is 20–30% per year, the number of cases of lymphoma appears to be dropping, while the infection rate remains relatively constant. In addition, the development of blood testing for BLV infection has permitted early identification of diseased animals, which are therefore more likely to be found at slaughter than in a clinical setting. Infected cattle which do not develop lymphoma appear to have few other specific problems related to retroviral infection, but may suffer a higher rate of culling for a variety of reasons that may be the result of subtle effects of the host–parasite relationship. *The sporadic forms of bovine lymphoma are not associated with BLV infection.*

Enzootic bovine lymphoma is therefore a disease of mature onset. Hematologically, the animals are normal or nearly so, without anemia or thrombocytopenia. There is a fluctuating lymphocytosis of moderate degree, which is the characteristic response of the cow to infection that is rather well controlled, and also occurs in trypanosomiasis and tuberculosis, and to a lesser extent in brucellosis. In herds in which the disease is endemic, infection is likely acquired in the first year of life. There may be little or no apparent effect of this exposure, but it does serve to perpetuate the virus in the herd. There may be a long period of occult transformation before clinical tumor develops. Cattle with the enzootic form of lymphoma react in lymphocyte stimulation tests against a membrane antigen derived from tumor lymphocytes, which constitutes a diagnostic test for occult tumor. This test remains positive until the later stages of the clinical disease when the animals become anergic. The same membrane antigen when given as a vaccine prevents lymphoma, but not BLV infection, in sheep subsequently challenged with live virus.

Clinically and morphologically, enzootic bovine lymphoma is subdivided on a topographic basis depending on the major organ systems involved. The most common presentation is an *enlarged lymph node* characteristically seen in high-producing dairy cows. Enlarged nodes may appear anywhere in the body but are common in the retrobulbar area where they cause unilateral or bilateral proptosis, and in the pharyngeal area where they result in dysphagia and stertorous respiration. The disease is frequently diagnosed on a pelvic examination on the basis of enlarged inguinal lymph nodes or involvement of the urogenital system.

The *enteric form of the disease* is, at least grossly, part of most cases and is characterized by diffuse thickening of the abomasal submucosa with eventual ulceration leading to hemorrhagic anemia. The latter tendency for gastric and also uterine homing suggests that, in many cases, the transformed lymphocytes are relatively mature and possess receptors allowing them to accumulate locally as a mucosal-associated lymphoid tumor. There is irregular involvement of the mesenteric nodes associated with the abomasal infiltration and these may, at times, be large enough to cause obstruction.

Hindlimb lameness, which progresses quickly to weakness and recumbency, reflects the spread of tumor from sublumbar nodes to the *spinal canal* where there is a relatively diffuse infiltration into the perineural fat and heavy involvement of the sheaths of the spinal nerves. Grossly, the perineural infiltration has only a slight fleshy pinkness to distinguish it from normal fat, although the distinction is readily made by an imprint of the affected tissues.

Animals occasionally are presented with signs of *central venous congestion* due to preferential involvement of the right atrium, colonization of the epicardial fat and irregular and often heavy infiltration into the myocardium that may be accompanied by tamponade.

Almost any organ can be involved, but *the liver is involved in most animals, as is the spleen*. Some cows die rapidly because of splenomegaly with rupture and abdominal hemorrhage. Rarely, the kidneys are primarily involved in a herd outbreak of lymphoma, again suggesting specific homing, in this case to renal tissue. Females may occasionally have primary and extensive involvement of the uterus and ovaries. On largely anecdotal evidence, it appears that cows that have been repeatedly superovulated for embryo transplant purposes may be more likely to develop lymphoma of the reproductive system. There is usually cytologic involvement of bone marrow in terminal cases which may become leukemic with very high cell counts, or rarely there is lymphopenia, but myelophthisis as is seen in the lymphocytic leukemia in the calf form is a rare occurrence. The hemolymph nodes are usually involved and occasionally they may be visible clinically as subcutaneous discoid masses 1–2 cm in diameter. The histologic type is consistent throughout the body and the duration of the disease is usually a matter of weeks once the disease has been recognized.

The **sporadic forms of bovine lymphoma** are not associated with BLV infection. They include the *calf type*, which is characterized by symmetrical lymphadenopathy and leukemia, the *juvenile type* with thymic lymphoma in yearlings, and the *skin type*, which occurs most often in 2-year-old cattle. These three sporadic types of bovine lymphoma do not react to membrane antigen from the enzootic form of bovine lymphoma in lymphocyte stimulation tests. As their name suggests, these diseases occur sporadically. It is not clear whether other viruses are involved in their genesis.

The **calf type** of lymphoma may be present at birth, but usually develops in the first 6 months of life and typically has symmetrical enlargement of lymph nodes. There is leukemia with leukocyte counts varying from 10 to 100×10^9/L, nonresponsive normochromic, normocytic anemia, and thrombocytopenia. Terminally, there is virtually complete myelophthisis and marrow infarction (Fig. 2.68) with neutropenia and thrombocytopenia but without hemorrhage. At autopsy, virtually all nodes are enlarged up to 10 times normal size, and the kidneys are usually diffusely involved but may not be markedly enlarged. The liver and spleen may be massively involved, or relatively spared. Calves may be born with lymphoma with the liver so enlarged at parturition as to cause dystocia. The cell type in the blood of the calf type of lymphoma resembles the L1 type of ALL, and histologically the nuclei are round and irregular in size and shape resembling Burkitt-type lymphoma. The phenotype of the calf-type tumors appears not to have been determined. The thymus is usually normal or atrophic, and skeletal muscle and even bone may be focally invaded by tumor.

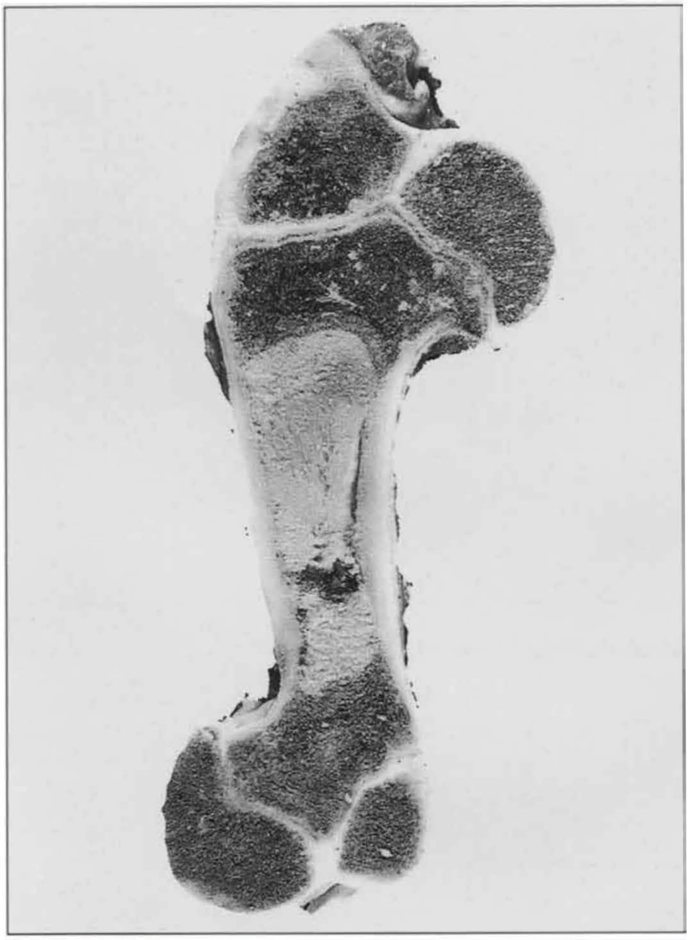

Figure 2.68 Lymphoma in a calf. Medullary infarction in humerus.

The **thymic form** of bovine lymphoma is described under diseases of the thymus (Thymic neoplasia, below). Most cases remain aleukemic.

The **skin form** of bovine lymphoma typically occurs in 2- to 3-year-old cattle, and is characterized by plaque-like, round, raised lesions which appear on the head, sides, and perineum, become depilated, and are frequently ulcerated. The lesions wax and wane over a period of months with some regressing entirely and new lesions appearing. The disease is remarkable in its indolent nature as compared to the other forms of lymphoma in cattle, and animals allowed to survive may do so for 12–18 months. Ultimately, there is deep organ involvement, and the visceral lesions are then indistinguishable from those of the enzootic type of bovine lymphoma. The skin lesions have architectural specificity and are dermotropic and characteristically result in dense infiltrations of tumor cells in the papillary dermis. There is focal invasion of the epidermis (Pautrier's microabscess) and, in the early stages, the disease resembles mycosis fungoides of humans but is more focally distributed, and in the advanced state with leukemia resembles Sézary syndrome. The tumor cells are of moderate size, with a very narrow rim of cytoplasm, and have cerebriform convolutions of the nuclear membranes. The skin form of bovine lymphoma is described under T-cell lymphoma of mycosis fungoides type.

Ovine and caprine lymphoma

Ovine and caprine lymphomas are widely disseminated tumors similar to the calf or juvenile type of bovine lymphoma, but without leukemia and marrow involvement. A retrovirus indigenous to sheep shares major proteins with *Bovine leukemia virus* (BLV); however, most spontaneous lymphomas of sheep and goats, and virtually all of the those produced experimentally, are *caused by BLV*. Lymphoma can be produced in sheep in 30–60% of animals 2–3 years after infection with BLV. In sheep, as in cattle, infection with BLV once established is lifelong, and the virus persists in integrated provirus in the face of a strong and persistent antibody response. Unlike cattle, the host–parasite relationship between BLV and sheep does not produce persistent lymphocytosis but does produce tumor, and the earlier that lambs are infected, the greater will be the proportion of infected animals that develop lymphoma. Unlike cattle, BLV is able to induce lymphoma in sheep without prior mutations in the wild-type P53 tumor suppressor genes. It appears that, unlike cattle, some sheep after exposure to BLV will develop transient antibody and then are free of infection.

In sheep, BLV infection can be detected by the tests used for diagnosis in cattle. Sheep that develop lymphoma react in lymphocyte stimulation tests against membrane antigen derived from BLV-associated bovine lymphoma, providing a test for the presence of occult tumor.

Morphologically, there is a characteristic and consistent portal involvement of the liver, and there is often hepatomegaly. The spleen is symmetrically enlarged with focal and diffuse involvement and the heart and kidneys are often very heavily infiltrated. Histologically, the tumors are largely of the Burkitt-like (small-noncleaved cell type) with B phenotype and diffuse architecture. The disease has a very rapid course with most animals dying within 1–2 months of clinical diagnosis.

Equine lymphoma

Lymphoproliferative disease in the horse, like that in the cow, has several characteristic topographically and cytologically distinct modes of presentation as *primarily leukemia or lymphoma.* In the **leukemic form**, which usually occurs in racing animals in training, there is primary marrow involvement with pancytopenia and severe thrombocytopenia, sudden onset of malaise, subcutaneous edema, and petechial hemorrhages. The bone marrow is diagnostic with myelophthisic destruction of normal cells by lymphocytes of the L2 or L3 type (see acute lymphoblastic leukemia; Fig. 2.31). The clinical course in this form of disease is less than a week. More commonly, the cells are more differentiated and typical of chronic lymphocytic leukemia, with leukemic lymphocytosis and the course is much longer. A disease like **mycosis fungoides** of humans occurs in horses, and progresses to a form of chronic lymphocytic leukemia with convoluted tumor cells like the human Sézary syndrome. The skin lesions may be minimal and confined to the mucous membranes, which are brick red and do not blanch on compression. Histologically, the tumor cells are dermotropic and of medium size, with cerebriform nuclear indentations, and mark positively with CD3.

The **solid forms** of lymphoid tumor in the horse can be characterized as *subcutaneous, alimentary, abdominal, splenic and thymic/multicentric.* **Subcutaneous** lymphoma is remarkable because of the indolent nature of the disease with some animals surviving for years, and because it occurs very predominantly in females. Regression of the disease has been observed during pregnancy and following removal of an ovarian granulose-theca cell tumor. A subsequent study of 29 cases of equine lymphoma for estrogen and progesterone receptor expression found that all cases were negative for estrogen receptors, but 16 of 29 were positive for progesterone receptors, of which 7 cases were of the T-cell-rich large B-cell type lymphoma. Affected animals may maintain body weight for many months, but are unsightly because of hundreds of subcutaneous masses 1–3 cm in diameter or larger. The lesions cluster on the lower half of the body, particularly on the chest, thorax, flanks and perineum, sparing the limbs and often involving the face and neck. One of the major reasons for biopsy of these animals is that an otherwise vigorous animal cannot be bridled or saddled without impinging on the masses. Histologically the tumors are truly subcutaneous, likely arise along lymphatics, and rarely involve the deep dermis which tends not to be fixed over them. Cytologically they are also diverse, but distinctive, and are *composed of a predominant population of benign small-cleaved T cells, and a minor population of large malignant B cells with prominent nucleoli.* Most of the small cell population marks positively with CD3 and the atypical large cells are positive with CD79α (see Diffuse large B-cell lymphoma). Characteristically, these subcutaneous neoplasms are interlaced at the cellular level with fine reticulin fibers, and on an architectural level with collagenous bands. Ultimately, there is involvement of regional lymph nodes, but deep organ involvement does not regularly occur in the time that most are allowed to survive. They remain hematologically normal, except for mild progressive anemia and hypoproteinemia. A second type of T-cell-rich B-cell lymphoma occurs in horses involving the dermis, and characteristically is seen as a protruding dorsolateral periorbital lesion 2–3 cm in length, with ulceration. Histologically, the lesions are sclerosing, but their most remarkable characteristic is a tendency to recur locally even after careful dissection. In all forms of the diffuse mixed tumor, the mitotic rate is very low and consistent with the indolent rate of progression.

The **alimentary form** of lymphoma occurs in adults that are characteristically thin, with reduced appetite and may be colicky, but usually do not have diarrhea. Anemia may be mild or quite severe, normocytic, and with hypoproteinemia. There is usually some degree of neutrophilia, with signs of toxemia due to ulceration of the intestinal mucosa, but leukemia is not present. There may be alpha heavy chain paraproteinemia as in Seligman's Mediterranean lymphoma of humans, but this aspect has not been frequently investigated. Some animals with this form of tumor will have hemolytic anemia that may dominate the clinical picture. Grossly, the peripheral and internally palpable lymph nodes are normal and the disease is difficult to diagnose short of an open biopsy. *The disease tends to be confined to the upper small bowel, pancreas and regional nodes, but there may also be involvement of the ileum* (Fig. 2.69A, B). There is laminar thickening of the intestinal wall with tight homing of the infiltrate to the muscularis mucosa and submucosa and relative sparing of the muscularis. The tumor cells are uniformly plasmacytoid, with round nuclei 1.5 red cells in diameter, and abundant highly basophilic and eccentric cytoplasm. There is mild nuclear atypia with nucleoli not generally present in mature-appearing plasma cells, hyperchromatic chromatin

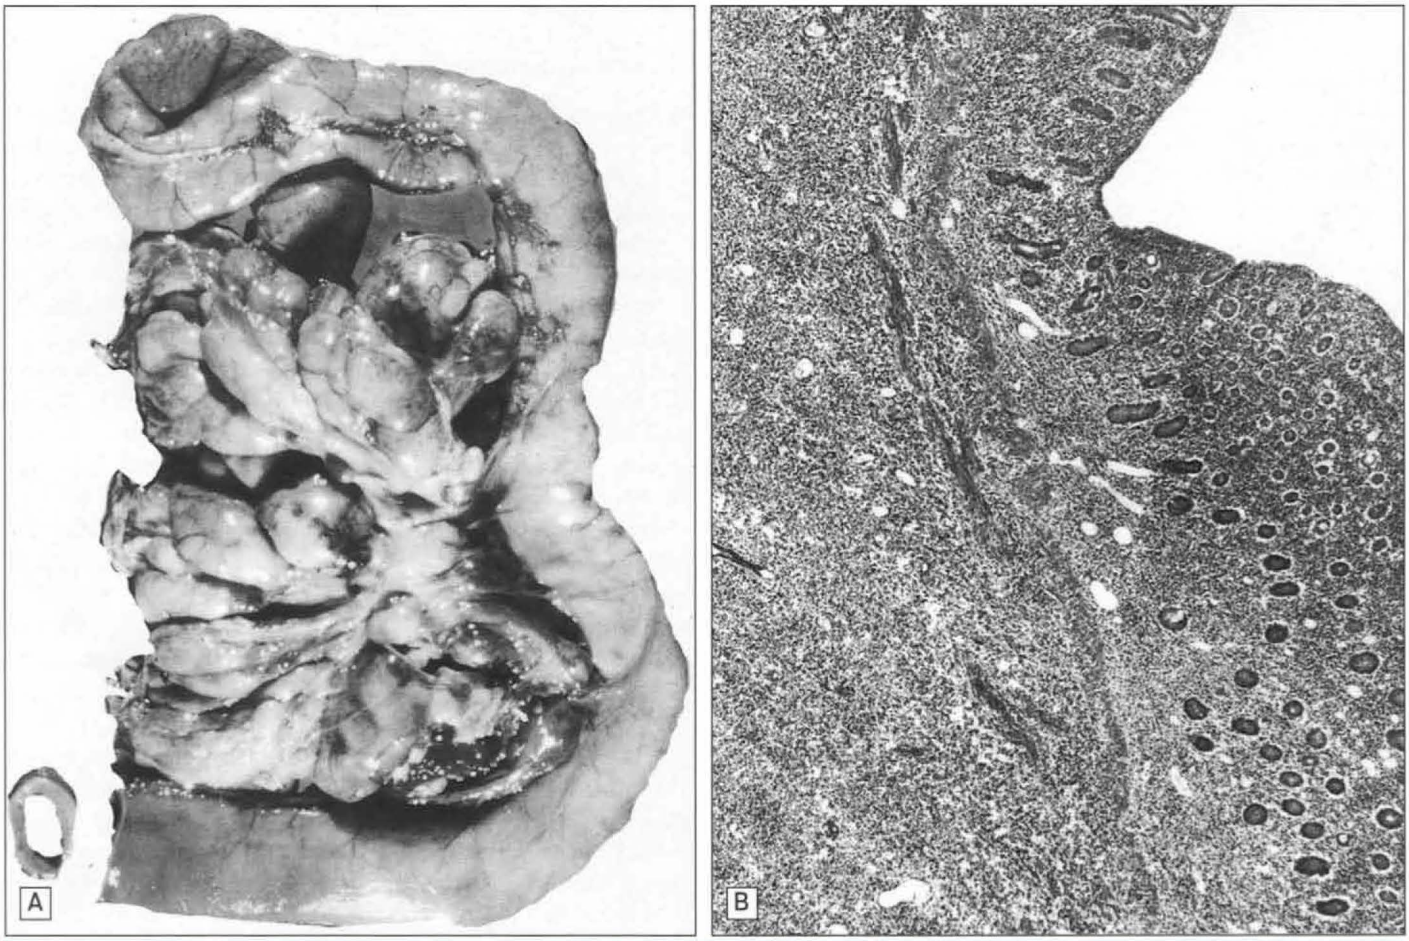

Figure 2.69 Lymphoma in a horse. **A.** Diffuse infiltration of duodenal wall and replacement of pancreas. **B.** Section of intestine of (**A**). The infiltrates may be confined to the mucosa but usually involve full thickness.

with an exaggerated heterochromatin clumping, and a low mitotic rate. Cytologically, in imprints, the tumor cells may be mistaken for plasma cell hyperplasia if the extent of the gross lesion has not suggested tumor. There is focal thinning and ulceration of the intestinal epithelium, and the tumor cells have the same morphology in the affected nodes, which tend to have thickened capsules and atrophy of normal cells. One is left with the impression that the disease begins as benign immune inflammation and progresses to lymphoma, albeit of well-differentiated type. The disease is an example of a well-ordered mucosal-associated lymphoid tumor with homing of the tumor cells to the submucosa until very late in the disease.

The **abdominal form** of equine lymphoma is not usually difficult to diagnose clinically because *tumor masses involve the large bowel and caudal abdominal nodes*. Clinically, the animals are thin and have poor appetite, dependent edema and recurrent diarrhea. The hematologic changes are typical only of chronic disease and inflammation. Grossly, there is widespread tumor in the abdominal cavity and there may be involvement of nodes in the thorax. There is splenomegaly, involvement of the hepatic hilar nodes, irregular thickening of the wall of the small and large intestine, and focal mucosal ulcers. There may be huge tumorous masses involving the intestinal serosa and mesenteric nodes. Histologically, the tumors are variable, but tend to be diffuse neoplasms of large B-cell type with quite a high mitotic rate. An undefined proportion of the abdominal form of equine lymphoma, particularly those with mediastinal involvement, appear to be neoplasms of the large granular lymphocyte type.

Splenic lymphoma is an isolated lesion that involves the lower part of the organ with a huge mass that may weigh 15 kg or more. This lesion is not usually palpable rectally and the superficial nodes are not enlarged. The animals are presented with responsive hemolytic anemia, and idiopathic immune or infectious equine anemia is usually suspected. There is an upward shift in the MCV and increased anisocytosis. Leukemia is not present, and the bone marrow is hyperplastic with an erythroid shift and synchronous maturation. The pathogenesis of the anemia appears to involve hypersplenism due to trapping of cells in the normal spleen adjacent to the tumor. Immune hemolysis may contribute as it does in other lymphoid tumors, but this has not been verified. Pathologically the disease usually is limited to the spleen, but occasionally adjacent organs are involved by direct extension. The tumors are of large B-cell type, typically with an immunoblastic nuclear configuration with a large single central nucleolus and a moderate amount of quite highly basophilic cytoplasm. The neoplastic cells mark with CD79α. Frequent use of ultrasound should permit the diagnosis of splenic lymphoma by directed needle aspiration. The major feature of this lesion is the difficulty in clinical diagnosis, and most cases are diagnosed at necropsy.

Multicentric lymphomas have a wide age range, but most occur in mature animals. Affected animals are usually in poor condition but continue to eat, and often have low protein levels and dependent edema. Many of these animals have a mediastinal mass as well as irregular enlargement of peripheral nodes, particularly those in the pharyngeal and mandibular area. Any of the superficial nodes may be involved, but the involvement is not symmetrical. Leukemia is occasionally present, but usually the blood is more typical of cachexia. Grossly, there is widespread tumor in the abdominal cavity, and often there is tumor in the mediastinum with involvement of the heart and even the lung. Cytologically, the tumors are not of consistent cell size, but most are large-cell lymphomas and may be of B- or T-cell type, and even the T-cell-rich B-cell lymphomas are found in the thorax.

Lymphoma in the horse, as in other species, may be very variable and primarily involve other tissues such as the central nervous system and urinary system.

Canine leukemia/lymphoma

Hematopoietic tumors in urban dogs occur at an age-adjusted rate of some 30/100 000. It appears that the referral rates for leukemias and lymphomas at teaching institutions may not accurately reflect actual incidence of these neoplasms. Practitioners may be more willing to refer leukemias than lymphomas, but because of their perceived poor prognosis, leukemias appear less likely than lymphomas to be properly worked up for treatment.

Acute lymphoblastic leukemia in the dog has been inadequately studied from a phenotypic standpoint, but it appears that B-, T-, and null-cell types all occur, and there are indications that, in the dog, T-cell phenotype may predominate in ALL as it does in CLL. In the dog, 3/4 of a large series of well-characterized cases of CLL were found to be of T-cell type and more than 1/2 of all cases were CLL of large granular lymphocyte (LGL) type. The LGL cells of canine CLL are almost all CD8 positive and are predominantly of the αβ T-cell receptor type, with about a third having the γδ receptor configuration. Canine B-cell CLL is positive for CD21 and CD79α. Recent studies in human pathology indicate that the numbers of bone marrow blasts required for the diagnosis of leukemia have reduced markedly, and it appears that if 20% or more of marrow cells are blasts with a peripheral blood picture of ALL, a diagnosis of leukemia is confirmed. On the other hand, with CLL, the marrow is more likely to be occupied by a very high proportion of lymphocytes of which only a small proportion will be blasts, but the diagnosis is more easily reached because of very high lymphocyte counts in the peripheral blood (see ALL and CLL). Some progress has been made in genotypic characterization of canine lymphoma, with trisomy 13 found as a primary chromosomal abnormality in 25% of cases studied, and this finding was associated with a better prognosis. Unfortunately, the morphologic subtype of lymphoma associated

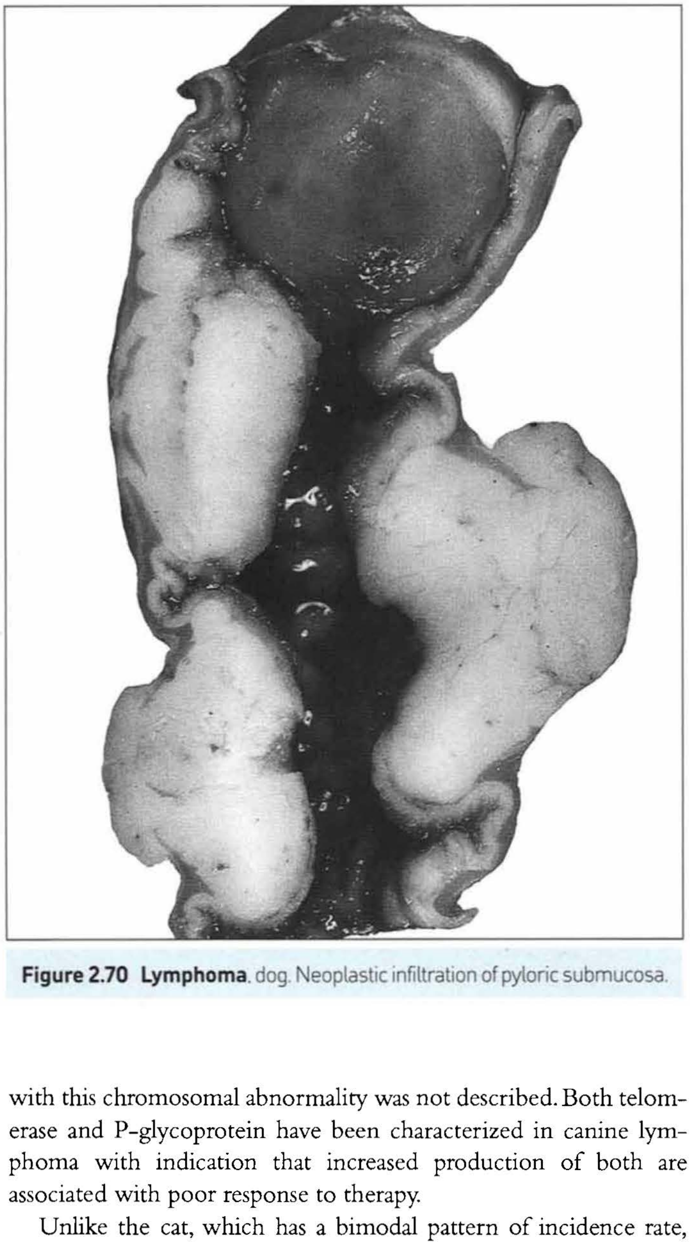

Figure 2.70 Lymphoma, dog. Neoplastic infiltration of pyloric submucosa.

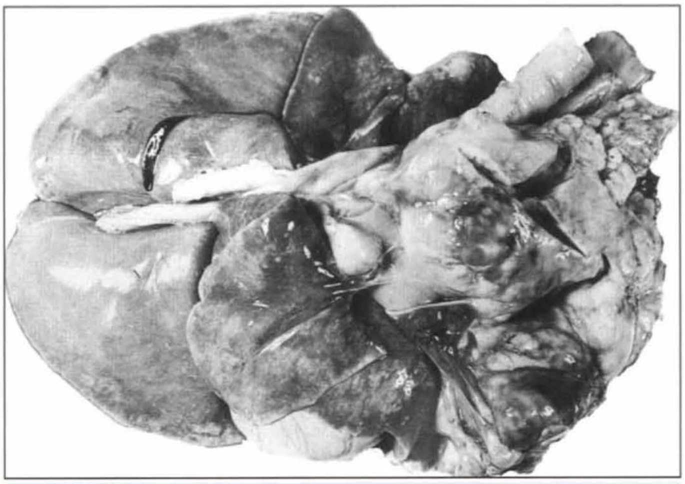

Figure 2.71 Thymic lymphoma of cranial mediastinum, dog.

with this chromosomal abnormality was not described. Both telomerase and P-glycoprotein have been characterized in canine lymphoma with indication that increased production of both are associated with poor response to therapy.

Unlike the cat, which has a bimodal pattern of incidence rate, hematologic malignancies in the dog occur with increased frequency throughout life. There is an equal sex incidence in intact animals, and a lowered risk for neutered males. *Most lymphomas in dogs are disseminated and of high-grade type*; however, there is some clustering of cases based on topographical distribution, with *multicentric most common, followed by enteric, cutaneous, and thymic types*. The presenting signs vary with the distribution of tumor and tendency, if any, for paraneoplastic changes. There is usually weight loss with some change in dietary habits. The **multicentric** type often has symmetrical lymphadenopathy and tends to be noticed when the animal is still in relatively good condition, as does the **cutaneous** form since the disease is usually focal and nodular. Dogs with hypercalcemia have polydipsia and polyuria and are usually in a state of collapse, while those with primary **enteric** lymphoma (Fig. 2.70) have some combination of vomiting and diarrhea, often bloody. There is mucosal ulceration in 50% of enteric cases, and these differ in having some degree of anemia accompanied by a moderate to marked neutrophilic leukocytosis. Dogs with **thymic** lymphoma (Fig. 2.71) have reduced exercise tolerance, often dysphagia and may have tamponade with severe impairment of circulation.

There are few correlations between cell type and topographical distribution of tumor; however, *there are more plasmacytoid tumors in the gut, skin and spleen than in other sites*, which suggests that for these areas malignant transformation is preceded by a period, perhaps prolonged, of benign immune hyperplasia. Cutaneous T-cell lymphoma in the dog may be of the epidermotropic or nonepidermotropic types, with the latter tending toward deeper involvement of the dermis and panniculus. Cutaneous B-cell lymphoma in the dog may be less common than the T-cell type and is more likely to be multifocal, presenting with a plaque or a nodular formation usually associated with erythema and variable hair loss. Canine cutaneous T-cell lymphoma (CTCL) of the nonepidermotropic type and canine cutaneous B-cell lymphoma (CBCL) are both characterized by a larger cell type than the epidermotropic T cells, but both may be very variable and have markedly atypical nuclei associated with anaplastic large-cell lymphoma subtypes (see Diffuse large B-cell lymphoma and Anaplastic large-cell lymphoma).

The enteric cases of canine lymphoma are also often preceded by the presence of lymphocytic-plasmacytic enteritis indicating prior long-standing benign inflammatory disease. The enteric counterpart of cutaneous epitheliotropic T-cell lymphoma occurs in the small intestine in both cats and dogs with heavy infiltration of small cells into surface and glandular epithelium. There is a clustering of the lymphoblastic type of lymphoma in the mediastinal cases, and T-cell phenotype and pseudohyperparathyroidism with hypercalcemia are also associated with mediastinal lymphoma.

The lymph nodes, liver and to a lesser extent the spleen (Fig. 2.72A), are involved in virtually all cases of canine lymphoma and, since there are usually lesions that are palpable or identifiable radiographically, most cases are diagnosed by fine needle aspiration biopsy. A canine counterpart of the hepatosplenic γδ T-cell lymphoma likely occurs in dogs and requires recognition and characterization. The lesions may be identified in almost any tissue including tonsils, which are often markedly enlarged (Fig. 2.72B), or in the eye. Involvement of lung (Fig. 2.73A) is uncommon, except as pleural implants from tumor in the cranial mediastinum. Secondary deposits in meninges and muscle tend to be diffuse, but those in myocardium tend to be more focal (Fig. 2.73B). About 50% of dogs have some degree of renal involvement and the proportion with impairment of

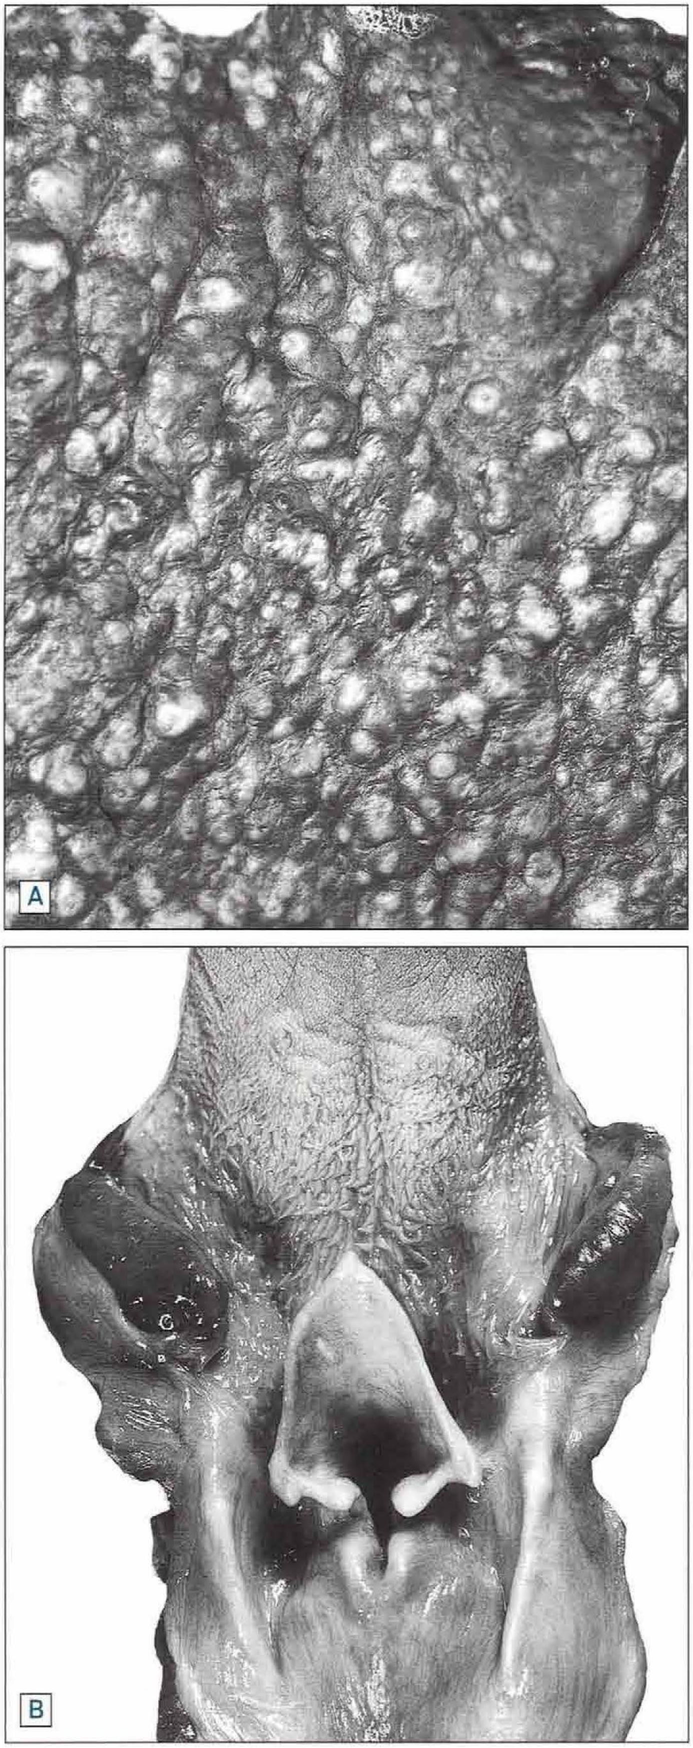

Figure 2.72 Lymphoma in a dog. **A.** Neoplastic enlargement of Malpighian bodies in the spleen. **B.** Bilateral tumor of tonsils.

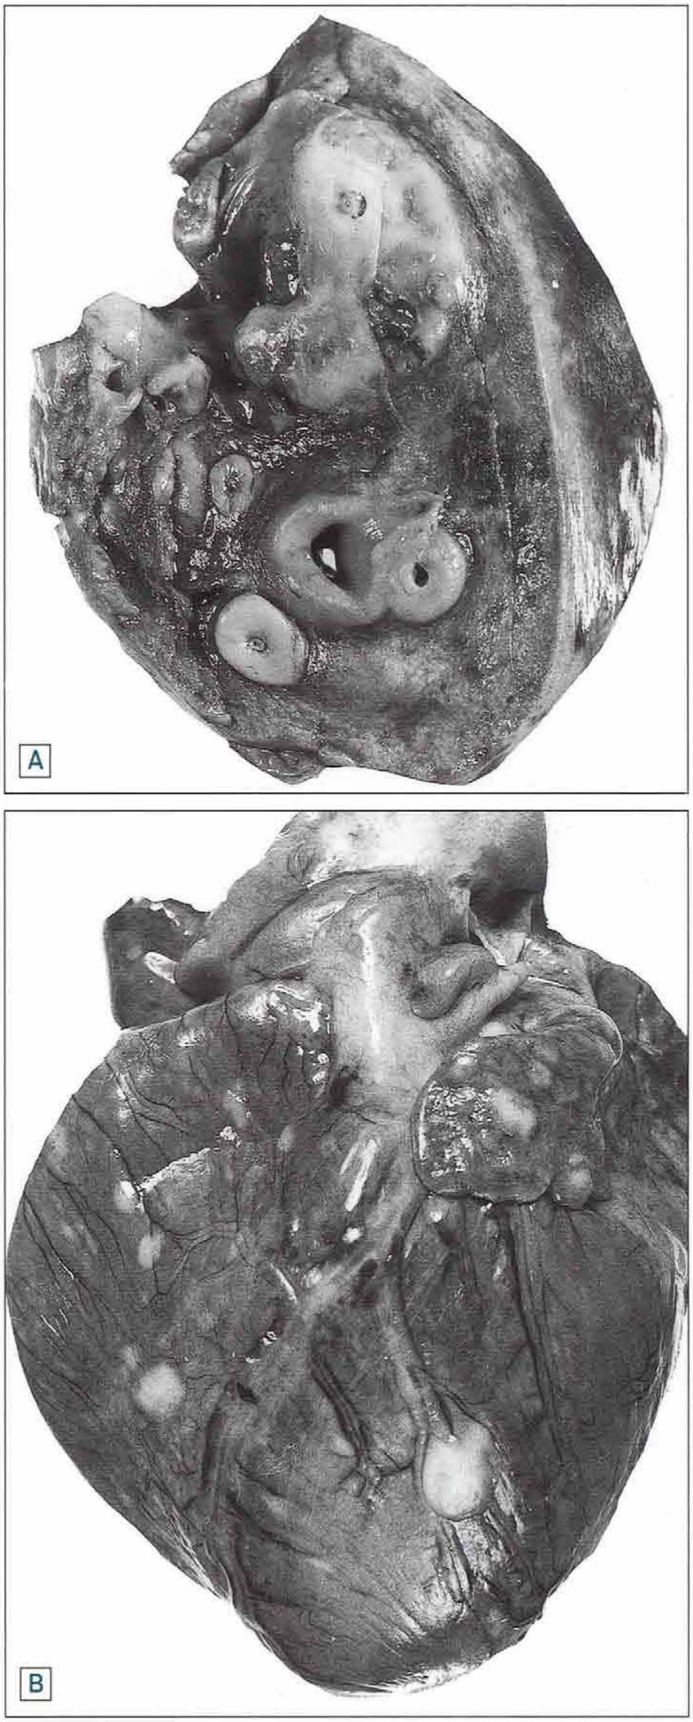

Figure 2.73 Lymphoma of Hodgkin type in a dog. **A.** Infiltrating perivascular and peribronchial lymphatics in lung. **B.** Multiple metastatic deposits in heart.

function, due to either or both tumor infiltration or hypercalcemia, is much higher. The bone marrow is involved to some degree in about one-third of cases and the histologic pattern of marrow involvement is a useful parameter in the evaluation of progression.

True follicular lymphomas in the dog appear to be relatively rare occurrences and constitute less than 5% of all cases. It is quite likely that the follicular variant of B-cell lymphoma is underdiagnosed because the lesions are either felt to be benign in their early stages of development and confused with follicular hyperplasia, or are dismissed as diffuse lymphomas in later stages of progression when the nodular follicular appearance is less apparent. The advent of routine use of immunophenotyping for B- and T-cell subtypes will likely significantly increase the rate of recognition of follicular lymphoma because these techniques serve to delineate follicular architecture even in advanced lesions. In the last decade, both mantle cell and marginal zone lymphomas have been recognized in the dog, and because both in the early stages can be seen as arising on germinal follicles are more likely to be recognized as having a unique and non-diffuse architecture. In the past, it has been felt that more than 80% of canine lymphoma was of high-grade or markedly aggressive histologic subtypes. With more accurate recognition of lymphoma subtypes in the dog, it is likely that a better approximation of prognostic categories would be 25% of cases as indolent, slowly progressing lesions over a period of 2 or more years, with another 25% as intermediately aggressive lesions that tend to progress to clinical attention over a year or more, and 50% of cases that are actually highly aggressive lymphomas, of which about 1/2 will enter complete remission with intensive combination chemotherapy.

Rarely, dogs develop a disease like human **myeloma** with focal lysis of bone, and are usually presented with lameness and nervous deficit. They have hyperproteinemia with monoclonal gammopathy that is in the 80–140 g/L range and may have heavy chain fragments in the urine. The spleen is often massively enlarged and may contain septic infarcts. The high level of high molecular weight plasma protein causes high blood viscosity, and anesthesia in these dogs for marrow or spleen aspiration may result in fatal hypotensive shock. The lesions may be widespread at the time of diagnosis, and qualify for the general term of "multiple myeloma," or only a single focus of tumor may be present. The tumor is always locally invasive and readily erodes bone, emphasizing the need for all destructive lesions of bone to be histologically evaluated so as to avoid inappropriate corrective measures such as excision arthroplasty of a femoral head that collapsed due to tumor lysis. Cytologically, the tumor is paradoxical in frequently having more rather than less cytoplasm than benign plasma cells. Nuclei are of moderate size, about 2 red cells in diameter, with more anisokaryosis than is seen in a plasmacytoma. They are round and hyperchromatic with irregular heterochromatin aggregation and small nucleoli. Binucleate cells are common. In the classic tumor, the cytoplasm is abundant, centered on the nucleus and pale staining so that the myeloma may resemble a clear cell tumor at low magnification. There may rarely be dedifferentiation of the myeloma to a more aggressive large type immunoblastic lymphoma in which the cells are smaller but the nuclei larger, with prominent central nucleoli. The latter type of lymphoma may on its own be secretory and associated with gammopathy.

Angiotropic large cell lymphoma is an unusual form of lymphoma that occurs in humans and dogs and likely in other species. In humans, there are a number of lymphomas characterized by angiocentric and angioinvasive characteristics including lymphomatoid granulomatosis and angioimmunoblastic lymphadenopathy. In these types of lymphoma, there is encirclement of small veins and muscular arteries with neoplastic cells that penetrate the wall of the vessel and colonize the lumen until it is completely obstructed with little overall distention of vessel diameter. These are characteristically T-cell neoplasms. In the intravascular lymphoma which is of B-cell type, there is colonization of the vascular lumen by neoplastic emboli which eventually obstruct the vessel (see Intravascular lymphoma; Fig. 2.51). *A third type of angiotropism occurs in animals in which the tumor cells selectively colonize and distend the space between the vascular endothelium and the vessel wall* (Fig. 2.74A, B). This lesion occurs in both veins and arteries and is characterized by marked distention of the wall with progressive compression of the lumen without penetration or colonization of the internal endothelial membranes by neoplastic cells. The form of angiotropic lymphoma seen in anaplastic large-cell lymphoma may occur in any tissue (Fig. 2.58), but is frequently seen in the skin and panniculus, whereas the variant involving subendothelial structures tends to occur in the heart and lung and lymph nodes in cases of small cell lymphoma. The intravascular variant is seen in the brain and spinal cord (Fig. 2.51) as well as other tissues. Each of these subtypes tends to be of large-cell type and the intravascular lymphomas mark strongly with CD79α, and those involving the subendothelium and characterized by angiocentric and angioinvasive properties mark strongly with CD3.

Feline lymphoma

Acute lymphoblastic leukemia (ALL) in the cat, like the dog, has had inadequate definition of immunophenotype and it is apparent that, like the dog, B-, T- and null-cell types all occur. *There appear to more acute myeloid leukemias in the cat than in the dog* and more systematic work-up of acute leukemias in the cat may identify a higher proportion of myeloid tumors than are generally considered to occur. All three types of ALL, as defined by the French–American–British (FAB) classification system occur in the cat, but it appears that L1 and L3 occur most frequently. Like the dog, ALL is diagnosed in the cat when there are blastic cells in the peripheral blood and 20% or

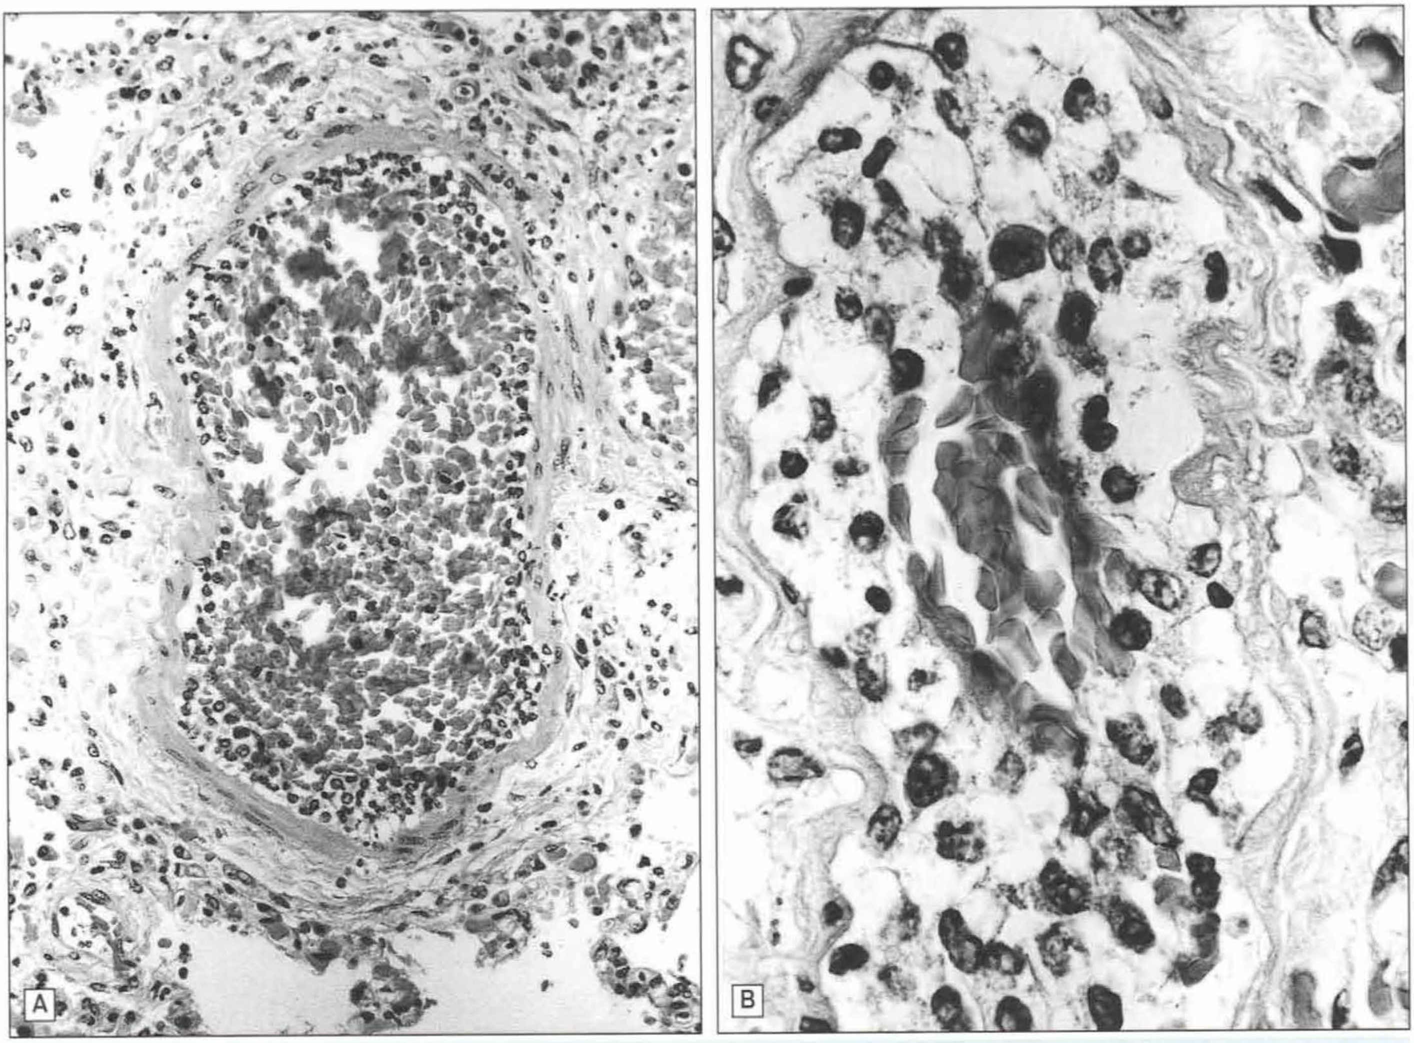

Figure 2.74 Angiotropic large cell lymphoma in the lung of a dog. **A.** Laminar subendothelial colonization of dilated artery. **B.** Detail of smaller arteriole. Marked luminal compression due to colonization of subendothelial area by lymphocytes with abundant clear cytoplasm.

more lymphoblasts in the bone marrow. *Chronic lymphocytic leukemia* (CLL) in the cat tends to be more of the small-cell type with very little cytoplasm and characterized by very high lymphocyte counts at presentation. Cats with CLL have greatly expanded areas of marrow hematopoiesis but solidly cellular areas of tumor in mid-femoral regions, suggesting that these lesions have been developing over a period of years.

Feline lymphoma is caused by the horizontally transmitted Feline leukemia virus (FeLV). The host–viral relationship in the cat, unlike the cow, includes persistent viremia which is associated with a high incidence of disease, but like the cow there may be latent infection with circulating antibody and persistence of provirus in target cells. The presence of a persistent viremic state in the cat likely explains the difference in rate of infection-associated disease in these two species. Like *Bovine leukemia virus* (BLV), the low molecular weight envelope proteins (p15E) are very highly immunosuppressive and, *in decreasing order of frequency, the disease syndromes associated with infection include leukemia/lymphoma, refractory anemia, feline infectious peritonitis, diseases of the oral cavity, and a variety miscellaneous problems.* Kittens are susceptible to infection with FeLV, and early infection with high rate of challenge and highly virulent virus favors the formation of myeloid rather than lymphoid tumor. It appears that feline leukemia is preceded by a period of myelodysplasia, which is likely true of leukemia in all species but is rarely observed outside of experimental infection.

The virus is worldwide in distribution with about 2% of cats infected. In a population of cats at veterinary clinics, as many as 90% of seropositive cats were ill with some form of disease. About 15% of cats infected with FeLV are also infected with *Feline immunodeficiency virus (FIV)*; however, the latter agent is not nearly as infectious as FeLV nor as likely to cause disease. The pattern of FeLV replication in cats begins first in lymphocytes and macrophages in the tonsils, and then is carried to the local lymph nodes of the head and neck. Viral replication is amplified in germinal centers. Within the first and second week of infection, the infected lymphocytes and macrophages carry the virus to the bone marrow, thymus, spleen, intestine and lymph nodes throughout the body. The most important of these tissues appears to be the intestinal lymphoid structures, with a critical balance or imbalance established between viral replication and the developing immune response. Those cats with an inadequate immune response develop persistent viremia that is life-long and increases the risk that the cat will die of FeLV-related disease within two to three years. In animals with a more effective immune response, the virus is controlled and may become latent, with a small number of cats testing negative by the FeLV, IFA, and even the ELISA, tests. Viral antigen may be detectable in body fluids and various tissues, particularly the spleen.

Commonly occurring syndromes of feline lymphoma include those with *thymic, alimentary, multicentric, and cutaneous presentations.* FeLV-related lymphomas have been identified as T-type in thymic lymphomas; however, some lymphomas of the multicentric type appear to arise from clones of very primitive cells which are of null cell type by phenotyping and have germ line organization of the T-cell receptor gene and the immunoglobulin heavy chain loci. Cytogenetic studies have been carried out on FeLV-infected cats with and without lymphoma, with chromosomal abnormalities identified in most cats with lymphoma with tetrasomy and trisomy observed but without correlation to histologic subtype or prognosis.

The means by which FeLV induces tumor is unknown, but the virus has been found to have multiple (up to 5) sites of integration into the feline genome with some of the sites consisting of incomplete virus. Molecular studies have shown that FeLV isolated from tumors contains a transduced cellular-myc gene with the viral-myc constituting the entire coding sequence of the cellular gene. Since FeLV is a slow-transforming retrovirus lacking an onc gene capable of direct leukemogenesis, the ability to acquire cellular oncogenes may be important in its ability to induce malignant transformation. In terms of detection of viral antigen or antiviral antibody, virus-positive cats are associated with the multicentric form of lymphoma whereas the thymic and alimentary forms of tumor predominate in cats negative for virus. However, in molecular studies, FeLV provirus was found in thymic lymphomas. Thus, viremia is associated with immunosuppression and secondary disease, while the latent form of infection (as in the cow) is not. Latent infection is, however, associated with tumor, suggesting that transactivation by integrated FeLV or action of its acquired v-myc oncogene is necessary for malignant transformation, but immunosuppression is not. A sterile vaccine based on a viral antigen-producing cell line appears able to produce protective antibody without inducing immunosuppression against FeLV or other feline vaccine viruses.

Since the distribution of lymphoid tumor in cats is so variable, the presenting signs are also variable, but *anemia and weight loss are the most consistent clinical signs.* Topographically, lymphoma in the cat is like that in the dog except for the more common presentation of the cat with advanced mediastinal lymphoma. In a histological review of 602 cases of feline lymphoma, 69 were of low-grade type, 210 of intermediate-grade type, and 323 of high-grade type, classified according to the NCI Working Formulation. The topographic distribution of tumor was 192 multicentric, 180 alimentary, 130 mediastinal, 36 renal, 35 peripheral node, 20 central nervous system, 12 cutaneous, 11 nasal, 8 eye/orbital, and 4 subcutaneous masses. In terms of cell type and topography, small-cell lymphomas were frequently found in cutaneous and alimentary tumors, and large-cell lymphomas were the most frequent types found in mediastinal, renal and multicentric cases. Tumor cells of the mediastinum were predominantly of the Burkitt-like or small-noncleaved cell type and, as would be expected, mitoses were more frequent in the high-grade lymphomas than in the intermediate- and low-grade types. Low mitotic rates were characteristic of lymphomas of the alimentary type, whereas high mitotic rates were characteristic of lymphomas of the mediastinum and renal tissues. In comparison with the dog, immunoblastic lymphoma is more common and constitutes a third of the cases in cats, but feline lymphoblastic lymphoma is much less common than in the dog. *Alimentary lymphoma in the cat* (Fig. 2.75) *deserves more attention* from a diagnostic sense because most reports have treated these diseases without regard to phenotype, and the enteric-associated T-cell lymphomas that are characterized by heavy epithelial colonization need to be distinguished from the B-cell lymphomas that tend to arise from lymphocytic–plasmacytic enteritis and may be of the diffuse B-cell type or of the mucosal-associated lymphoid tissue type (MALT) of which the latter may, in some cases, be surgically treatable diseases.

Porcine lymphoma

Lymphoma is the most common tumor in pigs, and in this species there is less diversity, both of topographical distribution and histologic type, compared to other domestic animals. B-lymphoma occurs in 25% of animals from herds of Large White pigs bearing an *autosomal recessive trait* for this condition. The disease may be detectable at 2–3 months of age and average survival is 4–6 months. It has not been possible to mate the homozygous affected animals because of their short survival. The disease appears to be similar in both the sporadic and familial occurrences, with generalized lymph node enlargement, splenomegaly, hepatomegaly and with particular involvement of the mesenteric nodes, stomach and intestines (Fig. 2.76). Discrete multifocal invasion of the renal cortex may be more common in the sporadic disease. There is gradual involvement of the marrow, and many cases die with leukemia, marrow failure, and widespread hemorrhages due to thrombocytopenia. Pigs with the inherited form of lymphoma have a heavy chain gammopathy with appearance of this fragment in the urine.

In lymphomas of outbred swine, most of which were diagnosed with tissues collected at slaughter, 60% were of diffuse large cell type, 24% Burkitt-like (small noncleaved cells), and 8% lymphoblastic. Acute lymphoblastic leukemia and lymphoma occur in outbred swine in animals as young as 3 weeks of age. An unusual form of lymphoma involves the lung, in which small arteries are ensheathed by a thick cuff of neoplastic T lymphocytes that have round nuclei, 2 red cells in diameter, and an immunoblastic appearance with a single central nucleolus, thickened nuclear membranes, and branched chromatin. The animals are presented with dyspnea and are suspected to have pneumonia. The neoplastic cells do not penetrate the walls of airways or vessels but cause dysfunction from compression of both and spread through the lung by encirclement of vascular channels. Neoplastic cells of similar type are found in the spleen.

Lymphomas in laboratory animals

Lymphomas are one of the most common tumors in rats and mice on 2-year or lifetime studies. There is much diversity of histologic type of tumor in various strains of animals, but the same types of tumors tend to cluster within a given strain. The murine lymphomas have been championed as models of human disease, but *unfortunately, rodent lymphomas have not been systematically reported as a function of animal genotype*, which is the information required by the pathologist dealing with the lesions in a specific strain of animal. A strain of *mice* infected with *Murine leukemia virus* (MuLV) developed a high incidence of hematopoietic tumors which are primarily B-cell lymphomas. Surprisingly, the tumors arising in these animals are more than 1/3 marginal zone lymphoma in histologic type as well as a much smaller proportion of follicular lymphomas and mantle cell lymphomas. Lymphomas occur as well in *ferrets* and in *hamsters* associated with a papovavirus. Lymphoma has been induced in *rabbits* by intravenous inoculation of Epstein-Barr virus (EBV) derived from cynomolgus leukocyte culture. One of the most studied and interesting spontaneous tumors is the large granular lymphocytic leukemia of the *Fischer rat* (F344; Fig. 2.56), which appears to be a tumor of natural-killer (NK) cells and has stimulated recognition of this tumor in many other species. Lymphomas have been increasingly found in *nonhuman primates*, particularly when infected with immunosuppressive lentivirus. They resemble their etiologic counterparts in humans, are very diverse, and have a tendency to involve the central nervous system.

Lymphomas may occur in *quail* (coturnix) utilized in laboratory studies, which may be associated with the avian reticuloendotheliosis virus. Breaks of lymphoma may occur in commercial *poultry* flocks as a result of infection with the same virus.

Hodgkin-like lymphoma

Hodgkin-like lymphoma in animals that meets acceptable criteria as described for humans is a rare occurrence. In animals, Hodgkin-like lymphoma has been suggested to occur in the dog and more recently in the cat. *The diagnosis of Hodgkin disease rests on the demonstration of an acceptable Reed-Sternberg cell in an appropriate background of lymphoproliferation.* Few cases meet these criteria. The Reed-Sternberg cell (Fig. 2.67B) is apparently derived from a B cell in the classical subtypes of Hodgkin lymphoma, but is likely to be a dendritic cell in the lymphocyte-predominant Hodgkin lymphoma (see section on Hodgkin lymphoma). The lymphocyte-predominant type of Hodgkin lymphoma is of most interest in animal pathology because it is the subtype of this disease that most closely resembles the T-cell/histiocyte-rich B-cell lymphoma. There is confusion between the diagnosis of lymphocyte-predominant Hodgkin lymphoma and T-cell-rich B-cell lymphoma in humans and, therefore, it might be expected that lymphomas of the latter type in animals might be suggested to resemble Hodgkin lymphoma of humans. Both the classic type of Hodgkin lymphoma (includes subcategories of nodular sclerosis, mixed cellularity, and lymphocyte depletion), as well as the lymphocyte-predominant type, are characterized by artifactual contraction of the Reed-Sternberg cells from surrounding cells in formalin-fixed tissues. This artifact makes these cells more obvious on low-power examination and assists the identification of a rare Reed-Sternberg cell, or lacunal cell as they are called in early stages of development.

There is regional lymphadenopathy and the enlarged nodes tend to be very firm. The spread of the disease, particularly in cats, is by contiguity to adjacent lymphoid tissue, as in human Hodgkin lymphoma (see section on Hodgkin lymphoma). *Diagnosis is based on the presence of an unequivocal Reed-Sternberg cell in a background of homogeneous or heterogeneous lymphoid proliferation with mild or extensive sclerosis.* The disease tends to be indolent and animals may have large tumor masses and retain body condition.

The erythron

The erythron may be defined as the circulating erythrocytes (red blood cells, RBCs), their nucleated precursors, and all elements involved in the control of erythroid proliferation. Diseases of the erythron are characterized by too many or too few red cells. *Polycythemia*, or too many red cells, is rare and usually due to dehydration and plasma volume contraction. *Anemia*, or too few red cells, is relatively common and is due to decreased red cell production or increased destruction or both.

ERYTHROCYTE PHYSIOLOGY

The erythrocyte is specialized to carry out gas transport, and in mammals is devoid of nuclei, mitochondria and ribosomes. Simplistically, the erythrocyte can be looked on as a cell membrane containing heme, globin and protective enzymes. The **red cell membrane** is a bilayer of lipid molecules oriented with the nonpolar groups directed inwards towards each other forming hydrophobic connections, while the hydrophilic overhead groups are directed outward, interacting with the plasma environment on the outer surface and cell contents on the inner surface. Studies of red cell membranes devoid of contents indicate the composition is 52% protein, 40% lipid and 8% carbohydrate by weight. Carbohydrate is largely made up of glycoproteins and a small amount of glycolipids. The *discoid shape of the red cell* ensures that all contents are close to a membrane surface, thus facilitating more efficient gas transport than would occur with a spherical shape. Another advantage of the discoid shape is its ability to undergo deformation in flow attaining an umbrella- or parachute-shaped configuration with the convex end oriented in the direction of flow, thus permitting red cells to pass through capillaries with the lumen only slightly more than 1/2 the diameter of the red cells. The indented area of the red cell is not fixed and can "flow" or move from one site to another as influenced by external forces. On the inner surface of the red cell membranes, fibrillar proteins form a supporting cytoskeleton. The lipid bilayer of the red cell is penetrated by a number of different transmembrane proteins, including glycophorin and ankyrin, both of which serve as anchor points for the fibrillar protein spectrin which, when linked by shorter chains of actin and tropomyosin, form an anchored "page-wire" network on the innersurface of the red cell membrane. *This fibrillar cytoskeleton provides and supports membrane shape, flexibility and durability.*

Cell volume is maintained by control of sodium and potassium levels through the action of ATP-dependent membrane enzymes. The membrane structural proteins are relatively fixed for the life of the cell, whereas the lipid, particularly cholesterol, is in dynamic interchange with that in plasma. This interchange is under enzymatic control and, in the presence of bile salts, cholesterol is gained by the cell causing increased membrane area and formation of the target cells associated with hepatic dysfunction.

The erythrocyte contents are largely proteins, of which some 95% is **hemoglobin** and the rest largely the enzyme systems required for glycolysis, protection of the heme and globin, and ATP production. The loss of the nucleus during maturation is accompanied by the loss of RNA and mitochondria. As a consequence, the mature erythrocyte has also lost the enzymes required for a functional tricarboxylic acid cycle, and the cytochromes essential for electron transport. The mature erythrocyte is, therefore, unable to derive phosphate-bond energy from the citric acid cycle and is unable to synthesize further heme. The remaining source of energy is through the metabolism of glucose to lactic acid to produce a functional level of ATP. This ATP functions to partition glucose from plasma, maintain homeostatic levels of intracellular sodium and potassium, maintain the biconcave shape, indirectly maintain iron in a ferrous state, and protect the integrity of the globin chains. As a consequence of glycolysis, there is production of the intermediate compound 2,3-diphosphoglycerate (2,3-DPG) which competitively binds to heme to control oxygen affinity and thus offloading. The balance between intracellular synthesis and utilization of glucose is such that glycogen is not formed and therefore erythrocytes are critically dependent on constant access to plasma glucose.

In circulation, red cells are constantly confronted with oxidant metabolites that are potentially injurious to heme, globin, enzymes and membranes. *The key antioxidant in the red cell system is reduced glutathione.* Reduced glutathione may be exhausted by oxidant attack from peroxides produced by macrophages or drugs. *This allows denaturation of the globin chains which form intraerythrocytic precipitates called* **Heinz bodies**. In animals, the major deficiency affecting glutathione regeneration is an (red cell) age-dependent deficiency of the glucose-6-phosphate dehydrogenase enzyme (G-6-PD). The G-6-PD enzyme is the rate-limiting factor in the hexose monophosphate shunt, and its deficiency in animals can be acquired by prolonged oxidant exposure as occurs in kale anemia or phenothiazine toxicity.

In order to function in oxygen transport, hemoglobin iron must be maintained in the reduced or ferrous state. Oxidant attack which reaches the heme iron forms ferric heme or *methemoglobin*, which is reduced by methemoglobin reductase or the diaphorase system. Some methemoglobin may be reduced by ascorbic acid and glutathione, but the diaphorase system is most important. Both the glutathione and the diaphorase reductase systems are critically dependent on a constant supply of glucose for energy. *Unlike the oxidation of globin, which results in hemolysis, the oxidation of heme causes cyanosis.* Deficiencies in methemoglobin reductase are inherited in humans and acquired in animals with nitrate poisoning.

Erythropoietin (EPO) is a constituent of plasma whose action is to increase the total number and volume of circulating red cells. The factor is class-specific, in that erythropoietin in one species of mammal is active in other mammals but not in birds or amphibians and vice versa. Erythropoietin is a glycoprotein synthesized by singly arranged cells within the renal cortex lined between the proximal convoluted tubules. Human erythropoietin contains 193 amino acids and consists of 39% carbohydrate with total molecular weight of 30 000 daltons. Erythropoietin must be glycosylated to be active, and is available as a recombinant pharmaceutical. Erythropoietin is able to pass the glomerular filtration process, and normally appears in urine at lower concentrations than in plasma. In anemic states, erythropoietin concentration in urine is greatly increased where its presence is indicative of a system responding normally to anemia and tissue anoxia.

Tissue anoxia is the specific stimulus for increased erythropoietin production and release. In this respect, arterial oxygen saturation is less basic to erythropoietin release than tissue saturation, since altered binding affinities may make blood oxygen unavailable to tissues. A DNA-binding protein in the area of the erythropoietin gene is tightly regulated by oxygen tension, and appears to be a physiological regulator of transcription from the erythropoietin gene.

Erythropoietin stimulates proliferation of primitive hematopoietic stem cells, which appear to be the target cells most sensitive to influence by erythropoietin and are identified by the highest density of erythropoietin receptors on their surface membranes. Hierarchically, these cells lie between the early committed stem cell and the proerythroblast, with the erythropoietin being absolutely essential for their survival, and, in the absence of adequate erythropoietin, these cells undergo programmed cell death. Continued presence of erythropoietin results in effective erythropoiesis and an increase in reticulocyte production. The continued administration of erythropoietin to humans with end-stage renal disease results in trilineage stimulation of bone marrow with an increase production of all cell types. Under increased hormonal pressure, accelerated hemoglobin synthesis occurs and, in sheep, a "switching" from synthesis of hemoglobin A to C, suggesting an action at the gene level above that of messenger RNA.

The net result of these changes is increased red cell production with an increase in mean cell volume and a greater proportion of maturation time spent in the peripheral blood. The presence of **"shift" polychromatic macrocytes** in the blood is erythropoietin-dependent, and they give a rough index of erythropoietin level and effect, indicating both increased levels of erythropoietin and a marrow capable and responding to it.

While in terms of evolutionary development, erythropoietin may be class-specific and human recombinant erythropoietin will stimulate increased erythropoiesis in domestic animals, the use of human recombinant erythropoietin in animals is not without risk. *Recombinant human erythropoietin (rhEPO) appears to be capable of causing the development of anti-rhEPO antibodies in both horses and dogs.* The human EPO genome appears to be 85% identical to that of cats and dogs and highly similar to the EPO genome of the horse. Since erythropoietin is a reasonably large polypeptide, it is not surprising that it could also act as an antigen in an unfamiliar host. Recombinant human EPO given to racing Standardbred horses, likely for non-medical reasons, later presented for medical examination and were found to have hematocrits of 16 and 24%. One horse had been given four injections of rhEPO and the second horse two administrations and both were presented for examination two months later when they were found to be anemic. Serum from these horses inhibited the growth of erythropoietin-dependent erythroid colony-forming units in culture assays, suggesting that their serum contained a factor that inactivated the rhEPO added to the culture median. Similar responses to rhEPO administration have occurred in the dog, whereas dogs given recombinant canine erythropoietin (rcEPO) responded normally with a temporary increase in reticulocytes and red cell counts, which was not followed by the development of anemia. *Androgenic steroids are able to increase endogenous EPO production and erythropoiesis,* which is accompanied by an increase in renal mass apparently associated with the proliferation of EPO-producing cells in the kidney.

Reticulocytes in the peripheral blood constitute a reliable index of new red cell production. Traditionally, reticulocytes have been enumerated using supravital stains in counting chambers which works well in the dog, cow and pig, but tends to be grossly inaccurate in the cat where large numbers of reticulocytes are produced with small amounts of residual RNA known as *punctate reticulocytes.* Cats also release reticulocytes with larger areas of RNA known as *aggregate reticulocytes,* which are more similar to those of other species. Reticulocyte counts in the cat based on aggregate reticulocytes provide an accurate assessment of erythropoiesis, but since the maturation from aggregate to punctate type of reticulocytes is a continuum, the differentiation between these two types and determination of their numbers is arbitrary and prone to error. In the *horse, which does not release reticulocytes into the peripheral blood,* the determination of increased erythropoiesis is largely dependent on changes in red cell numbers and the association of an increased mean cell volume with increased red cell production. The advent of electronic counting systems based on deflection of a laser beam rather than the Coulter system based on displacement of saline electrolyte has permitted the use of nucleic acid binding fluorochromes, which permits counting of reticulocytes in large numbers with more accurate results. It has also been possible to establish software gating programs that effectively differentiate between feline punctate and aggregate reticulocytes in electronic counting, permitting accurate determination of their numbers with very large samples counted. These results show that aggregate reticulocytes in the cat respond with up to 3% reticulocytes in response to phlebotomy, which is less than would be expected in the dog but adequate to provide a baseline for the species. The reporting of reticulocyte counts should always be made in *absolute numbers,* with percentage counts relatively meaningless without the added information of the total red cell count. Normal dogs with a total red cell count of 6×10^{12} red cells/L and 1% reticulocytes have 60×10^{9} new red cells/L to maintain homeostasis. This level of production is compatible with the red cell lifespan of 120 days at a turnover of approximately 1% of red cells per day. Evaluation of erythroid responses then needs to be based on a comparison of the absolute reticulocyte count in a canine patient in comparison to the normal level. Thus, a dog with 120×10^{9} reticulocytes/L in an absolute count has twice the normal output, and a dog with 300×10^{9} reticulocytes/L has five times the normal level and is at a level of production frequently reached by dogs with hemolytic anemia. Cats, in contrast, with anemia due to phlebotomy starting at a PCV of 20% and recovering to 27% over 12 days produced aggregate reticulocyte counts of 12×10^{9}/L prior to bleeding with gradual increases to 160×10^{9}/L on day 12. Over the same period, the punctate reticulocyte counts varied from 180×10^{9}/L to 1.7×10^{12}/L, without bearing any constant relationship to the number of aggregate reticulocytes.

Reticulocytes that are moderately larger (1.5 times the diameter) than a normal homologous erythrocyte lose their basophilia in about 1 day of circulation. *Macroreticulocytes or "shift" red cells* (2.0–2.5 times the diameter of normal erythrocyte) require 2 or more days to become normochromic, during which time they continue to synthesize hemoglobin. Remodeling of normochromic macrocytes continues for a week or more, during which time there is loss of membrane and hemoglobin until the cell is of characteristic diameter for the species. This distinction is important, since reticulocytosis is indicative of present production whereas macrocytosis indicates previous production and, in the absence of reticulocytosis in an anemic animal, signals recent cessation of red cell production.

Young red cells have unique characteristics that affect their behavior. Because of their larger size, lack of concavity and greater surface charge, they do not form rouleaux. Because of their reduced hemoglobin saturation, they have lower specific gravity and in the absence of rouleaux formation settle more slowly in sedimentation tubes giving a biphasic reaction. Since they contain mitochondria and are capable of aerobic glycolysis, they are more resistant to crenation and hypotonic lysis.

Prior to the understanding of the effects of EPO on the prevention of programmed cell death in erythroid precursors, it was frequently proposed that increased erythropoiesis was accomplished through an increase in numbers of erythropoietic cells and a decrease in mitotic intervals. Current understanding favors maintenance of normal kinetics of production with increased erythroid output, the result of a greater number of proliferative phase cells and the survival of their progeny through to the reticulocyte stage. These concepts are in agreement with earlier work on red cell production in calves where, in autoradiographic studies of bone marrow of calves given tritiated thymidine in vivo, the mean production time of labeled marrow metarubricytes in normal calves was 3.79 days, and in calves made leukopenic by endotoxin 3.83 days, and 3.76 days in calves bled to one-half their normal hematocrit level. Thus, it appears that *the production time of the red cell is very close to four days in most species* and the major difference between hematologic responses of the dog and the calf are in a much greater rapidity with which the dog can amplify the stem cell pool.

The **metabolism of iron** is central to the function of the erythron. Iron is tightly conserved in the body, and is lost in very small amounts in urine, sweat, and intestinal epithelial cells. The kinetics of iron absorption and its control are complex, but certain principles apply to all species. First, when storage iron is decreased, iron for absorption from the intestine is increased and vice versa. Second, iron absorption varies directly with the rate of erythropoiesis, being increased when erythropoiesis is increased and decreased in proportion to red cell production.

The key to iron absorption from the intestine resides in a mucosal absorptive cell that is able to absorb iron but is able to respond to reduced body iron stores by increasing the efficiency of iron absorption. The process is not understood, but an iron-binding protein called *mobilferrin* that may act as an iron messenger is built into the mucosal cell at the time of division in the intestinal crypts and programs for a given level of iron absorption. Transferrin, the plasma transport protein for iron, and its level of saturation are not the controlling factors in intestinal iron absorption since it has been found that subjects lacking transferrin have a normal level of iron absorption but abnormal transport and deposition in abnormal tissues. Iron is contained in a variety of compounds and compartments within the body. These are referred to as *iron pools,* and it is convenient to consider amount and proportions of iron present in a normal 70 kg human who has 4 g total body iron. In normal steady-state circumstances, 66% of those 4 g would be contained in hemoglobin, and thus there could not be sufficient reserves to replace the iron lost by significant hemorrhage. In young and growing animals, there are virtually no reserves and any iron loss is therefore more serious than in adults.

Free plasma iron, like other heavy metals, is toxic and a three-tiered system of protein-mediated transport and storage exists. *The most labile form of iron is contained in the beta globulin transport protein,* **transferrin**, which is produced in the liver and which is normally 40–50% saturated with iron. In the normal adult, transferrin contains 3 mg of iron and 0.07% of total body iron. In iron deficiency, transferrin levels may double, and levels decrease in protein starvation. The level of transferrin in serum is referred to as "*total iron-binding capacity*" while that portion carrying iron is called "*serum iron.*" Transferrin saturation levels of less than 16% are rate-limiting to erythropoiesis. This limiting level is easily reached in deficient states since, as serum iron drops, total iron-binding capacity increases. Each transferrin molecule is able to carry 2 molecules of iron, of which the first is more easily transferred than the second. The developing rubricytes have some 50 000 specific transferrin receptors that cleave the iron molecules into the erythroid cytoplasm. Although the erythroid marrow receives only 5% of cardiac output, 85% of the iron in transport is retained.

Iron must exist in the ferric state to bind to transferrin. **Ceruloplasmin**, *a copper-containing globulin, facilitates iron transport and converts ferrous to ferric iron in the presence of reducing metabolites.* Ceruloplasmin decreases in starvation and copper deficiency. It appears to act as an acute-phase protein and increases in late pregnancy, infections, leukemia-lymphoma, and in anemia of ineffective erythropoiesis of iron- or B12-deficient origin. Deficient ceruloplasmin results in impaired iron transport and hypochromic microcytic anemia indistinguishable from that caused by iron deficiency, except that marrow hemosiderin is increased rather than absent. Reticulocytosis following supplementation of deficient animals is delayed for several days while ceruloplasmin is synthesized.

Ferritin *forms the second level of iron transport and storage,* and acts as a buffer between transferrin, where iron turnover is very high, and hemosiderin, where iron turnover is low. Ferritin is an iron–protein complex occurring in most cells and plasma, and *consists of apoferritin protein subunits and iron.* Ferritin constitutes a labile source of storage iron and, in the normal human, 0.7–1.5 g of iron are bound to this protein. In inflammatory states, an acute-reacting system continuously scavenges iron from transferrin to ferritin where it is less available to both invading microorganisms and erythropoiesis. This system appears to be the basis for the paradoxical anemia of chronic disease, in which body iron stores are increased but serum iron is rate-limiting to erythropoiesis. *Serum ferritin levels, unlike serum iron levels, are an accurate measure of body iron stores.*

Hemosiderin *is the most stable and least available form of storage iron.* It is always intracellular, usually in macrophages, and is not found in plasma. Ferritin molecules have been observed in hemosiderin granules, and immunologically the proteins in both are identical. It appears that hemosiderin is a variable compound consisting of native and denatured ferritin with a total iron content of 25–30% by weight. The iron in hemosiderin is available only after what appears to be prolonged proteolysis. Thus, *hemosiderin constitutes the nonlabile iron storage system,* and the normal human adult has 1.2 to 1.5 g of total body iron bound in hemosiderin. Animals with abundant marrow hemosiderin do not respond maximally to blood-loss anemia unless supplemental iron is given. Iron from all sources, including that derived from hemolysis, hemosiderin, lysis and oral and parenteral supplementation, appears to be additive in achieving erythropoiesis.

Hemoglobin synthesis begins early in the sequence of erythroid differentiation. *The three essential components of hemoglobin are iron, protoporphyrin, and the globin chains.* The assembly of these components probably is closely coordinated so that the organic structures are not produced in excess if iron is limiting. Hemoglobin synthesis is under genetic control. The amino acid substitutions of the globin chain seen in human hemoglobinopathies are not found in animals. In animals, there is some switching of hemoglobin type as a result of alternate globin chains being produced under conditions of severe anemia and very high erythropoietin levels. This process may represent an acquired mutation that aids survival by substituting a chain with greater efficiency of oxygen delivery in anemic states. It also suggests that erythropoietin influences DNA transcription. Two-thirds of the erythrocytic hemoglobin is synthesized during the rubricyte stages, and one third is completed under the direction of messenger RNA left in the reticulocyte at denucleation.

The initial step in heme synthesis is the intramitochondrial union of glycine and succinyl-CoA to form *δ-aminolevulinic acid.* This step is dependent on the presence of pyridoxal phosphate of pyridoxine (vitamin B6) origin. The δ-aminolevulinic acid is then transported to the cytosol where two molecules are combined to form the ringed pyrrole *porphobilinogen.* Four of these pyrroles are then joined and closed to form the tetrapyrrole intermediates, *uroporphyrinogen* and *coproporphyrinogen,* which are then transported back into the mitochondria for the conversion to protoporphyrin and the addition of iron to form *heme.* In this sequence, *the porphyrinogens are the true intermediates, and the uroporphyrin and coproporphyin are byproducts of heme synthesis.*

The process of heme synthesis is accelerated by the presence of iron and is slowed by a build up of the end-product *hemin* (protoporphyrin–iron chloride) probably at the level of δ-aminolevulinic acid synthesis. *Lead poisoning* blocks the formation of protoporphyrin and causes δ-aminolevulinic acid to circulate in excess; its urinary excretion constitutes a test for lead toxicity. In addition, tetrapyrrols accumulate due to inhibition of iron insertion. These compounds are photodynamic and may be detected by fluorescence under ultraviolet examination.

The term **ineffective erythropoiesis** is used to indicate *hematopoietic production that does not result in functional release of new cells.* When erythropoiesis is ineffective, there is peripheral blood anisocytosis and poikilocytosis without appropriate reticulocytosis, and a tendency for increased bilirubin as a result of increased intramedullary erythrocyte catabolism.

ANEMIA

Anemia is a sign of disease that results either from an *increased rate of destruction or loss of erythrocytes*, or from a *decreased rate of their production*. Anemia may be classified on the basis of the bone marrow response (*regenerative or nonregenerative*) or on the basis of red cell indices (*macrocytic/microcytic, normochromic/hypochromic*) which indirectly reflect the nature of the anemia itself. Anemia is classified here on an etiologic or pathogenetic basis with reference to various mechanisms for assessing bone marrow production. The descriptions which follow provide morphologic criteria to assist in the differentiation of the various types of anemias.

The function of hemoglobin is to supply oxygen to the tissues, and the signs and lesions of anemia are largely referable to hypoxia. Depending on the cause, however, other manifestations of the diseases of which anemia is a part are often foremost in appearance. Thus, in anemia of massive hemorrhage, the manifestations relate to hypoxia and sudden reduction in the volume of circulating blood; in hemolytic anemia, the prominent features may be icterus and hemoglobinuria, with fever whether or not the cause is infectious. The rate at which anemia develops will also influence the manifestations: when the development is rapid, signs of anoxia are likely to be predominant; when the development is slow, as in deficiency and aplastic anemia, the condition may be masked by physiologic compensations until some increased requirement, often exercise, places overwhelming demands on the organism.

The appearance of an anemic animal is characterized by *pallor*, perhaps obscured by icterus. Pallor is due to a reduction in total levels of hemoglobin, and, if the disease has developed slowly, to a dilution of the red cell mass by a proportionate increase in the plasma compartment in order to maintain normal blood volume. Grossly, the pallor is accompanied by edema of the *lung*, and tracheobronchial foam is typical. The *heart* is dilated and, if the anemia has been chronic, the myocardium tends to be flabby, friable, and pale as a result of fatty degeneration. The proportion of white to red blood clot is increased, and the *liver* and kidney are pale and may be fatty. In acute anemia, there is frequently the "nutmeg" appearance of periacinar hepatic necrosis. In acute hemolytic anemias, the *gallbladder* is distended and the feces are intensely stained with bile pigment. In chronic anemias of deficient hemoglobin production, the gallbladder is empty and the feces are pale. The character of the *spleen* varies with the cause and course of the disease. In the acute posthemorrhagic anemias, the spleen is contracted; in the acute hemolytic anemias, it is enlarged and pulpy; in the chronic hemolytic and deficiency anemias, it is enlarged and meaty. Since the spleen is a site of both production and destruction of red cells, the splenomegaly of hemolytic diseases may be the product of extramedullary hematopoiesis, or sinus hyperplasia of increased blood destruction, or both. In chronic anemia, the skeletal muscles tend to be pale in proportion to the loss of myohemoglobin. *Edema* is a frequent accompaniment of anemia, and serous fluid is found in the serosal sacs and in the dependent tissues of the limbs, ventral wall of the body, and throat. *Since the full characterization of an anemia may require the examination of both blood and tissues, it is important that diagnostic examinations begin with the live animal.* Cytologic preparations of bone marrow, like those of blood, can best be made prior to clotting and therefore both should be collected prior to death.

Congenital abnormalities of red cell number and function: congenital aplastic/hypoplastic anemia

Anemias due to a congenital error in stem cell number (*reticular dysgenesis*) are rare or lethal defects that are infrequently identified in animals. In contrast, *those diseases characterized by normal or increased production of defective red cells with shortened life span are much more prevalent* and, because of their potential for dissemination through artificial breeding, they are of much more economic importance. Neonatal *llamas* suffer a severe anemia associated with slow growth, limb deformity, and hypothyroidism. The disease has not been adequately characterized, but may be a primary defect of red cells or a reflection of systemic errors in metabolism. A disease of *polled Hereford calves* characterized by anemia and cutaneous abnormalities is described in Vol. 1, Skin and appendages. A condition that strongly suggests congenital marrow aplasia has been described in a *Holstein calf*. A rare congenital pure red cell aplasia occurs in *humans* known as *Diamond-Blackfan anemia*, which has been treated with corticosteroids. It has been shown that interleukin-3 is able to support trilineage marrow production in these individuals. Animal counterparts of this condition have not been identified.

Hereditary hemolytic disorders of red cell membrane or enzymes

Hereditary stomatocytosis

Red cells with a rectangular unstained area across their center are termed **stomatocytes** (Fig. 2.77). A hereditary anemia with these membrane changes occurs in *chondrodysplastic dwarf Alaskan malamute dogs* (see Vol. 1, Bones and joints). The anemia in these dogs is mild, and characterized by stomatocytosis, macrocytosis, reduced mean corpuscular hemoglobin, increased osmotic fragility, shortened red cell life span, reticulocytosis with marrow erythroid hyperplasia, and increased iron turnover. The glutathione levels are reduced. The anemia is thus hemolytic and partially compensated. Intracellular sodium and potassium are also abnormal in affected dogs. Changes are most severe in homozygotes in which both sodium and potassium are elevated. In heterozygotes, only sodium is elevated.

The hemolysis is low grade but intravascular, resulting in reduced serum haptoglobin, deposition of iron in renal epithelium, and hemosiderinuria. The defect is intrinsic to the red cells, since cells of affected donors have a shortened survival in normal dogs, whereas cells of normal donors survive normally in affected dogs. The reduced glutathione level does not render the affected cells more susceptible to oxidative denaturation of globin (Heinz bodies), because the enzyme present is unusually stable.

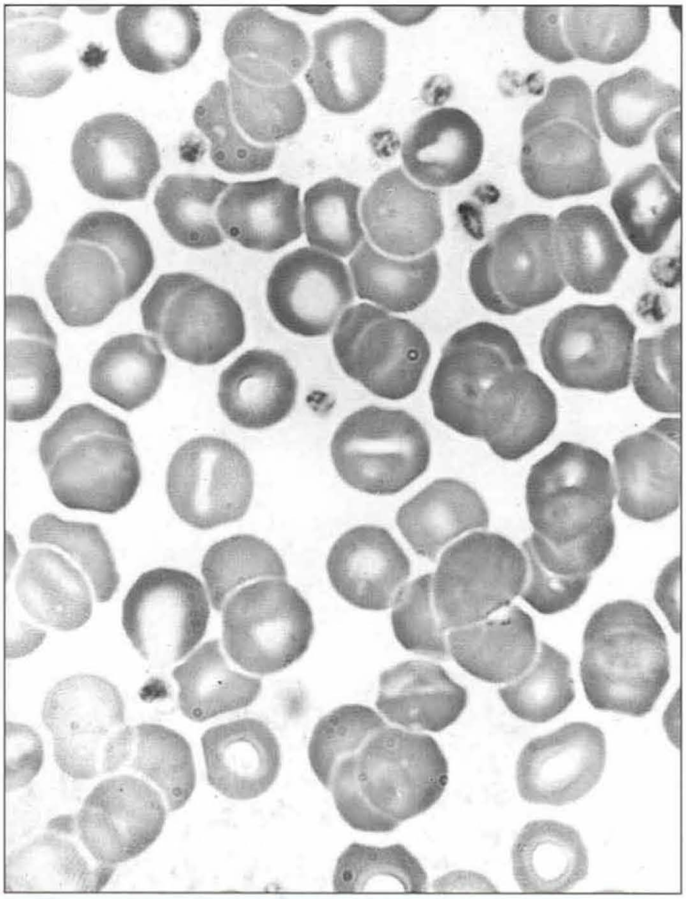

Figure 2.77 Hereditary stomatocytosis. dog. Central pallor of red cells with rectangular clear areas.

Familial anemia of *Abyssinian and Somal cats* has been described, in which there is prominent stomatocytosis and markedly increased somatic fragility.

Familial anemia in dogs

A familial hemolytic anemia found in Basenji and Beagle dogs is due to **pyruvate kinase deficiency**. The dogs are of normal appearance, size and weight. They are less active than normal, and on clinical examination have pale mucous membranes and often splenomegaly.

The anemia is moderately severe (60 g Hb/L), marocytic (MCV 86 fL), with large partially saturated cells (MCH 23 pg, MCHC 27%). There is a reduction in red cell count ($2–3 \times 10^{12}$/L) with a *remarkable reticulocytosis of 40%*. The young red cells with mitochondria are able to carry out aerobic metabolism and are protected until they mature. There is increased resistance to osmotic lysis for the same reason. There is a marked marrow erythroid hyperplasia with myeloid:erythroid ratios of 0.2–0.4. The apparent (^{51}Cr) red cell lifespan of normal Basenjis is about 20 days and 2.5–3.0 days in affected dogs. Plasma iron turnover rate is twice normal. Heterozygous carriers are asymptomatic but have higher than normal levels of red cell 2,3-diphosphoglycerate, as do the fully affected homozygous animals. The oxygen dissociation curve of affected animals is shifted to the right with reduced hemoglobin oxygen affinity due to the high intracellular levels of 2,3-diphosphoglycerate. Morphologically, Basenjis with pyruvate kinase deficiency develop *progressive myelofibrosis with osteosclerosis* as well as splenic and hepatic hemosiderosis.

Hereditary disorders of heme synthesis: the porphyrias

Porphyrias are diseases that result from abnormal metabolism of porphyrins which may be excreted to excess in urine and feces or deposited in various tissues. The pigments are fluorescent, unless iron is chelated in them. Fluorescent activation leads to the local production of free radicals in skin and exposed mucous membranes in the condition known as *photosensitization*.

Porphyrins are basic components of enzymes that contain heme, including hemoglobin, the cytochromes, catalase and many peroxidases. Porphyrias occur when toxic or inherited metabolic defects limit the activity of one of the enzymes in the synthetic chain.

Bovine protoporphyria affects *Limousin cattle* and is *caused by a deficiency in the activity of ferrochelatase*, the terminal enzyme which catalyzes the insertion of ferrous iron into protoporphyrin IX to form heme. The inheritance is recessive and heterozygotes are asymptomatic. Bovine protoporphyria differs from bovine congenital porphyria in that there is no excretion of porphyrins in the urine, no anemia and no discoloration of bone or teeth; *photodynamic dermatitis is the only consistent clinical manifestation.* Pigment is, however, deposited in the liver and heavy concentrations resembling lipofuscin are found in the cytoplasm of hepatocytes, Kupffer cells, endothelium, and portal stroma.

Congenital porphyria occurs in *humans, cattle, and cats* and results from the production of the *abnormal protoporphyrin isomer I.* It also occurs in swine, but the biochemical defect is not known. All cells in the body share this defect but, since the effects on the blood system are most apparent, the disease is usually called *erythropoietic porphyria*. Only isomer III can be synthesized into heme, although the enzymatic block is never complete and some normal heme is produced. The abnormal porphyrinogen intermediates accumulate in tissues and are readily oxidized to porphyrins capable of absorbing visible light and emitting visible fluorescence causing *photosensitization* (see Vol. 1, Skin and appendages). The disease is transmitted as a recessive trait (dominant in pigs) and heterozygotes are unaffected.

The enzyme uroporphyrinogen III cosynthetase is much reduced in affected animals and intermediate in heterozygotes. The disease results from either an absolute or relative deficiency of this enzyme because of overproduction of proximal cosynthetase enzymes. The type I isomer builds up in red cells and tissues and may be detected by fluorescence.

There is mild-to-moderate anemia (60–110 g Hb/L) exacerbated by exposure to light. The anemia is macrocytic normochromic in recovery. Polychromasia is mild and increases with light exposure. Marrow is hyperplastic with increase in late stage rubricytes. Red cells fluoresce and urine is brown. Red cell protoporphyrin is increased (350–450 mg/L of red cells, normal being 0.1–0.2 mg/L red cells). There is reduced ferrochelatase activity, but the level of immunoreactive protein is normal, suggesting a point mutation in the gene coding for the synthesis of this enzyme. Human patients with congenital porphyria develop hepatic hemosiderosis terminating in cirrhosis and suffer severe hemolytic anemia following hepatic orthopic transplantation. It is suggested that there was a consistent mild hemolytic anemia due to the hypersensitivity of the red cells to photo-oxidation such as might occur during a prolonged operative procedure.

Acquired porphyrias may follow exposure to *lindane* and related substances (see Vol. 1, Bones and joints).

Anemia of deficient cell production

Anemias due to reduction in red cell production are characterized by hypoproliferation that primarily affects cell division as opposed to hemoglobin production. *The causes of inadequate cell production include immune phenomena, often drug-induced, toxins both exogenous and due to hepatorenal failure, myelophthisis, chronic inflammation, endocrine dysfunction and nutritional deficiency.*

Aplastic pancytopenia

Aplastic pancytopenia occurs in all species but is *most often seen in cats and dogs*. It may be congenital, but is *usually acquired and idiopathic*, and may be associated with specific infections or toxic agents. Marrow aplasia may be absolute and rapidly fatal or, more commonly, hypoplastic and chronic. Any of the three blood cell lines may become aplastic, but *characteristically the disease is either one of generalized aplasia resulting in pancytopenia, or of pure red cell aplasia* (Fig. 2.78) with a hyperplastic myeloid and megakaryocytic marrow. Rarely, diseases characterized by leukopenia are accompanied by marrow myeloid hyperplasia with apparent immune suppression of myeloid maturation. Thus, the apparent marrow hyperactivity is ineffective, and output is deficient. The accepted criteria for aplastic pancytopenia (aplastic anemia) are peripheral blood neutrophils less than 0.5×10^9/L with platelets less than 20×10^9/L, an

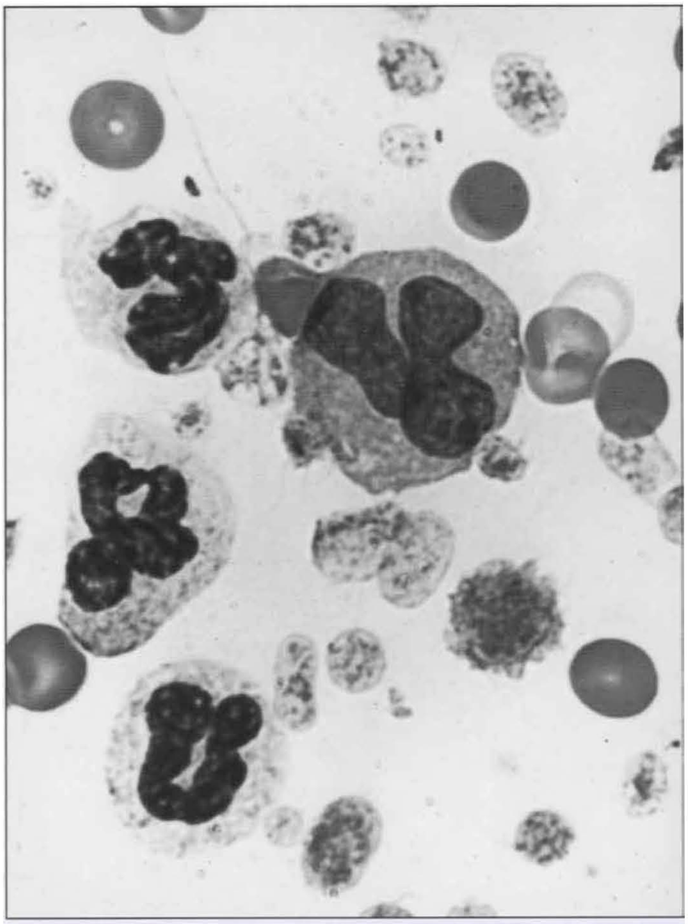

Figure 2.78 Pure red cell aplasia, peripheral blood from a dog. Nonresponsive anemia with excess neutrophils, monocytes, platelets.

absence of reticulocytes, and severe marrow hypocellularity in which fewer than 30% of residual cells are of hematopoietic type. *Suggested mechanisms for aplasia include decreased numbers of normal stem cells, inhibition of stem cell maturation, abnormal marrow microenvironment, lack of hematopoietic factors, and marrow depression associated with thymoma.*

Viruses may cause marrow depression. The most important of these in animals are the canine and feline parvoviruses and *Feline leukemia virus.* **Phenylbutazone** causes aplasia in humans but appears not to have this effect in animals unless there is prolonged exposure at high dosage. All forms of **estrogenic drugs** are potentially myelotoxic in dogs, and disease is characterized by an initial leukocytosis followed by thrombocytopenia, hemorrhage and aplasia which is usually irreversible. **Chloramphenicol** causes irreversible myeloid aplasia in humans as an apparent idiosyncratic reaction. It does not have this idiosyncratic effect in animals, in which marrow suppression is dose-related at above-normal rates of administration. **Furazolidone** at high dose rates is acutely neurotoxic in calves and pigs. When administered long-term to calves at dose rates used for prophylaxis of infection, furazolidine causes toxic depression of bone marrow manifested acutely as agranulocytopenia with widespread embolic infections, clinically best revealed as discrete necroses and ulcers of mucous membranes.

Animals with **aplastic pancytopenia** have epistaxis, bleeding into joints and dependent areas, and are often febrile due to sepsis. Animals with **pure red cell aplasia** are presented with mucosal pallor, lethargy and reduced activity, and are usually afebrile. Pancytopenia may be either moderate and chronic, or severe and acute with an absence of neutrophils. Those granulocytes present show toxic changes and little immaturity. Thrombocytopenia is severe and nonregenerative, with all platelets aged, small and with little basophilia. Anemia is moderate-to-severe and normochromic normocytic without polychromatic response. Differences in lifespan and rates of consumption of the cells of blood dictate that the aplastic syndromes are dominated by the purpura of thrombocytopenia and the sepsis of agranulocytosis. Morphologically, hemorrhage and sepsis will predominate in proportion to the relative deficits of platelets and/or neutrophils. If neutropenia is severe, there will be widespread bacterial emboli in lung, liver and kidney unaccompanied by the edema and cell reaction characteristically seen with a competent marrow.

Bracken fern poisoning

Bracken fern (*Pteridium aquilinum*) is abundant in many humid grassland areas of the world, and poisoning by it is often the factor that limits the utilization of pastures. There are other species in the bracken-fern genus, notably *P. esculentum*, the common bracken, which are toxic and the diseases produced are identical. *Cheilanthes sieberi*, the **mulga or rock fern**, contains much higher levels of thiaminase then does bracken, and produces the typical hematopoietic syndrome in cattle and polioencephalomalacia in sheep.

Bracken fern poisoning produces a variety of disease syndromes in grazing animals. The acute disease occurs in horses and pigs as a *neurologic and cardiac manifestation of thiamine deficiency*, in sheep as *polioencephalomalacia*, and in cattle as *aplastic pancytopenia*. The chronic syndromes occur in cattle and sheep as "*enzootic hematuria*" and "*bright blindness*," and in cattle there is an association with *epithelial tumors of the alimentary tract.* Some of these syndromes are appropriately discussed in other chapters.

Bracken fern appears to be most poisonous when it is green and growing actively. Hay made from the fern is also toxic, providing that the plants are well dried and retain some of the natural color. The fern is not particularly palatable and the ecological conditions which are conducive to the ingestion of toxic amounts of the plant are drought resulting in inadequate top growth of improved forage, or an excess of lush pasture in which animals seek out coarse growth in order to obtain sufficient roughage. The *poisoning is cumulative* and the disease may not be evident until after many weeks of continuous exposure, or for as long as 8 weeks after last exposure. *Cattle and horses are the most susceptible species*, sheep are relatively resistant as well as being fastidious eaters, and pigs, which eat the rhizomes, are occasionally poisoned. The manifestations of poisoning differ in the different species, but *depression of hematopoiesis is common to them all.* In cattle and sheep, the essential change is *irreversible trilineage marrow hypoplasia.* This results in **aplastic pancytopenia** and death due to thrombocytopenic hemorrhage (Fig. 2.79A, B) complicated by septicemia of neutropenia (Fig. 2.80A, B).

Horses and rats suffer myelosuppression but die of a nervous disease, which is curable by thiamine, before the effects of pancytopenia are fully developed. Horses whose diet contains 40% or more of bracken fern suffer inappetence, loss of weight, bradycardia, and nervous signs which progress to recumbency. The illness can be both prevented and treated with thiamine. The syndrome is comparable to that in horses poisoned by *Equisetum* spp., especially *E. arvense*, in which a thiaminase is present as it is in bracken fern and other pteridophytes. As expected in thiamine deficiency, there is, in horses and rats poisoned by bracken fern, a gradual rise in the pyruvate levels in blood. The hematological changes are not of prognostic significance in bracken poisoning in these species. The hematological changes are reversed by thiamine, but this effect appears to involve prevention of thiaminase toxicity rather than by correcting a thiamine deficiency, since a simple deficiency in rats does not cause anemia.

The disease in **cattle** apparently depends on a *direct inhibition of a pluripotent stem cell* and not a disturbance of the metabolism of thiamine. The principal hematological change in nonruminants is thrombocytopenia but there is also a tendency to neutropenia and anemia complicated by hemorrhage. The changes are consistent with what would be expected with inhibition of proliferation of blood cells in a "pipeline production" where the platelets have a 4 day production time and a life span of 9 days and the neutrophils a 6- to 7-day production time with a life span of only 6–8 hours. The anemia of hypoproliferation is less significant, unless complicated by bleeding, because of the long lifespan of the erythrocyte.

The morbidity from bracken poisoning in cattle is not high, but the mortality is, and recovery is rare once clinical signs are evident. This is logical since clinical signs are secondary to a complete loss of the "pipeline" of blood cell formation, and even a return of stem cell function would require survival through a week of thrombocytopenia and neutropenia before the results of renewed production become functional in the peripheral blood. In cattle, *thrombocytopenia occurs first* and is followed in hours by *leukopenia and neutropenia*, both likely complicated by increased consumption as hemorrhagic foci remove both from circulation. In contrast to the platelet and neutrophil precursors, some rubricytes persist in the

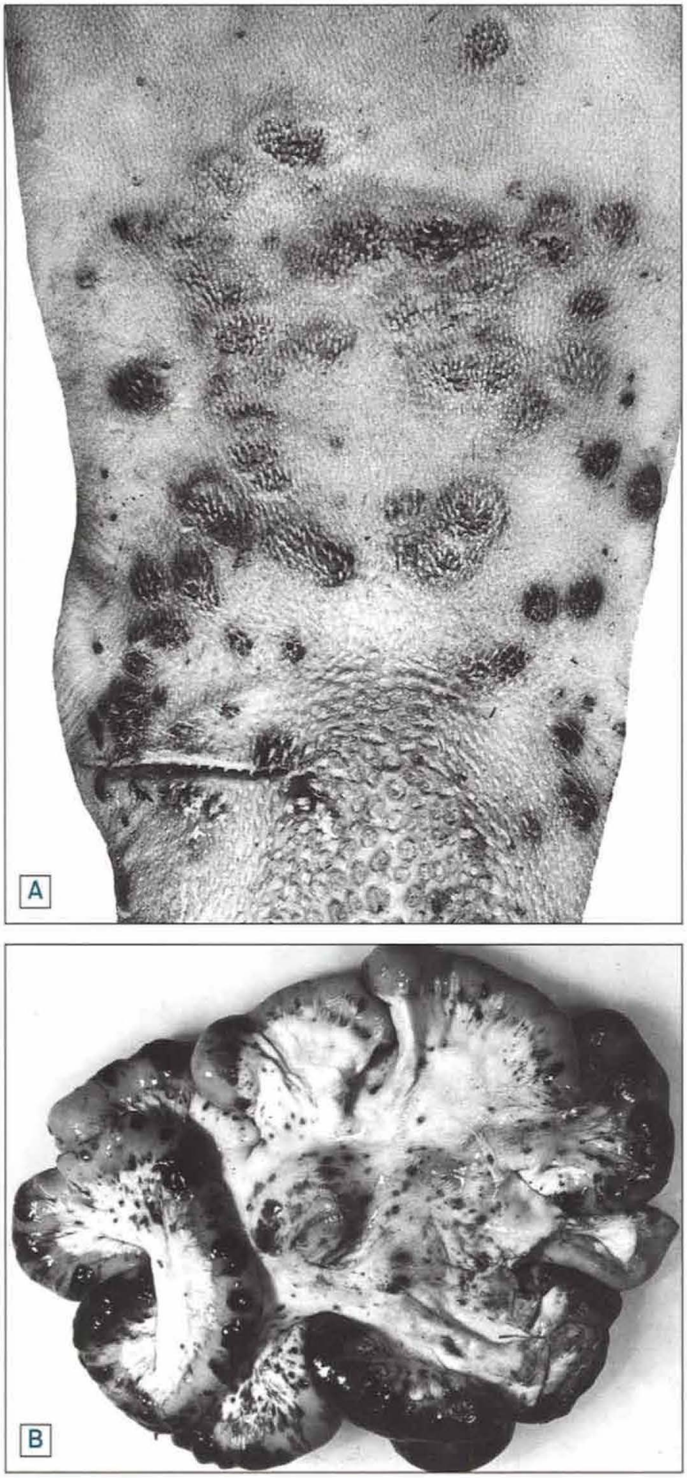

Figure 2.79 Bracken fern poisoning in an ox. **A.** Hemorrhagic infarcts in the tongue. **B.** Serosal hemorrhages of the intestine.

marrow, but the anemia is nevertheless largely nonresponsive. Because of the long (155 days) red cell lifespan in cattle, the anemia is, however, largely due to *hemorrhage* which is both enteric and generalized. As the disease develops, clot retraction is impaired out of proportion to the reduction in the platelet count, suggesting impaired function (thrombasthenia) as well as deficient numbers. Increased capillary fragility has also been proposed and is likely a consequence of unremitting thrombocytopenia.

The dominant features of the clinical disease are hemorrhages, bacteremia, and fever. The hemorrhages are due to thrombocytopenia, and the bacteremia due to neutropenia. Bacteremia and bacterial embolism contribute to the genesis of hemorrhage. The latent period of bracken poisoning in cattle is 2 months or more, and even longer in sheep, but the clinical episode develops suddenly and acutely, with high fever, hemorrhages on mucous membranes, and hemorrhages from natural orifices including the urethra. Calves frequently show excessive discharge of mucus, sometimes blood-stained, from the nose and mouth, edema of the throat, and focal, necrotic stomatitis and cheilitis (Fig. 2.79A). The course is usually less than 3 days. In the rare cases where recovery has been followed, the return of the leukocyte count to normal may require several months, which suggests continuing toxicity or injury to a very primitive stem cell pool of restricted numbers that requires weeks to replenish.

Grossly, *there is hemorrhage in almost all tissues but without any particular pattern* (Fig. 2.79B). They are particularly numerous, however, in the stomach and intestine, to the mucosal surface of which the blood tends to adhere in clots; in the large intestine, the hemorrhages are more diffuse, and copious free blood may be present in the lumen. *Hemorrhages beneath mucous membranes usually lead to overlying ulceration.* Hemorrhages in the liver may be sufficiently numerous to give it an odd variegated appearance, especially when it also contains many infarcts (Fig. 2.80A). The *hepatic infarcts* are spherical or wedge-shaped areas of white or yellow and similar to the lesions of black disease; they may be absent, few, or numerous. The hepatic infarcts, like those in other tissues, are caused by bacterial emboli which localize in small branches of the portal vein, the sinusoids, and the central veins. The bacteria are ordinary saprophytes in many cases and, if the postmortem interval is prolonged, the focal lesions expand about the colonies because of local postmortem putrefaction. The heart has extensive subserosal hemorrhage but, in addition, there are foci of *myocardial infarction* which are discrete yellow areas up to 1 cm long. There is usually little or no cellular reaction to these embolic bacteria or to the necrosis of tissue in the infarcts (Fig. 2.80B). *Infarcts in the kidney* are usually red and also caused by bacterial embolism. Extensive hemorrhages are rather consistently present in the walls of excretory passages of the urinary system. The red *bone marrow*, which in adults should be firm and fatty, is instead pink and soft, and it dehydrates and shrinks on exposure to air. Marrow cellularity is markedly diminished to the point where either only small islets of erythropoiesis remain, or there is complete aplasia with edematous stroma and dilated sinusoids, and only a few fat cells are present.

Pigs fed rhizomes show only *minor signs of toxicity* including, depression of growth rate, increases in blood pyruvate, and a reticulocytopenia, all of which can be corrected by administration of thiamine. Neurological signs such as occur in horses are not observed, but there is myocardial injury of the type observed in experimental thiamine deficiency in pigs. The rhizomes contain substantially more thiaminase than do the fronds.

The experimental production of bracken poisoning in **sheep** is very difficult. Sheep find the fern unpalatable and are slow to develop signs of poisoning. The clinical and pathologic manifestations of the disease are analogous to those in cattle, including the development of pancytopenia.

The discussion above relates to *two toxic factors in bracken fern*, one a *thiaminase* and the other a *substance that causes bone marrow depression*, especially in ruminants. A nosesquiterpene glucoside, *ptaquiloside*,

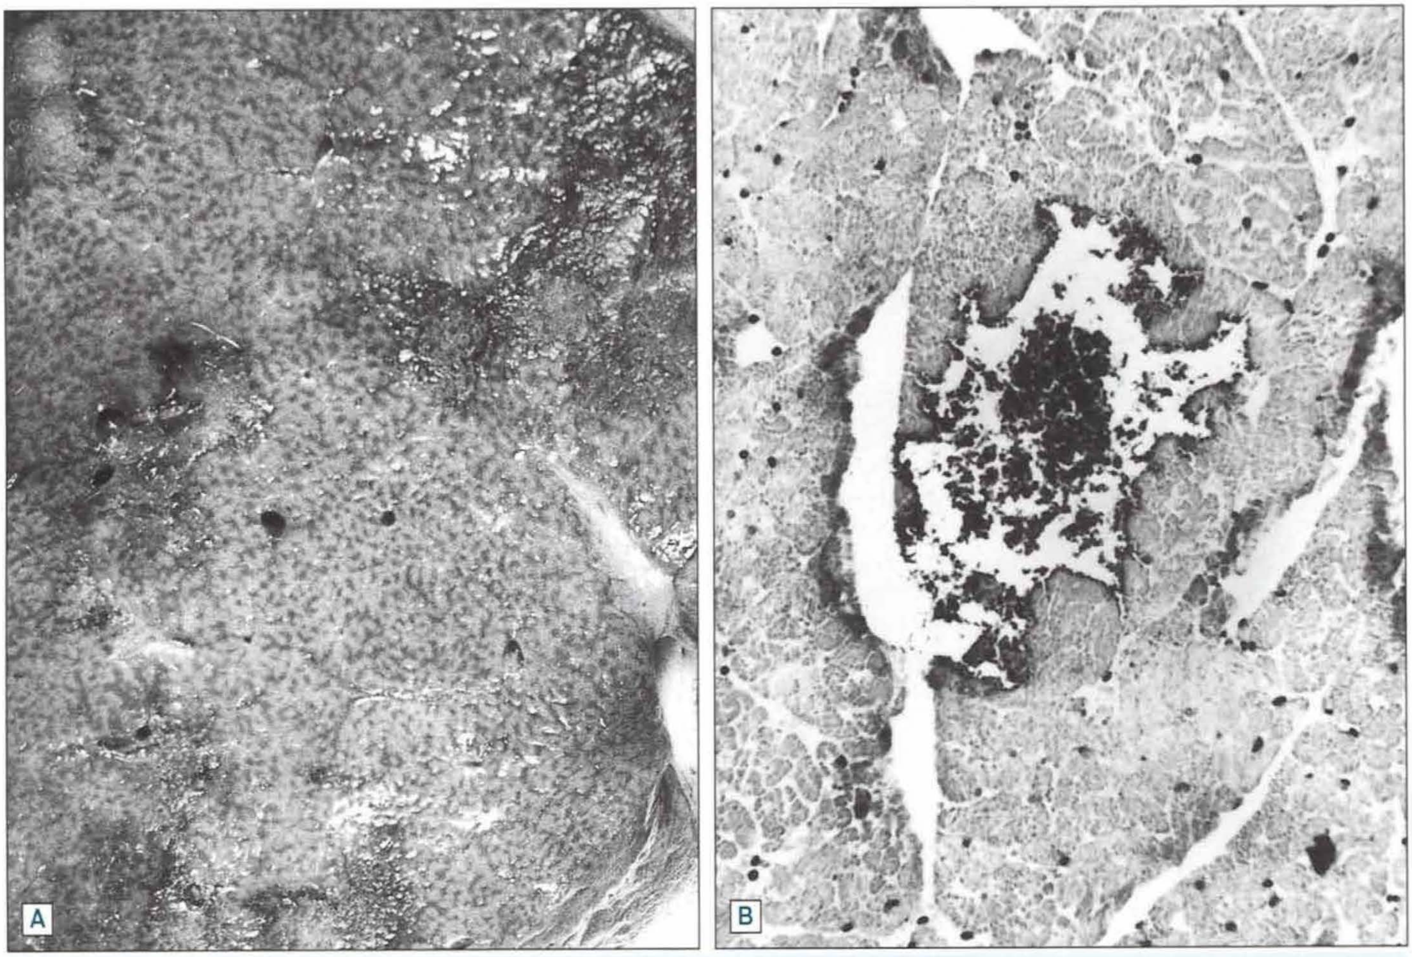

Figure 2.80 Bracken fern poisoning in an ox. **A.** Fatty liver with pale and red infarcts resulting from bacterial embolism. **B.** Bacterial embolism without inflammatory response.

extracted from bracken fern, has produced bone marrow depression in a calf but its significance to the naturally occurring disease is unclear. It appears to be the responsible agent in enzootic hematuria.

Disease in cattle, apparently identical to that produced by bracken fern, has resulted from feeding of *soya bean meal which had been extracted with trichlorethylene*, and in calves fed diets to which *nitrofurans* were added for bacteriostatic purposes.

Pure red cell aplasia

Pure red cell aplasia is seen in *humans and dogs*. Pathogenetically, there is *immune suppression of differentiated red cell precursors that is T-cell driven and mediated by interferon, and there may also be antibody against erythroid nuclei.* T-cell inhibition may be of several types, including that associated with the proliferation of benign clonal or malignant large granular lymphocytes, particularly those with the γδ T cells and some NK cells. In human disease associated with leukemias of large granular lymphocytes, there tends to be a more general suppression of bone marrow with neutropenia as the most important persisting deficit. In dogs, neutropenia does not appear to be a feature of neoplasms of large granular lymphocytes; however, nonresponsive anemia appears to be a consistent finding. Therapy, which is likely to be effective if vigorous, is indicative of the mechanism of aplasia and includes immunosuppression by drugs, antithymocyte globulin, and plasmapheresis.

Clinically, the disease is likely to occur in a mature dog and may result from exposure to a drug or virus, or be associated with a lymphoid tumor of the large granular lymphocyte type (see B-cell chronic lymphocytic leukemia/small lymphocytic leukemia). There is weight loss and exercise intolerance but the appetite is usually retained. There is pallor of membranes but no tendency for bleeding or infection. Hematologically, the anemia may be severe, with hemoglobin less than 50 g/L, and worse than the red cell numbers might suggest, since the red cells, while normochromic and normocytic, become small with age. While reticulocytes are consistently absent, there appears to be stimulation of those lineages able to respond and there is characteristically mature neutrophilia of 15–25 × 10^9/L and a thrombocytosis of 500–1000 × 10^9/L with marked variation in size, basophilia, and granulation, such that the larger platelets may interfere with the red cell count (Fig. 2.78). Monocytes are increased, likely as part of the stress reaction, to 2–3 × 10^9/L. The bone marrow has normal cellularity but the myeloid:erythroid ratio is greatly increased as are megakaryocytes, but rubricytes are rare. Grossly, *pallor is the dominant finding*, often with pulmonary edema and cardiac dilation. There is ischemic damage to periacinar hepatocytes and proximal renal epithelium. The spleen and nodes are of normal size without extramedullary erythropoiesis, reflecting the generalized suppression of the red cell system.

Feline panleukopenia

Feline panleukopenia (infectious feline enteritis), a *parvoviral infection* to which all Felidae are susceptible, is described in Vol. 2, Alimentary system. Clinically the disease may be of such sudden onset that poisoning is suspected. Signs begin 5–6 days after exposure of a susceptible animal and may be mild or fatal. Typically there is prostration with vomiting, diarrhea, and severe dehydration. Fever is variable and may not be present after onset of disease, likely because of the need for functional granulocytes for production of pyrogen. Pathogenetically, the disease is radiomimetic and the signs and lesions are referable to destruction of proliferating cells, principally in marrow, intestinal epithelium, spleen, lymph nodes and thymus. Hematologically the leukocyte counts decrease to less than one third of normal level on day 5 after experimental infection, remain low for 5 days, and then rise rapidly in cats that survive. In those that die, the leukocytes decline to less than $1 \times 10^9/L$ by the 7th and final day. This drop is almost entirely due to a *reduction in granulocytes*, and the timing of both the decline and recovery is related to the production time of the neutrophil, which can be deduced to be 5–6 days as in the calf and dog. Thus, there is complete cessation of all lines of hematopoiesis shortly after infection, and those cells in the postmitotic pool continue to mature and are delivered to the blood in pipeline fashion. After a short period of aplasia, there is recovery of the stem cell pool and an advancing front of early myeloid cells that appears as "maturation arrest" at days 7–8 when death due to dehydration usually occurs. The intestinal signs do not begin until granulocytes become deficient and, in the germ-free cat, there is a mild decline in total leukocytes but no loss of intestinal epithelium or diarrhea. In recovery, erythropoiesis is delayed until there is a peripheral blood neutrophilic leukocytosis (peak day 13) indicating a shunting of stem cell commitment to the lines essential for survival. The marrow in this disease is extremely labile and changes occur within hours, accounting for the variation seen with disease progression and recovery. Marrow cellularity drops to less than one-third of normal by the third day after inoculation, is less than 20% of normal between days 5–7, and returns to about half of normal on day 10. Platelet counts decrease to half the normal level on day 5, and in survivors return to original levels between days 7–10 postinfection. Animals that die have severe aplasia, with complete loss of the myeloid and erythroid proliferative phase cells. Survivors have the lowest levels of myeloblasts on day 3 followed by recovery on day 5, whereas erythroblasts reach their lowest level on day 5 and recovery is delayed until day 10.

Histologically, lymph nodes, spleen and Peyer's patches have *both thymus- and marrow-dependent hypocellularity*. Follicles are characteristically large and occupied by a background of pale dendritic reticular cells made apparent by lysis of the follicular center cells. Fragmented nuclei are usually absent, indicating that lympholysis occurred several days previously. Follicles are rimmed by a narrowed zone of small lymphocytes, and paracortical areas are also hypocellular. All tissues are lacking in neutrophils, and there is often extensive erythrophagocytosis in the medullary sinuses of mesenteric nodes. The latter is presumably the result of erythrocyte injury, possibly due to the adherence of luminal toxins during their passage through the capillaries of denuded villi. Striking changes occur in the thymus and consist of complete cortical collapse. The thymus becomes a thin band of facetted lobules composed of hypoplastic medullary areas with collapse of the fascial boundaries around the depopulated cortices. *Thymic atrophy* is the major lesion in experimental infection of germ-free cats where clinical disease is minimal.

Stachybotryotoxicosis

Stachybotryotoxicosis, as a *pancytopenic disease*, occurs in horses and ruminants in Eastern Europe and Russia. The responsible fungus *Stachybotrys alternans* (*atra*) grows on substrates rich in cellulose, and contaminates hay and cereal grain. *The nature of the marrow depressant toxin is not known*, but appears to be related to the trichothecenes produced by *Fusarium*. Although best documented as the cause of extensive outbreaks of disease in horses, episodes of comparable magnitude also occur in cattle, and sporadic episodes occur in sheep and swine. Other species including humans are susceptible. The syndrome occurs in *three stages*: the initial *local signs of irritation*; a period of *quiescence* in which blood dyscrasia occurs; and a final episode being the consequence of *severe pancytopenia*.

Following ingestion of contaminated food, there is drooling, hyperemia of buccal mucosa, and deep fissuring of the lips, leading to extensive inflammatory edema of the soft tissues of the buccal cavity. Local lymphadenopathy may persist for several weeks. There is early leukocytosis, followed by progressive depletion of formed elements of blood, especially platelets and leukocytes, with prolonged prothrombin and clot-retraction times. The terminal stage is fairly brief and manifested as *hemorrhagic diathesis and bacterial infection*.

The pathological picture in cattle closely resembles that observed in bracken-fern poisoning; in horses it is characterized by profuse hemorrhage and necrosis in many tissues. In sheep, the fleece may be shed at about the time when hemorrhages occur. Necrotic processes in the mucous membranes of the alimentary canal are characteristic, especially of lips, tonsillar fauces and large intestine. There is more or less severe depletion of hematopoietic and lymphopoietic tissues.

Myelophthisic anemia

Myelophthisic anemia of myelofibrosis is discussed with Myeloproliferative diseases, and the displacement of marrow in osteopetrosis and osteodystrophia fibrosa is discussed with Vol. 1, Bones and joints.

Myelophthisis of leukemia is seen most often in dogs, cats, and cattle. The anemia of leukemia has *4 mechanisms: stem cell displacement, panmyelosis, immune depression, and cachexia. Marrow failure with consequent loss of all normal cells represents the end stage of acute leukemia.* These cell deficits occur earlier and with greater diversity in acute myelogenous leukemia than in acute lymphocytic leukemia. The basic difference between these two diseases appears to depend on the relative distribution of the leukemic stem cells in the bone marrow. Normally the pluripotent stem cells are in highest concentration in the subendosteal marrow, apparently because of the tropism resulting from the bone-marrow portal capillary drainage. Leukemic lymphoid cells tend to be distributed randomly throughout the marrow cavity without predisposition for subendosteal hemopoietic areas, and, although the marrow may be solidly infiltrated by tumor, marrow failure is a late occurrence. In contrast, in acute myeloid leukemias, malignant stem cells compete directly with their benign counterparts driving them centripetally, in which location they are stimulated to enter a pattern of differentiation rather than of self-renewal, ultimately leading to depletion of the normal stem cell pool. The anemia in myelogenous leukemia may also be related to the fact that the erythroid cells are themselves the progeny of neoplastic precursors that do not respond to normal demands for proliferation.

In the lymphoid leukemias particularly, there are often immune phenomena associated with the appearance of the neoplastic clone. In chronic lymphocytic leukemia, therapy of the disease may result in the development of immune hemolytic anemia. Similar changes are observed in some lymphomas, and the effects may vary from a subtle immune depression of erythropoiesis to destruction of apparently normal peripheral blood erythrocytes.

All animals with leukemia that survive for more than a few weeks show some degree of the cachexia characteristic of cancer, due apparently to the systemic production of tumor necrosis factor by defensive cells. In addition to the wasting of cancer, there is the specific impairment of hemoglobin synthesis as a result of scavenging of serum transport iron, which is part of the biochemical response to chronic disease.

Anemia of uremia

Anemia of uremia occurs in all species but is most often recognized in the *dog and cat*, which are the domestic species that most commonly survive to old age. *Anemia is a characteristic feature of chronic renal failure*; urea levels of 35 mmol/L or higher are almost always associated with a hematocrit of 30% or less. There are *4 principal mechanisms* of anemia in renal failure. *These are excessive hemolysis of red cells due to retention of creatinine and guanidinosuccinic acid, toxic depression of erythropoiesis, loss of renal erythropoietin, and blood loss from the kidney*. All of these processes may be operative to some degree with variation in their relative importance from case to case, but the major limiting factor in the anemia of uremia in humans and animals appears to be *inadequate levels of erythropoietin*.

The anemia is normocytic, largely normochromic, and of mild-to-moderate severity. Polychromasia is rare or absent, and there is some poikilocytosis with an occasional hypochromic red cell. Toxic changes in neutrophils are usually prominent. The diagnosis is based on clinical signs and other biochemical evidence of uremia (see Vol. 2, Urinary system).

Anemia of endocrine dysfunction

Mild anemia of marrow hypoplasia is associated with loss of function of the pituitary, thyroid and adrenal glands, and to a lesser extent of the gonads. Anemia related to **pituitary dysfunction** appears to be due both to loss of thyroid stimulating hormone and adrenocorticotrophin, as both are required to maintain hemoglobin levels. **Hypothyroidism** is associated with normal red cell survival, but decreased red cell production, red cell mass and blood volume. Therapy may temporarily exacerbate the anemia, since the plasma volume recovers more rapidly than does the red cell mass. Mild normochromic normocytic anemia occurs in **adrenal insufficiency.** Its true extent is masked by a concomitant reduction in plasma volume. The anemia is corrected by steroid therapy, although the mechanism is unclear. There is often a mild increase in red cell numbers in hyperadrenocorticism, however, it is likely that the effect is erythropoietin mediated and not a direct effect of adrenal steroids on marrow. **Castration** lowers hemoglobin levels 10–20 g/L in male animals, to just above the normal female level. If females are spayed, their hemoglobin levels rise to that of castrated males.

Anemia is rarely of clinical significance in hormonal dysfunction, except in the need to distinguish it from anemia of other cause, and the reduction in hematocrit is usually an incidental finding. It is a mild normochromic normocytic anemia without toxemia or polychromatic response.

Anemia of deficient hemoglobin production

The anemias of deficient hemoglobin may be subdivided on the basis of pathogenesis into *anemias of deficient heme and anemias of deficient globin*. In animals, *anemias due to insufficient heme are largely a result of iron or copper deficiency or chronic inflammatory disease*. In erythropoietic porphyria, there is production of an ineffective isomer of protoporphyrin and this disease is considered under congenital disorders of red cells. *Anemias due to deficient globin (e.g., thalassemia) are not of clinical importance in veterinary medicine*; however, true imbalances in the production of the α and β chains of globin have been identified in mouse models of this disease.

Iron-deficiency anemia

Iron is an essential component of hemoglobin, myoglobin, the cytochrome enzymes of mitochondria and hepatic microsomes, and the metalloflavoproteins (NADH), and is required as a cofactor for the function of other enzymes. Thus, *while anemia is the principal sign of iron deficiency, there are other diverse effects*, which include neutropenia, decreased capacity for killing ingested bacteria, impaired T-cell response to mitogens, and decreased capacity for interferon production. Iron deficiency results in alterations in several biogenic amines that are thought to be responsible for irritable behavior and cognitive defects observed in humans and animals. In addition, deficient states result in increased catecholamine levels leading to cardiac hypertrophy in rats and impaired temperature regulation and cold tolerance. A deficiency of body iron stores, as distinguished from iron deficiency anemia, may develop from deficiency of iron in the diet, impaired absorption, or excessive loss. In discussing the pathogenesis of iron deficiency, it is convenient to consider each of these possibilities.

The only natural **diet** of animals that can result in a **deficiency of iron** is milk, and therefore deficiency of this pathogenesis is seen only in sucklings. Supplementation of the diet of the dam does not influence the occurrence of iron deficiency in the sucklings. In terms of animal husbandry, the recognition of the need for supplemental iron for neonates has been a relatively recent development which followed serious losses when confinement rearing of swine came into vogue.

Impaired absorption of iron is rarely of significance in animals, but does occur in dogs with acquired malabsorption syndromes. Absorption takes place from the stomach and duodenum, and the degree of absorption within limits is geared to demand. About 5% of dietary iron is absorbed in the replete animal and this proportion may increase to nearly 20% in deficient states. Absorption varies with the form in which iron is ingested. Thus, heme iron is well absorbed, whereas inorganic iron is much less available but in adequate amounts is adequately absorbed. *Iron absorption appears to be regulated as a function of the level of saturation of the serum transport protein transferrin.* Transferrin has a high binding coefficient for iron and is normally about 50% saturated. In deficient states, saturation drops below the 16% level, at which point iron is not partitioned to the marrow rubricytes and iron supply becomes rate-limiting to red cell production. The developing enterocytes become imprinted with ferritin, the next level of iron transport, in proportion to body iron stores, and subsequently they absorb iron in proportion to the body's needs. Thus, absorption is partially blocked by high body stores and vice versa.

Free iron in serum in excess of the binding proteins is toxic and promotes bacterial invasion. In well-fed dams and sucklings, these binding proteins rapidly scavenge excess iron given parenterally, so that toxicity or infection does not occur. In debilitated animals, particularly the young, parenteral iron should be withheld until animals are gaining weight and serum proteins can be assumed to be replenished. Thus, teleologically, *the physiological anemia of the young is a defensive strategy to deny bacteria access to iron during the period of transition from passive to active immunity*. Since sucklings of all species are born with minimal stores, the increased requirements for iron concomitant with rapid growth and expansion of blood volume guarantees that they will develop iron deficiency if not given access to dietary iron or are otherwise supplemented.

Excessive loss of iron is the result of *chronic loss of blood* and is an important cause of iron deficiency; it is the only cause in adult animals, since normally only very small amounts of iron are excreted and lost.

The signs of iron deficiency are those of chronic anemia although they may be visibly complicated by the underlying pathologic process. Apart from the effects on blood and those changes which are the result of anemia, lesions specifically attributable to iron deficiency are limited to the recognition of the anemic state in conjunction with an absence of stainable iron in tissues. Body iron stores can be estimated as a function of plasma ferritin where 1 μg of ferritin can be equated with about 120 μg of iron/kg body weight. The *depletion of body iron* can be considered at *three levels of severity* based on the levels of saturation of transferrin, the level of hemoglobin, and of red cell protoporphyrin. At the *first stage of depletion*, the hemoglobin and transferrin saturation are normal, but ferritin is decreased and hemosiderin is absent. At the *second stage of depletion*, both ferritin and transferrin saturation are deficient and red cell production is slowed. Finally, in *iron-deficient anemia*, there is not only loss of all iron stores, but hemoglobin is decreased and red cell protoporphyrin is increased as a result of impaired heme synthesis. Rubricyte maturation is coordinated to produce heme and globin in proportional amounts. Lack of iron slows protoporphyrin and globin synthesis, and there is delayed rubricyte maturation which results in an increased proportion of mature rubricytes in the bone marrow (*mature asynchrony*). The marrow is hyperplastic with an erythroid shift but without peripheral blood reticulocytes. The marrow transit time of the rubricytes is extended beyond the normal 4 days, and erythropoiesis is thus termed *ineffective*.

Hematologically, *the anemia is classically hypochromic and microcytic in all species*, and accompanied by neutropenia with hypersegmentation and marked thrombocytosis of small platelets. Red cells are not only small and poorly saturated but also distorted in shape. The plasma is pale, as is the urine due to reduced formation of bilirubin. Serum iron is generally less than 9 μmol/L, and the total iron-binding capacity is increased, generally in the 70–110 μmol/L range. Apparently in a multiply transfused human, the typical anemia can develop in the face of adequate iron by the development of an antibody against the rubricyte transferrin receptor.

Anemia of iron deficiency is common in **piglets** and in **puppies** of the larger breeds; it is probably responsible also for the anemia which is often observed in *calves* on diets solely of milk, but it is seldom clinically important and probably never fatal. Unless special measures are taken to prevent the disease in piglets, a morbidity of 90% may occur with a mortality of approximately 10–50%. The higher figure for mortality includes those animals which die of secondary infections. As noted above, iron deficiency seriously impairs defensive mechanisms and predisposes piglets to a variety of infectious diseases, especially colibacillosis and swine dysentery, as well as spirochetal granulomas, omphalophlebitis, and streptococcal meningitis, pericarditis and polyarthritis, and other pyogenic processes.

The piglet is particularly predisposed because of its rapid growth rate. Mortality is higher in the winter than in other seasons, partly because of confinement and partly because of increased susceptibility to cold. The requirement of a young piglet for iron is set at about 7 mg per day; milk supplies only half of this amount.

The disease is varied in its manifestations and course, but it can be described in *three discrete syndromes*. The piglets are normal at birth. In the *classical syndrome*, they become progressively unthrifty after the first week of life and grossly there is pallor of all tissues, edema of muscles and connective tissues, edema of the lungs, and a thin-walled, flabby heart. In a *second syndrome*, the piglets often die suddenly in the third week. These piglets are well grown, pale and appear plump due as much to edema as to fat. At necropsy, all tissues are extremely pale, wet, and there is pericardial effusion with the heart dilated to more than twice its normal size. The *third syndrome is one of secondary infections*, and the age incidence is broadened to include pigs of 4–8 or 10 weeks of age and is seen where the piglets are not given parenteral iron and do not begin to feed from a creep feeder until they are 4–5 weeks old. In chronic cases, there will be dyskeratosis with abnormal ringing of horn and hooves or nails.

In all species with iron-deficiency anemia, the bone marrow has high cellularity and cell density with an erythroid shift and mature asynchrony with increased numbers of megakaryocytes and eosinophils (Fig. 2.81A, B). *The* **histologic diagnosis** *of iron-deficiency anemia is based on a hypercellular marrow with increased numbers of late stage rubricytes and an absence of hemosiderin.*

Copper-deficiency anemia

Copper is a cofactor in a variety of oxidative enzymes of diverse function, and deficiency of the element may affect electron transport (cytochrome oxidase), the absorption of iron and its utilization in hematopoiesis (ceruloplasmin), protection from antioxidants (superoxide dismutase), tyrosine degradation and pigmentation (tyrosinase), neurotransmitter metabolism (dopamine hydroxylase), or cross-linkage of elastin and tropocollagen (lysyl oxidase). *Copper deficiency can therefore be manifested in a variety of ways and in several organ systems.* Cytochrome oxidase is a copper-dependent enzyme, and *diminished activity of cytochrome oxidase is a sensitive indicator of copper deficiency which apparently limits the synthesis of heme, the prosthetic group of the enzyme.* This association of copper with cytochrome oxidase is probably its fundamental physiological function, but its participation in other enzymological processes may account for the diverse manifestations of copper deficiency within and between species.

Disturbed hematopoiesis is not the sole or even the most important aspect of copper deficiency, but it is one aspect which is common to all species in which the deficiency is discussed in detail here; reference to neurological, vascular and cutaneous manifestations of the disease will be repeated briefly in the chapter on the appropriate system.

Uncomplicated copper deficiency is probably not of widespread occurrence in animals, but in many endemic areas there are chronic diseases with local names, due to a complicated or uncomplicated deficiency of copper. Factors which control the uptake of dietary copper and its excretion are discussed under chronic copper poisoning. There, reference is made to the ability of high dietary intakes of *molybdenum* in the presence of sufficient inorganic sulfate to limit hepatic retention of copper by sheep, either by lowering absorption or increasing excretion. There is some evidence for both. The experimental production of a conditioned copper deficiency by appropriate use of molybdenum and sulfate is sometimes successful, sometimes not, which, together with the observation that copper deficiency can occur in ruminants on diets normal with respect to copper, molybdenum and sulfate, indicates that there are additional unrecognized factors influencing the availability, absorption, excretion, storage and utilization of copper. There are differences between species, and between breeds of sheep, in the levels of activity of intestinal absorption mechanisms and, probably also, in hepatic excretory mechanisms.

Approximately 25% of ingested copper is absorbed, primarily from the stomach and upper small intestine. Absorption is like that of iron in that it is an energy-dependent, two-step process involving an intraepithelial metallothionein-like protein that may transfer the copper to the plasma carriers or be shed with the senescent enterocyte. It may be that absorption is more efficient in monogastrics, since deficiency can reliably be reproduced in swine whereas in sheep copper deficiency may be more a function of molybdenum toxicity. The absorption is influenced by the chemical form of the copper and by its tendency to form insoluble complexes in the gut. The absorbed copper is transported in blood loosely bound to serum albumin from which it is rapidly distributed to tissues and concentrated principally in liver, kidney, heart and brain. Copper in blood exists as copper–protein complexes in red cells, loosely bound to serum albumin, and as part of **ceruloplasmin**, a copper-containing α-2 globulin. Ceruloplasmin is produced in the liver and contains 7 copper atoms in each protein molecule, one atom being labile and the remainder structural. The copper of plasma is much more labile than that of red cells and is a better indicator of fluctuations in copper status than is the copper content of whole blood. Bile is the principal medium of copper excretion.

Copper is present in all cells with principal reserves contained in the liver, although significant amounts are in kidneys, bone marrow and central nervous system. The latter areas likely represent metabolically functional rather than storage forms. Considerably more copper is found in the liver of the fetus and newborn than in the liver of adults of the same species. An exception is in sheep; ewes, irrespective of their copper status, have much greater hepatic stores than their lambs. In adult ruminants, the levels of hepatic copper vary widely and reflect to some extent the animals' nutritional history with respect to this element. Much smaller, and rather stable, concentrations of copper are found in the liver of nonruminants. In general, determination of hepatic liver copper is a better indicator of the body's copper status than is determination of blood or serum copper concentrations.

Anemia is not invariably present in copper deficiency, but it is probable that anemia will occur if the deficiency is sufficiently severe and prolonged. Several mammalian species when made deficient in copper develop anemia, the severity of which depends on the duration of the deficiency as well as on host factors such as age and pregnancy. The morphological characters of the anemia vary with the species, that in rats, pigs, rabbits, and lambs is microcytic, hypochromic; in cattle and adult sheep, it is macrocytic, hypochromic; and in dogs, normocytic and normochromic.

Unlike iron, where the transport protein transferrin carries the metal in a high affinity bond with variable saturation, *copper circulates in the plasma in an integral bond with ceruloplasmin.* Since copper is required for the synthesis of ceruloplasmin, the ceruloplasmin level drops in copper deficiency. This is unlike iron deficiency in which the total iron-binding capacity rises as the serum iron drops. Ceruloplasmin acts as a specific oxidant for conversion of ferrous to ferric iron, in which state it is available for transferrin transport. The protein has been called *ferroxidase* to indicate this function.

The manner in which copper deficiency leads to anemia is not clear; however, the coincident development of marrow erythroid hyperplasia indicates that, as in iron deficiency, the stem cell system is not impaired but, because of reticulocytopenia, rubricyte maturation must be. *The disease is therefore one of* **ineffective hematopoiesis** *with hyperplastic marrow but deficient output.* The fact that the ineffective asynchrony is not uniformly of the late type in all species, as it is for iron deficiency, and that the red cells are not always hypochromic suggest that the mechanism of development is not solely one of iron inhibition. Rather it appears that the coordination of heme and globin synthesis, that is heme-limited in iron deficiency, is more generally affected in copper deficiency, and downregulation of rubricyte maturation may be mediated by deficits in both. In iron deficiency, marrow late-stage rubricyte mitoses are not prominent but probably do occur, and division without cytoplasmic production is the mechanism of microcytosis. In contrast, in the dog with copper deficiency the rubricytes are not predominantly late stage, but are generally younger. Mitoses are common and the anemia is normocytic, normochromic. Thus the net effect of copper deficient anemia in the dog appears to be defective maturation, increased intramedullary cell death and as in iron deficiency, deficient cell production. A shortened survival time of red cells occurs in copper-deficient, and also occurs in iron-deficient, pigs but kinetically the anemia in both is very largely due to reduced production.

Extensive hemosiderin deposits occur in sheep and cattle naturally deficient in copper, and in pigs made experimentally deficient, suggesting defective reutilization of endogenous iron. Copper-deficient swine have: impaired ability to transfer iron across the intestinal basement membrane; lowered plasma iron levels; an increase in plasma transferrin, and a lowered rate of turnover of iron from the liver. Thus, although the body is iron replete, there is impaired inter-organ transport, and in the pig the anemias of iron or copper deficiency look morphologically similar. There is abundant iron in the latter, however, and the thrombocytosis of iron deficiency is not seen in anemia of copper deficiency.

Anemia of suckling piglets associated with copper deficiency may account for some of the instances in which piglet anemia fails to respond to iron. In copper deficiency, the hemoglobin may fall to 10–20 g/L and the red cells to 2×10^{12}/L. The entire syndrome parallels that of iron deficiency except that it does not respond to iron; a good response follows the administration of copper but the reticulocytosis is delayed by the 3–8 days required for the synthesis of ceruloplasmin. In contrast, if plasma from a copper-replete animal is given, the response is immediate.

Anemia is an important sign of the enzootic maladies of copper deficiency, but is not invariably present, and in general, develops late in the course of the deficiency. The severity as well as the morphological features of the anemia are influenced by the severity of copper deficiency, the duration, whether complicated or not, and also by host characters such as age, growth rate, pregnancy, and parasitism. Rarely, anemia of copper deficiency may occur, where, for various reasons, there is dietary zinc excess with a competitive inhibition of enteric copper absorption.

Cobalt-deficiency anemia

Cobalt deficiency is a disease of ruminants expressed as ill-thrift; if death occurs, it is due to inanition (see Vol. 2, Liver and biliary system). The disease is known in many parts of the world but the distribution, especially of marginal deficiencies, is not well plotted; occurrence is often seasonal and complicated by concurrent deficiencies of copper and phosphorus. The minimum concentration of cobalt in forage consistent with adequate nutrition of ruminants is one part per million on a dry weight basis, but the only effective test of cobalt deficiency is in the response to oral supplementation. Cobalt deficiency produces a *chronic wasting disease* to which sheep are slightly more susceptible than cattle and to which horses are immune; lambs and calves are even more susceptible than their respective adults. The disease is characterized by a gradual reduction of appetite for both food and drink, progressive emaciation, and death from starvation even though food may be plentiful. The European name, *licking disease*, places emphasis on the allotriophagia which accompanies inappetence in cattle. Abortion, temporary sterility and decreased production are common in cattle. Pallid mucous membranes are characteristic but, as mentioned above, *anemia may or may not be demonstrable by routine tests* and may be masked by blood volume contraction with loss of weight.

In recognized endemic areas, sickness is usually evident after the animals have been at pasture for 4–6 months. Calves and lambs may not survive more than a further 6 months, although adults introduced to deficient pastures may survive for 2 years or more. The postmortem picture is that of starvation.

Cobalt deficiency is a deficiency of vitamin B_{12}. Parenteral treatment of deficient animals with the vitamin will sustain them for long periods, suggesting that hepatic storage is efficient. Pair feeding studies show that the cachexia of cobalt deficiency is largely due to inanition although there is apparently some loss of absorptive or metabolic efficiency. Remarkably, the parenteral administration of cobalt as $CoCl_2$ to deficient sheep has no effect on the disease and much of the injected dose is lost in the urine. In contrast, the administration of cobalt orally, or vitamin B_{12} by any route, is curative if enough of either is given. Synthesis of the vitamin occurs in the rumen, and even if there is adequate storage of cobalt in the liver, the disease will progress unless there is enteric cobalt available for microbial metabolism. In horses, the concentration of vitamin B_{12} in the enteric contents increases from the stomach to the rectum. This may explain why *horses are refractory to cobalt deficiency*, and indicates that the supplementation of racing animals is unnecessary.

Energy metabolism in the ruminant depends on acetic, propionic and butyric acids, and the conversion of these to succinate. The enzyme, methylmalonyl-CoA mutase contains vitamin B_{12} and is responsible for the conversion of methylmalonyl CoA to succinyl-CoA. In cobalt deficiency, there is accumulation of methylmalonic acid in liver and blood, and high levels of propionate and acetate in blood; the latter may be responsible for inappetence. Vitamin B_{12} also participates via a methyltransferase in the conversion of homocysteine to methionine, an essential amino acid. It is possible that methionine deficiency is responsible for the fatty liver which occurs.

Inadequate ruminal cobalt is permissive of the chronic neurologic syndrome of *Phalaris* poisoning of sheep.

Megaloblastic anemia

Anemia characterized by reticulocytopenia and marrow erythroid hyperplasia with early asynchrony of rubricytes occurs infrequently in cats and dogs. **Vitamin B_{12}** is stored in the liver in amounts sufficient to maintain animals for many months without further absorption. On the other hand, there is very little storage of **folic acid**, and signs of deficiency may appear after relatively short periods of disease in animals that are anorectic or receive chemotherapy. This may be due to acceleration of folic acid depletion with the inanition produced by rapidly growing tumors such as the high-grade lymphomas that cats and dogs are prone to develop. Vitamin B_{12} deficiency occurs rarely in the dog secondary to immune gastric atrophy. It is possible to produce the typical immune destruction of the gastric mucosa in dogs by immunization with homologous gastric juice or mucosal homogenate. A congenital anemia of *Giant Schnauzers* that is nonresponsive but not macrocytic is apparently due to an inability to absorb the vitamin since parenteral vitamin B_{12} reverses the syndrome. Dogs which survive *gastric torsion* with loss of most or all of the glandular portion of the stomach are at risk of developing vitamin B_{12} deficiency, but seem to have sufficient hepatic stores until they die of other causes. A variety of drugs may inhibit the absorption of either folic acid or vitamin B_{12}. Since analyses for these substances are rarely performed, the two deficiencies are not often specifically identified. They will be described together.

Hematologically, the first sign of disease due to deficiency of either folate or B_{12} is the presence of *large neutrophils with hypersegmented nuclei* in an animal with nonresponsive anemia, usually associated with acute leukemia or lymphoma. The marrow precursors of these neutrophils are *giant metamyelocytes* that have apparently become tetraploid but have not proceeded to division. In the early stages, the rubricytes appear of normal age distribution and the peripheral blood red cells are normochromic, normocytic. With progression, which appears most often in the dog, there is development of marrow erythroid hyperplasia with a predominance of young rubricytes, and macrocytosis in the blood with thrombocytopenia and increased variation in size of platelets. Pathogenetically, the disease is an example of an intact and functional stem cell system which is capable of producing a hyperplastic marrow that is ineffective in mature cell production, due to inhibition of DNA synthesis and subsequent cell division. Since divisions are skipped, the few resulting cells are larger than normal.

Anemia of chronic disorders

In inflammatory states, acute-phase reacting proteins scavenge molecular iron from transferrin and tie it up in ferritin and later, if the reaction persists, in hemosiderin. Thus hypoferremia has been considered the primary mechanism in the development of the anemia of chronic disease. However, because the hypochromia is at most mild (MCHC less than 310 g/L) while the anemia may be moderate (Hb 70–100 g/L), *it appears that anemia is due primarily to reduced red cell production rather than inhibition of hemoglobin synthesis*. Further, while shortened red cell lifespan can be demonstrated in anemia of chronic disorders, the hemolysis is mild and the red cells survive normally in normal animals, demonstrating that the problem is environmental and not intrinsic to the red cell itself. Finally, it is recognized that in primarily hemolytic anemias, the bone marrow is highly productive and can increase output 6 or more times normal levels, yet in the anemia of chronic disorders the red cells are normocytic and there is reticulocytopenia out of proportion to the degree of the anemia. Cats with sterile abscessation and anemia respond partially to additional iron by continuous infusion and, more completely, to iron plus cobalt, the latter treatment to increase erythropoietin by tissue anoxia. Thus, pathogenetically, *the anemia of chronic disorders is primarily a problem of decreased and deficient production of red cell numbers* and, like the anemia of uremia, it may be compensated by increased levels of erythropoietin if iron is available. While the mechanisms operative in the syndrome of chronic disorders are defined, *the only practical therapy is reversal of the primary problem.*

Collectively, the *anemias associated with inflammatory, degenerative, immune and neoplastic disease form a large and important group in all species* (Fig. 2.82A, B). The common pathway by which erythropoiesis is selectively depressed in anemias of such diverse association is *related to tissue injury*, and mechanistically to the constant production of *tumor necrosis factor* or *"cachexin,"* a monokine produced by activated macrophages that has both toxic and cytostatic effects on the rubricyte system. Teleologically, this process appears to be a system to deny access to iron to invading microorganisms, with anemia as an acceptable exchange for survival. The anemias of chronic disorders are of moderate severity, largely normochromic, normocytic and poorly responsive, with associated toxic changes in leukocytes.

Anemia of malnutrition

Anemia of malnutrition is most commonly a disease of the young and is seen most frequently in sheep and goats, and less often in kittens and puppies where poor nutrition may be complicated by ecto- and endoparasitism (Fig. 2.83A). Malnutrition in animals, as in humans, is sporadic and world wide in distribution. The disease is worthy of consideration because of the regular tendency for the anemia to worsen once corrective measures are taken. Hematologically, the anemia of malnutrition is largely normochromic, normocytic, but may be hypochromic if complicated by parasitism and blood loss. Kinetically, *the anemia is primarily due to reduced red cell production with minor hemolysis*, as in anemia of chronic disorders. Since malnutrition is so often associated with delayed healing and infection, the two syndromes are

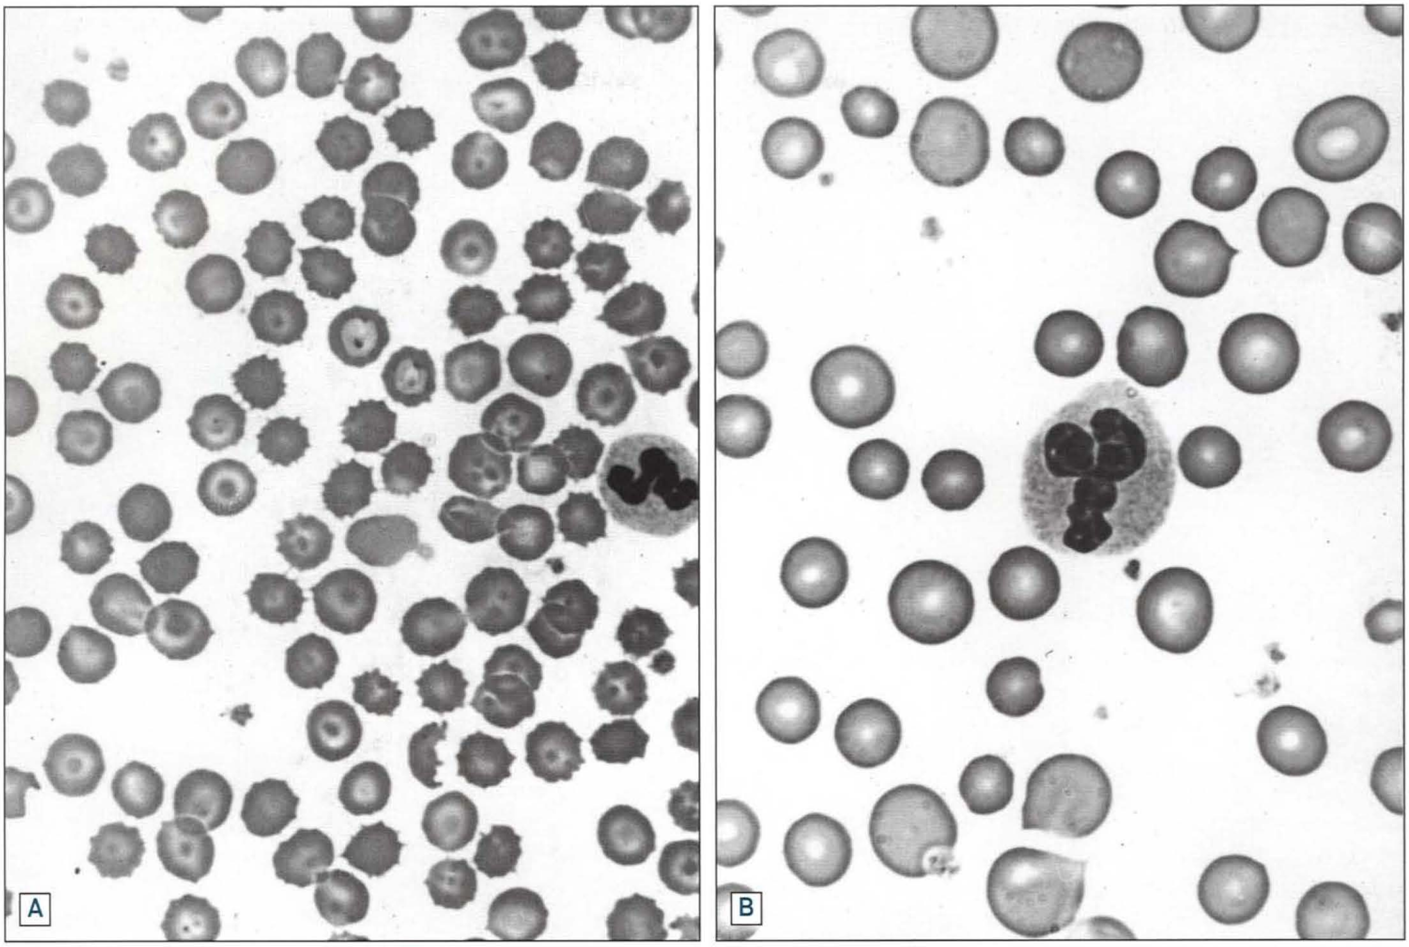

Figure 2.82 Anemia of chronic disease in a dog. **A.** Target cells resulting from altered serum cholesterol and lipoprotein in liver disease. Membrane pliability results in acanthocytosis and poikilocytosis. **B.** Microcytosis characteristic of portocaval shunting.

often coincident and may share a combined development. Malnutrition that is primarily due to **caloric deprivation** is called *marasmus*. In swine, the anemia is mild, and the response to phlebotomy is vigorous and curative, reflecting a functional stem cell system, adequate iron supply, and normal erythropoietin production.

Protein-calorie deprivation is more common, and when severe is called *kwashiorkor*. It is a syndrome of cachexia characterized by *hypoplastic marrow, mild anemia and reticulocytopenia*. Since serum proteins are also deficient, low serum iron is not rate-limiting to red cell production because transferrin is also low and the saturation level is adequate for iron delivery. The anemia in these syndromes is partially adaptive and due to reduced activity and partially to multifactor deficiencies. In the development of *starvation*, there is first a loss of muscle mass followed by parenchymal atrophy, anemia and lastly *a reduction in all serum proteins*. Since the latter are the major transport for many minerals, and the major source of amino acids, *their loss is most limiting to all aspects of hematopoiesis*. In repletion, these elements are replaced in reverse order and the recovery of all tissues is dependent on first increasing the levels of plasma albumin and globulins. As plasma protein levels rise, the plasma volume contraction that developed with loss of oncotic pressure is also reversed. Since this volume expansion is much more rapid than the expansion of the red cell mass, the anemia becomes more severe, and may be misinterpreted as therapeutic failure. The pattern of recovery is a rise in level of plasma proteins followed by blood volume expansion, reticulocytosis, a slow rise in hemoglobin, and finally a gain in body weight. The course of these changes takes 3–4 weeks, depending on the level of complicating factors such as specific vitamin deficiencies, parasitism and other infections. Grossly, starvation is characterized by atrophy of all organs but particularly the thymus, lymph nodes, spleen and liver. There is pancreatic acinar atrophy and serous atrophy of marrow fat (Fig. 2.83B).

Deficiencies of specific vitamins are capable of causing anemia in animals, but in general their importance is more in the prevention of related disease. Swine fed **vitamin E** deficient diets develop moderately severe nonresponsive anemia characterized by marrow erythroid hyperplasia with multinucleated dyserythropoiesis, increased turnover of serum iron, and increased unconjugated bilirubin. Red cell lipids are markedly reduced and red cells are highly susceptible to oxidant attack. The mechanism appears to be at least partially due to inhibition of pyrrole and thus heme synthesis. This mechanism is important in a practical sense since an abundant pool of protoporphyrin is an efficient sink for tying up iron in the synthesis of heme. Piglets that are vitamin E deficient are more susceptible to toxicity when given iron by any route. Premises where other vitamin E and selenium-related diseases have occurred are likely to have pale piglets that do not respond to repeated iron administration and have characteristic dyserythropoiesis.

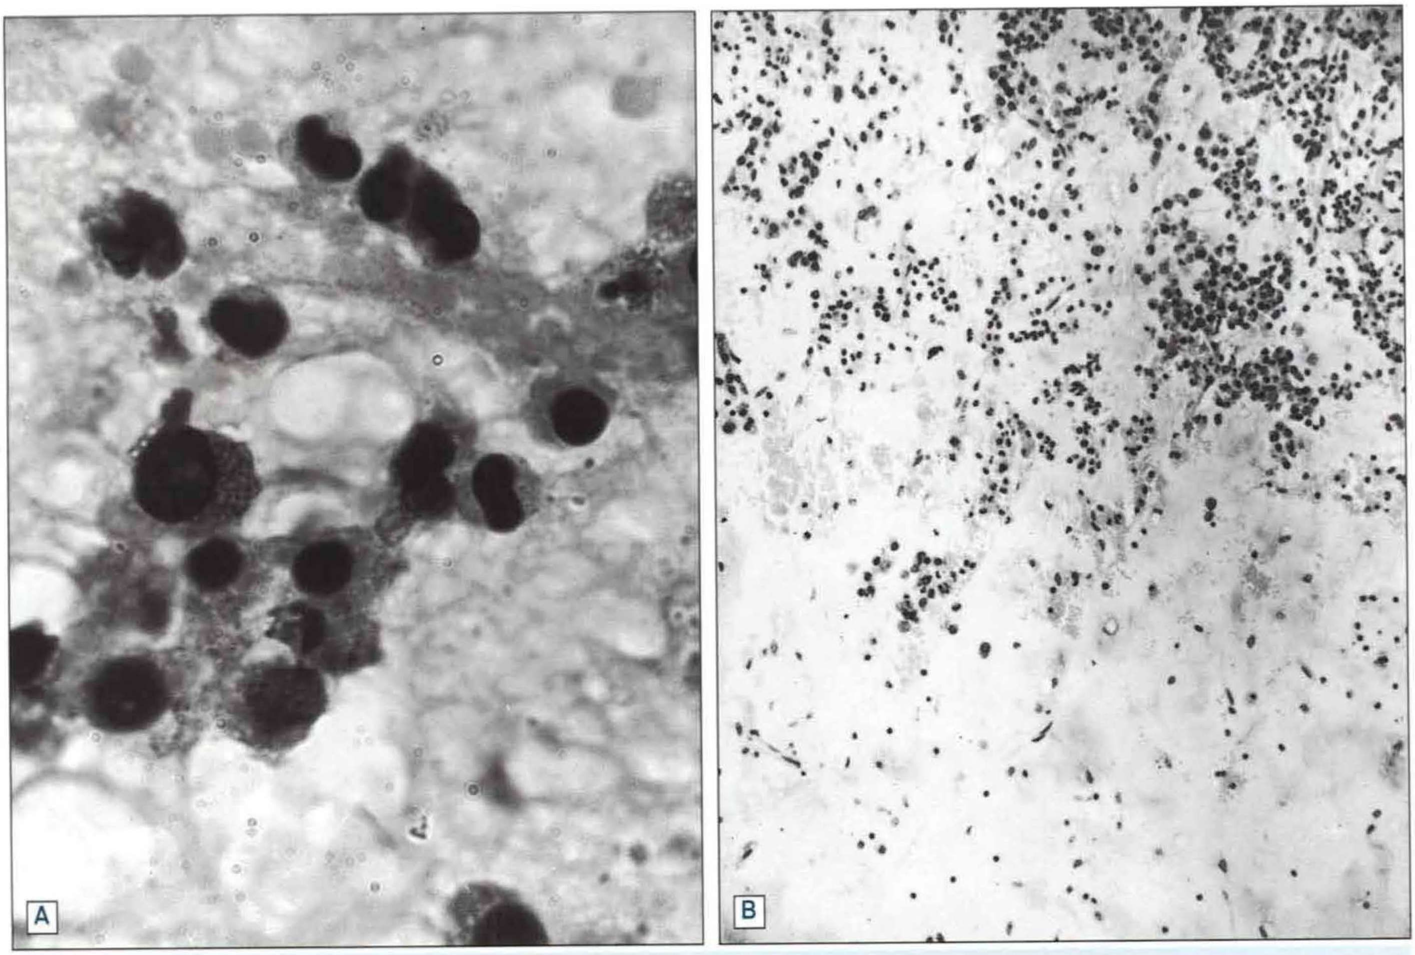

Figure 2.83 Anemia of starvation in a sheep. **A.** Late erythroid asynchrony and increased proportion of eosinophils. **B.** Serous atrophy of marrow fat with residual cuffs of subendosteal hematopoiesis.

Vitamin B_6 deficiency induced in swine results in a microcytic but not hypochromic anemia of moderate severity characterized by marrow erythroid hyperplasia and hyperferremia, and by hemosiderosis of marrow, spleen and liver, and hepatic centrilobular fatty degeneration. Vitamin B_6 is required for formation of the precursors of δ-aminolevulinic acid, which then forms the pyrrole ring and ultimately protoporphyrin. Blockage at this early stage of ring synthesis prevents iron utilization and leads to ineffective hematopoiesis. In the cat, in addition to anemia, vitamin B_6 deficiency causes stunting of growth, emaciation, convulsions and oxalate nephrosis.

Hemolytic anemias

Anemia of hemolysis develops when the rate of destruction exceeds that of production. Since the products of hemoglobin catabolism are readily reutilized, *the anemias of hemolysis are characteristically and predominantly highly responsive with reticulocytosis and an upward shift in mean corpuscular volume (MCV).* It is stated that human marrow can increase output 6-fold in hemolytic anemia and the cat and dog have a similar capacity for regeneration while horses, pigs and ruminants are somewhat less responsive. The response to anemia is most efficiently measured by the **reticulocyte count**, which should be expressed in absolute numbers and not as a function of the number of leukocytes or peripheral blood rubricytes. Reticulocytes have a maturation time of about 1 day and *their level in the blood is always an indicator of current marrow output.* With very high levels of erythropoietin, some mitoses are skipped resulting in the release of even larger "shift" red cells which have a maturation time of 2–2.5 days. The presence of a few larger red cells that are not polychromatic in the absence of reticulocytosis indicates red cell shut-down within the last 1–2 days. Attempts to correct the reticulocyte count for the number of large shift red cells present is subjective, and introduces a misleading concept of precision to a process that is not reproducible. *The raw number of reticulocytes expressed in absolute terms is in itself the most accurate measure of marrow erythroid response*, just as the neutrophil count is an accurate measure of current myeloid output. In responsive anemias, there is a variable but much lower number of rubricytes accompanying the reticulocytes, while in stress erythropoiesis rubricytes may appear alone. *It is important that these nucleated precursors are not considered an indication of a responsive marrow.* If their absolute numbers, usually less than 10×10^9/L, are compared to expected levels of reticulocytes at $300–500 \times 10^9$/L, it can be seen that this level of contribution is minuscule and far below the normal level of production in a non-anemic animal. *Reticulocytes are not released to the blood in the horse*, but the upward shift in the MCV can be used as a relative measure of response. Blood loss in "hot blooded" (Thoroughbred and Standardbred) horses results in an upward shift of <6 fL, whereas in hemolytic anemia the shift will increase to >12 fL.

The iron economy may be rate-limiting in hemolytic anemia, with the contributions from recycling, enteric absorption and mobilization from stores being additive in their effect. This point is worth emphasizing, since *even animals that have abundant iron stores in hemosiderin will respond more strongly if given additional iron by any route.*

Intracellular destruction of red cells is the normal route of removal and occurs in the monocyte–macrophage system in marrow, spleen, liver and nodes. In hemolytic states, the spleen may become quantitatively more important than marrow. The actual process of lysis is rapid and, if erythrophagocytosis is observed, the level of destruction is likely also rapid. This catabolism releases iron from heme to transferrin or to storage as ferritin or hemosiderin, while the protoporphyrin ring is opened and released to the plasma as unconjugated bilirubin. Globin is reutilized via the amino acid pool.

Intravascular destruction of red cells occurs in normal circumstances at a very low rate as a result of high velocity trauma in small arteries. In some cases of accelerated hemolysis with complement fixation, red cells are lost by intravascular lysis at very rapid rates resulting in *hemoglobinuria*. Normally, *free plasma hemoglobin is rapidly scavenged from circulation by binding to first haptoglobin then hemopexin and finally albumin.* Free hemoglobin rapidly dissociates into dimers which are quickly bound with high affinity to haptoglobin and are then too large for renal excretion and are removed from circulation by the liver. If haptoglobin is saturated, iron unprotected by the normal cytosol reductase system is oxidized to the ferric state, causing breakage of the heme–globin bond. The free heme is then picked up by hemopexin which in the bound state is cleared with a half time of 7–8 hours by the liver. Even minor hemolysis will remove haptoglobin from circulation, but reduced levels of hemopexin constitute a sensitive test of intravascular hemolysis. Mild overloading of these systems allows the filtration of heme which is reabsorbed in the renal proximal tubules. The intracellular accumulation of hemosiderin constitutes a record of previous hemolysis that can be read by detecting the epithelial cells on urinalysis or on histological examination of the kidney. Severe intravascular hemolysis is a double hazard to the kidney because the toxic and vasoactive effects of the free heme are added to anemia, with resultant ischemic injury to the nephron (see Vol. 2, Urinary system).

Immune-mediated hemolytic anemias

Adherence of antibody to the red cell membrane, with or without complement fixation, causes red cells to become spherical. Their lifespan is then reduced either by destruction by the monocyte–macrophage system or by intravascular hemolysis. Since the damage is usually to the most mature cells, *most hemolytic anemias are highly responsive.*

Immune anemias are classified on the basis of mechanism or association. Serologically there are three types: **warm-antibody** type with maximal activity at 37°C; **cold-antibody** type with maximal activity at 2–4°C; and those **without detectable antibody.** Classification by association is based on identification of an underlying cause and includes *primary (idiopathic) immune hemolytic anemia* and *secondary (symptomatic) immune hemolytic anemia.* These may be isoimmune, drug-induced, associated with infectious disease, associated with other immune disorders (systemic lupus erythematosus), or associated with lymphoid or other malignancy.

In **symptomatic immune anemias**, the cause is identified, and is usually adherence of drug or virus to red cells thereby sensitizing them to the immune system. In **idiopathic immune anemias**, which form the bulk of cases, it is not clear whether the error is due to an actual change in red cell antigenicity or to loss of self-recognition by the immune system.

The detection of antibody on the surface of red cells is performed by means of the **Coombs' (antiglobulin) test**. In this test, an antiglobulin for the intended species (e.g., dog) is prepared in another species (e.g., rabbit, sheep). Antiglobulins are usually prepared against both immunoglobulin and complement for broader reactivity. About 500 molecules of IgG must be bound to each red cell to give a positive Coombs' test, yet significant shortening of red cell lifespan can occur with as few as 24–34 molecules per red cell. Therefore, a negative Coombs' test does not rule out clinically significant hemolysis. The test is conducted at 37 and 4°C to detect warm- and cold-reacting antibodies. In general, the warm-reacting antibodies are IgG or IgA, and the cold-reacting are IgM. Cases of cold-reacting IgG have been described and these may be the cause of agglutination which appears due to complement alone.

The warm-reacting antibodies are termed "incomplete" and generally do not fix complement on the red cells. The anemias produced are characterized by a slower rate of intracellular hemolysis.

In contrast, the cold-reacting antibodies fix complement and may cause acute intravascular hemolysis with hemoglobinuria if extremities are cooled. The IgM antibodies tend to elute from red cells, but if complement is fixed it remains attached and may cause increased destruction in vivo and give a positive Coombs' test.

Whereas a negative Coombs' test does not rule out immune hemolytic anemia, a positive test may occur in the absence of anemia. Since macrophages do not pick up red cells bound by all classes of IgG, there may be cases that have a positive Coombs' test but are asymptomatic.

Five types of immune hemolytic disease occur:

1. erythrocytic type characterized by severe anemia with hyperplastic marrow (most common);
2. hemolytic anemia and immune thrombocytopenia with hyperplastic marrow;
3. pure red cell aplasia with selective immune depression of erythroid precursors;
4. pancytopenic type in which there is immune anemia, neutropenia and thrombocytopenia with hyperplastic marrow; and
5. the aplastic type which resembles pancytopenia but with marrow aplasia.

Isoimmune hemolytic anemia is recorded in kittens and pups but remains of most importance in foals, calves and piglets.

Isoimmune hemolytic anemia in the foal

Mares are isoimmunized naturally by focal placental hemorrhage which allows foal red cells to enter the maternal circulation. Clinical *isoerythrolysis* rarely occurs in primiparous mares and generally is not seen until the third or fourth foal. It is likely that a considerable amount of fetal blood is required for initial sensitization but restimulation in subsequent pregnancies may require much less blood of the same genotype, and therefore *repeat pregnancies by the same sire carry a greater risk of an affected foal.* Blood transfusions and tissue-origin vaccines may complicate the problem of maternal sensitization. Isoimmunization can only occur when the sire and foal possess a blood antigen absent in the mare, usually Aa or Qa. Stallions homozygous for an offending factor will always sire susceptible foals, while heterozygous sires will produce susceptible foals in about 50% of matings.

Foals are normal at birth but can absorb dangerous levels of colostral antibody for up to 48 hours after birth and likely longer. Foals that develop clinical disease and are removed from the dam may suffer recurrence of signs if put back on the dam a week or more later. Signs of the disease may occur as early as 8 hours or as late as 120 hours after birth. The severity of the anemia varies greatly depending on the amount and type of isoantibody that is absorbed. Hemolytic antibodies are most damaging and highest titers exist in the first milk. Thus, strong foals that nurse vigorously soon after birth may be most severely affected.

Earliest signs are lethargy and reluctance or inability to stand and infrequent suckling. Clinical signs include pallor of mucous membranes with icterus, dyspnea, pounding heart, and hemoglobinuria in severe cases. Mild disease may not be noticed.

There is severe normochromic anemia that becomes moderately macrocytic (Fig. 2.84A, B). Polychromasia is absent but an occasional rubricyte may be present. The marrow is hyperplastic with an erythroid shift. The hematocrit may drop below 15%, while the leukocyte count is elevated, usually to 25×10^9/L or more, and the platelet count is normal or elevated. The serum bilirubin may rise to 300 μmol/L or more, with much of it unconjugated and therefore fat soluble. Transaminase levels are elevated and a continuing rise suggests a poor prognosis. The urine is dark brown. The foal's cells are strongly Coombs-positive if the hemolysis is severe. Rouleaux formation, or rafting, of red cells is exaggerated (Fig. 2.84A). The **diagnosis** is confirmed by demonstration of antibody in maternal serum or milk that will agglutinate foal red cells and usually sire red cells. Foals with isoimmune anemia are usually treated with high levels of immunosuppressive steroids which, with high levels of iron released from lytic cells and inadequate passive transfer of antibodies in colostrum, *renders them extremely susceptible to bacterial infection.* In foals thus treated, the appearance of *toxic changes in blood neutrophils* with rising transaminases may be the first indication of infection, since fever and malaise are prevented by the steroids. Prophylactic antibiotics and/or very careful monitoring are indicated. Bovine colostrum has proven effective and may be helpful by stimulating development of the foal's complement system.

Foals that die of isoimmune anemia are usually *remarkably icteric*, and unless they are under a week of age there is usually some degree of *cachexia*. The lungs are pale, icteric and edematous, and there is increased pericardial fluid. The liver is turgid, friable, fatty and bile-stained. The spleen is enlarged with rounded borders and may have subcapsular hemorrhage. The splenic parenchyma is friable and bulging on cut surface but does not ooze blood on standing. The kidneys are pale with yellowed papillae, and the intestinal tract is usually empty of ingesta and moderately distended with gas. The femoral marrow is diffusely reddened, with translucent fat that rapidly retracts on drying.

The **histological lesions** vary with the treatment and period of survival. If repeated transfusions have been given, there will be *hemosiderosis* of the spleen, liver, marrow and lung despite the usual absence of storage iron in neonates. There is pulmonary alveolar flooding, often with foci of septic alveolitis. In animals that die acutely, there is ischemic hepatic periacinar degeneration, while those surviving 2 weeks or more and receiving steroid therapy have irregular ballooning of hepatocytes with canalicular cholestasis and hyperplasia of highly pigmented Kupffer cells. Extramedullary hematopoiesis is absent. The spleen has follicular and parafollicular lymphoid atrophy with germinal centers occupied by dendritic reticular cells with an epithelioid appearance. The sinus areas are densely cellular with increased fixed stromal cells and macrophages. Hemosiderin and erythrophagocytosis are prominent, but hematopoiesis is not. Kidneys have ischemic epithelial degeneration with flattened proximal epithelium that has heavy bile pigmentation and irregularly spaced nuclei. There are often granular and cellular casts in collecting tubules. The lymph nodes and thymus are hypocellular, and node sinuses are usually devoid of macrophages if steroid treatment has been prolonged. The marrow has a reduced amount of fat, and that present is undergoing serous atrophy and becoming eosinophilic. In acute cases, there is an erythroid shift and cellular packing is high. Later, the erythroid shift remains but the cell density is reduced and hemosiderin and erythrophagocytosis are prominent. Thrombopoiesis is normal and mature granulocytes are reduced.

Isoimmune hemolytic anemia in the calf

Spontaneous sensitization of cows to fetal red cell antigens is *very rare.* The calf derives its iron from maternal red cells deposited at the

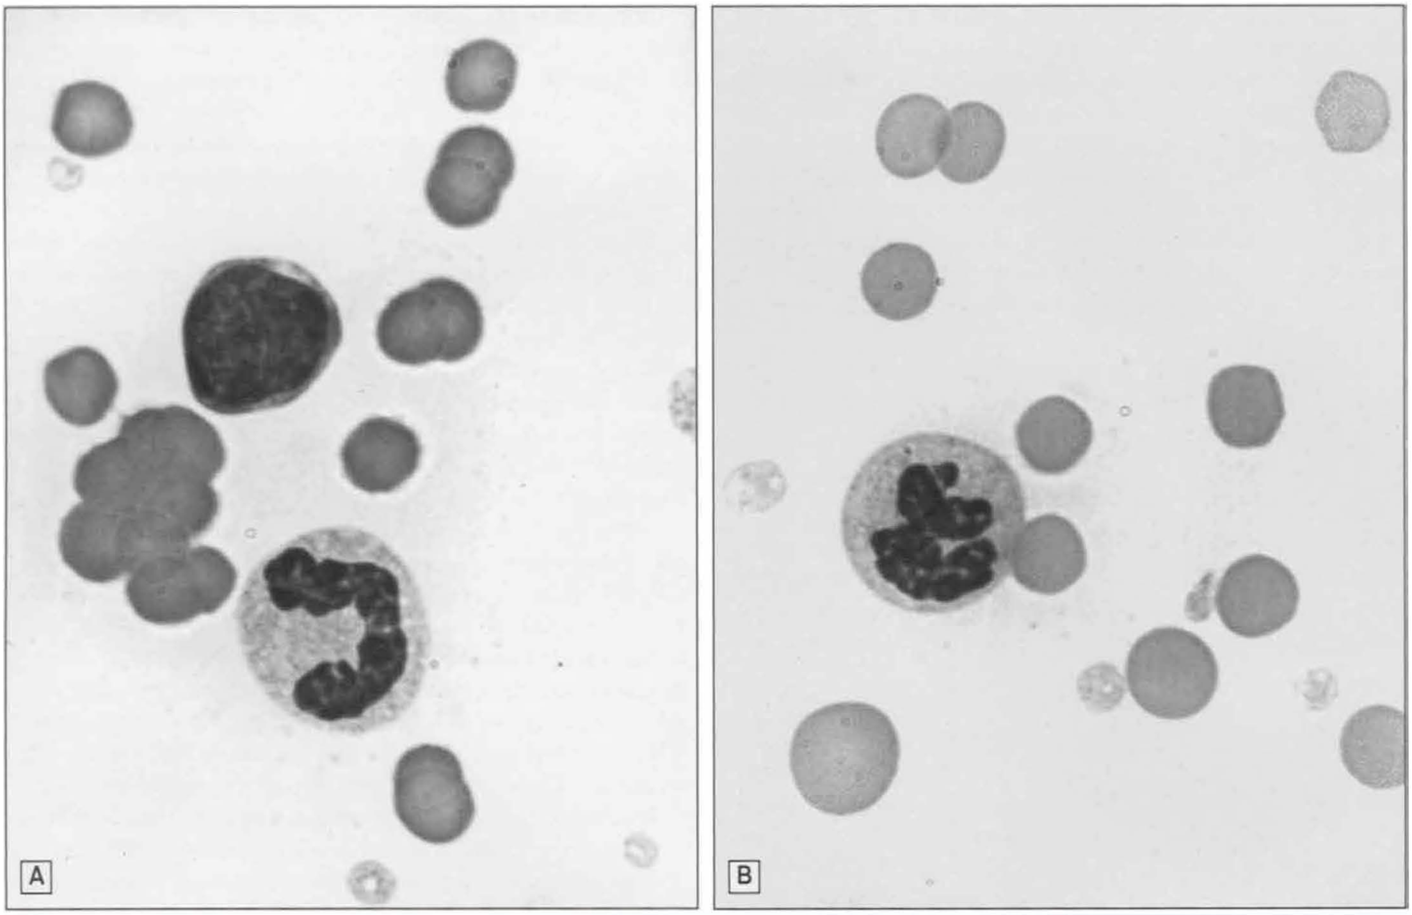

Figure 2.84 Isoimmune hemolytic anemia, in a foal. **A.** Rafting of red cells. **B.** Spherocytes and macrocytes indicative of defective erythroid response in this species.

trophoblastic junction, but the reverse cellular exchange does not appear to occur. Vaccines of blood origin for prevention of babesiosis and anaplasmosis may contain red cell antigens which immunize the dams. If the bull has the same red cell antigens as the vaccine donor, then the calves will share these antigens and may develop isoimmune hemolytic anemia when they receive colostrum. Gestation is normal.

The disease may be mild or peracute with signs occurring within hours of birth and severe and terminal dyspnea developing at 1–7 days of age. Severely affected animals are dull and have reduced activity. Jaundice develops in those that survive 1–2 days.

In the *peracute form* of the disease, there is hemoglobinuria, hypofibrinogenemia and fibrin degradation products in the blood, and death is rapid. At postmortem, the spleen is large and spongy and the kidneys are discolored by hemoglobin. There is excess blood-stained pleural fluid and the lungs are congested and edematous. Histologically, there are widespread fibrin thrombi, and *death is due to disseminated intravascular coagulation.*

In the *acute form,* the PCV drops to 0.06–0.07 L/L and there is often hemoglobinuria. Death is expected at ~5 days with anemia and icterus. The marrow is responsive but inadequate with only 1–2% reticulocytes, and rubricytosis that exceeds the level of leukocytes. The Coombs' test is positive and the dam's milk agglutinates the calf's red cells. Hemolysis occurs if complement is added. The A, B, C, F-V, and S-U antigen systems are most often the target of maternal antibody.

In the *mild form,* the hematocrit drops to 0.18 L/L at a week after birth and rises to 0.30 L/L at 3 weeks of age. The anemia is normochromic and macrocytic and recovery is slow.

Isoimmune hemolytic anemia in piglets

Isoimmune anemia of piglets was originally attributed to maternal sensitization by a crystal violet-inactivated classical swine fever vaccine of blood origin. However, *spontaneous transplacental sensitization occurs in swine and the disease is primarily an isoimmune thrombocytopenia with lesser effects on the red cell system.* The piglets are normal at birth and disease occurs after suckling. The isoantibodies are usually against the Ea, Ee, Gb, and Kb red cell antigens (see Platelet disorders).

Signs occur between 1–4 days after birth, and consist of pallor, inactivity, dyspnea and jaundice. These signs gradually subside. After 10–11 days, widespread petechiation develops, particularly in ventral areas, in association with *severe thrombocytopenia.* Most piglets die at this time. The first signs are due to red cell and platelet destruction in the peripheral blood. The marrow is at first responsive and the disease is self-correcting for the first week. As antibody continues to be absorbed, there is depression of marrow precursors and the terminal petechiae are associated with decreased platelet production because of marrow aplasia. The terminal anemia is due both to hemorrhage and hypoproliferation.

The erythrocyte count drops from a normal level of 4.5–5.3 × 10^{12}/L at birth to 1–3 × 10^{12}/L at 4 days of age. As the red cell count drops, anisocytosis and polychromasia develop, along with some circulating rubricytes. The mean corpuscular volume rises from a normal of 70 fL at birth to 100–120 fL at 7–14 days of age and returns to normal in survivors at four weeks of age. The neutrophils rise to 9–10 × 10^9/L at 4 days when the red cells are lowest and then decline to normal at 3–4 × 10^9/L. Platelets have a bimodal response and drop from 300 × 10^9/L at birth to 100 × 10^9/L at day one, then rise to normal at the first week, followed by severe thrombocytopenia after 10–14 days.

The bone marrow is hypoplastic in piglets which die, and megakaryocytes are absent. Red cells are Coombs-positive from day 1–7 and are negative by day 14.

Drug-induced hemolytic anemia

Many drugs have been associated with Coombs-positive hemolytic anemia and these same drugs may cause immune thrombocytopenia. *The most commonly implicated drugs are quinidine, quinine, para-aminosalicylic acid, phenacetin, penicillin, insecticides, sulfonamides, chlorpromazine, and dipyrone.*

There appear to be *two types* of immune hemolytic anemia associated with drugs. One is *caused by an antibody that reacts only with cells exposed to the drug*. In the other, the *antibody reacts with normal red cells in the absence of the drug*. The latter disease thus is indistinguishable from "auto"-immune hemolytic anemia except for the history of drug exposure and exacerbation with retreatment. Drug-related hemolysis is usually highly specific, but occasionally closely related drugs cause hemolysis in the same patient. Some drugs require only small doses to cause disease, while hemolytic anemia after penicillin therapy is limited to cases with prolonged high-level treatment. In most cases, the antibody eluted from sensitized red cells is drug-specific and does not react with normal red cells. Most cases caused by drugs other than penicillin have little IgG on red cells, but complement is usually present.

Since drugs and environmental contaminants are so ubiquitous, and since some drugs induce an "auto"-immune type hemolysis, *it is usually not possible to distinguish between spontaneous and drug-induced immune anemias.*

Primary or idiopathic immune hemolytic anemia

This type of anemia is *most common in dogs and cats*, less common in cows and horses, and probably occurs in all species.

Clinically, there is usually depression of sudden onset in an animal in good body condition. Occasionally the history may indicate previous attacks. Rarely, red urine is seen and the animal is examined for suspected urinary infection. There is mild-to-marked pallor and often mild icterus. When hemolysis and thrombocytopenia are present, there will be mucosal bleeding and often epistaxis, dark stools and hematuria. Heart rate and respiratory rate are increased in proportion to the degree of anemia, and a hemic murmur may be present. The spleen may be palpably enlarged.

Occasionally, immune hemolytic anemia in the dog may resemble systemic lupus erythematosus of humans. The canine form of **systemic lupus erythematosus** is characterized by Coombs-positive hemolytic anemia with thrombocytopenia, polyarthritis and glomerulonephritis. Rarely these lesions are accompanied by symmetrical facial dermatosis, serositis with accumulation of fluid in body cavities, and combinations of leukopenia, hepatosplenomegaly and lymphadenopathy. Antibodies to double-stranded DNA are relatively common, as are positive lupus erythematosus preparations. All breeds of dogs may be affected and the disease, as in humans, is most severe in young females. Canine systemic lupus erythematosus is considered also in Vol. 1, Bones and joints; Vol. 1, Skin and appendages; Vol. 2, Urinary system.

There is *moderate-to-severe anemia that is highly responsive*, with 10–20 polychromatic red cells per oil immersion field or 300–400 × 10^9 reticulocytes/L of blood. The anemia is macrocytic and slightly hypochromic with a normal mean corpuscular hemoglobin concentration. Spherocytosis, leptocytosis and marked anisocytosis are present (Fig. 2.85A–C), usually with rubricytosis of 1–20 × 10^9/L. Rouleaux formation is usually marked, and slide aggregation may be present. The direct Coombs' test is positive in the majority of cases, but may be negative; a negative result should not eliminate the diagnosis if the other findings are consistent with the disease. Large immature red cells occur in most microscopic fields.

There is *accompanying neutrophilic leukocytosis,* usually of 30 × 10^9/L in the dog and cat, which increases to 40 × 10^9/L with initial heavy steroid therapy. There is a mild left shift with eosinopenia, lymphopenia and characteristic monocytosis in dog and cow, and to a lesser extent in other species. Thrombocytosis is usually present with many large young platelets. The marrow is hypercellular with erythroid shift and normal maturation.

Biochemical icterus may be present and is usually less than 50 μmol/L except in the horse where 170 μmol/L or more may be present. In all species, free and conjugated bilirubin both tend to be markedly elevated. Icterus on presentation usually indicates previous attacks, or chronicity with ischemic hepatic damage. Icterus tends to increase with each blood transfusion, especially if the PCV is maintained for only 1–2 days. The erythrocyte sedimentation rate is very rapid.

Lesions are usually prominent. Those described here refer to the dog but the changes are similar in the cat, calf and horse. In the horse, immune hemolytic anemia is more often associated with (occult) lymphoma than in other species. Grossly, there is at least mild *icterus* and in some cases it is marked. The carcass is usually in good condition with some history of weight loss. In dogs, if steroid treatment has been prolonged, there may be abdominal enlargement and ventral hair loss. The lungs are edematous and may contain infarcts. The heart may be normal, or atonic, rounded and dilated if anemia has led to congestive failure. There is often a prominent yellow chicken-fat clot. The abdominal viscera are pale except the kidneys which have dark red-brown cortices if the disease has been prolonged. The liver is usually enlarged, fatty and friable with distended gallbladder and a nutmeg pattern visible through the capsule. The spleen is enlarged, sometimes up to 6–10 times normal weight. Lymph nodes are usually small if steroid treatment has been given, and red-brown medullary pigmentation due to hemosiderosis is present. The femoral marrow has subendosteal reddening if clinical signs have been present for a month, and diffuse reddening if the disease has persisted 3–4 months or longer. If the immune hemolysis is complicated by thrombocytopenia, *hemorrhagic lesions* may dominate the gross picture. In the combined immune destruction of erythrocytes and platelets, the lymph nodes are reddened, and may be enlarged, edematous, and cyanotic if draining an area with interstitial hemorrhage. Hemorrhages are most prominent on serosal surfaces including those of the enteric and respiratory systems, and on the heart and diaphragm.

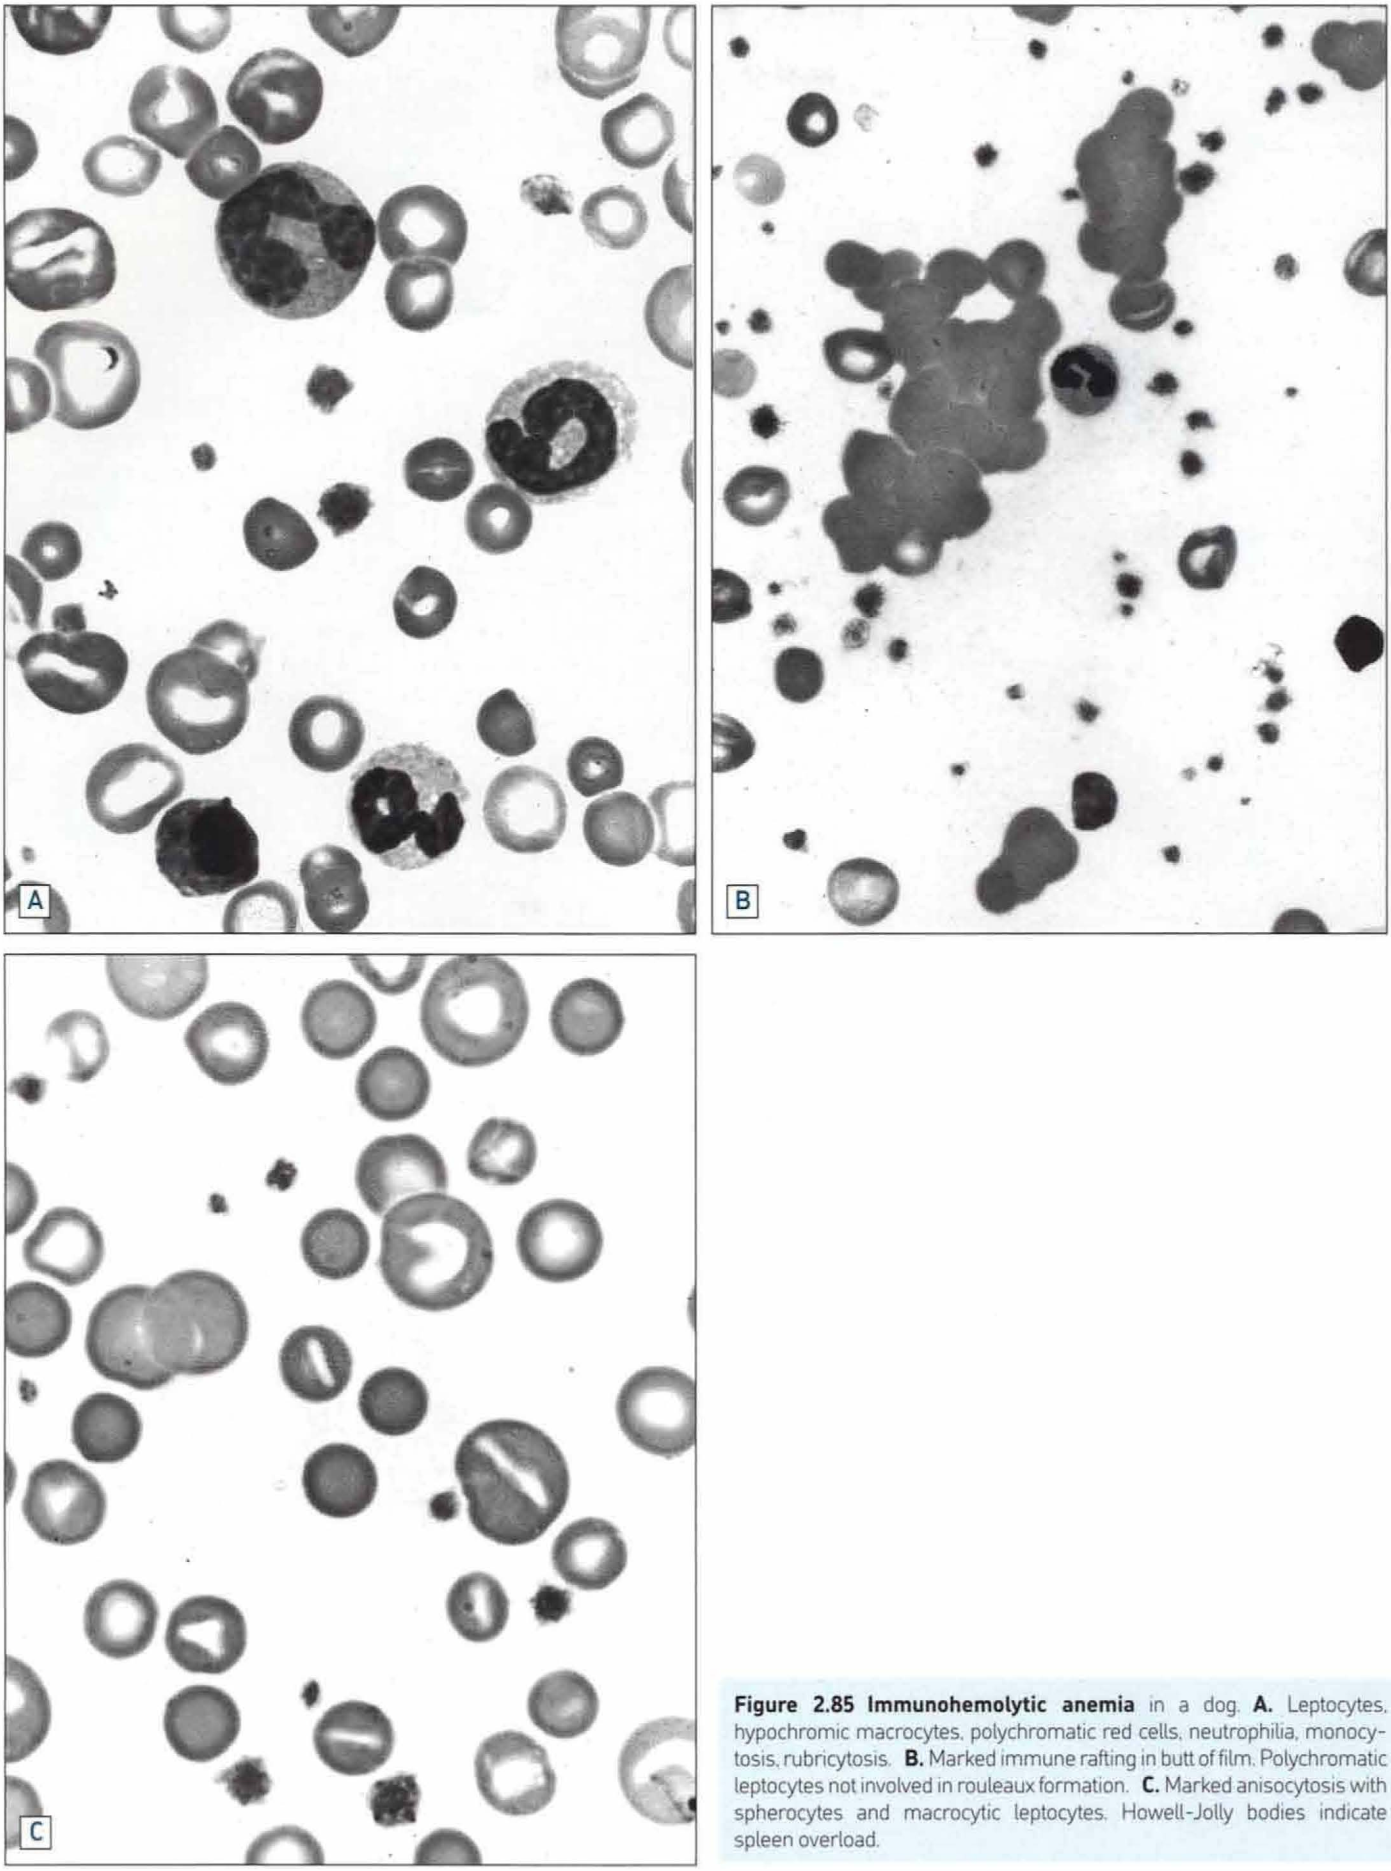

Figure 2.85 Immunohemolytic anemia in a dog. **A.** Leptocytes, hypochromic macrocytes, polychromatic red cells, neutrophilia, monocytosis, rubricytosis. **B.** Marked immune rafting in butt of film. Polychromatic leptocytes not involved in rouleaux formation. **C.** Marked anisocytosis with spherocytes and macrocytic leptocytes. Howell-Jolly bodies indicate spleen overload.

Histologically, the *thymus* is atrophic, though rarely there is a follicular reaction with plasma cell accumulation or a lymphoid thymoma. There is *pulmonary* alveolar flooding and, if congestive failure has developed, there are alveolar macrophages with hemosiderin. Some animals have pulmonary thrombosis with focal peripheral infarction. The *liver* has Kupffer cell hyperplasia of variable degree, and hemosiderin accumulation may be prominent. There is minimal periportal lymphoid reaction or hematopoiesis, and vacuolar degeneration is present in periacinar, and often in midzonal, hepatocytes. Inspissated bile plugs form in canaliculi, but the ducts themselves are empty. If changes of circulatory failure are added to the anemia, there is irregular necrosis of periacinar hepatocytes, swelling of sinusoidal endothelium and separation of hepatic cords. The *splenic* capsule is thin, and muscular trabeculae are narrow and sparse, reflecting splenomegaly and sinus hyperplasia. There is atrophy of follicles and periarteriolar sheaths. In addition, the normal small lymphocytes of the thymus-dependent cuffs are loosely rather than compactly arranged, and nuclear size is increased with vesiculation so that these areas are inconspicuous and identifiable by the vessel rather than the lymphoid cuff. Major changes occur in the sinus areas, which have diffuse extramedullary hematopoiesis with prominent erythropoiesis and thrombopoiesis. Hemosiderosis is often marked, with focal and diffuse clusters that may exceed 3–4 red cells in diameter. Erythrophagocytosis is present and often prominent. Plasma cells are increased and all free cells are enmeshed in a stromal network that is markedly hypertrophied and can be identified by the oval reticular nuclei and cellular cleavage planes created by their processes.

Lymph nodes have follicular hyperplasia with "bare" follicles due to paracortical atrophy. If steroid treatment has been intense and prolonged, there is generalized cortical atrophy and sinus expansion. There is always some degree of sinus histiocytosis, and variable accumulation of plasma cells in medullary cords. If hemorrhage has occurred, there is increased hemosiderin in sinus phagocytes, and erythrophagocytosis is often very marked. The *kidneys* have minimal to moderate thickening of glomerular basement membranes, and there are occasional hemosiderin granules in mesangial areas. The juxtaglomerular nuclei are prominent with large nucleoli, and the proximal epithelium is variably flattened and bile-pigmented. Occasionally, there are (incidental) loose lymphoid cuffs around corticomedullary arteries, and the kidney, like the lung, liver and spleen, may have focal thrombotic infarction. The *adrenal* zona glomerulosa is usually hypertrophic and the reticularis reduced.

Femoral bone marrow has 50–60% cellularity or higher in the normally fatty central medullary areas. Cellular packing (density) is high in highly responsive anemias, and reduced in animals which die with marrow depression. As in the spleen, hemosiderin is markedly increased and of both fine and coarse character, indicating chronic accumulation and continuing increased turnover. Erythrophagocytosis is often extensive and more easily identified than in the spleen. The marrow has an erythroid shift, and megakaryocytes are increased in numbers and multinuclearity. Animals with concurrent immune thrombocytopenia may have dysthrombopoiesis characterized by reduced megakaryocyte cytoplasmic volume and many pyknotic nuclei. Neutrophil migration through megakaryocytic cytoplasm is often prominent but is apparently without diagnostic value.

The *myeloid system* usually maintains a picture of early asynchrony due to steroid effects and early release of maturation phase cells. The relative reduction in myelopoiesis is apparently much more than compensated for by the expanded volume of hematopoietic marrow. Erythropoiesis is usually normal, but there may be mild early asynchrony if there is prominent peripheral blood rubricytosis with release of maturation phase cells. Occasionally there is mild dyserythropoiesis with satellite nuclei (incipient Howell-Jolly bodies), and mitoses may be observed in polychromatic rubricytes. Plasma cells are increased and may be found in cuffs around small arteries. *The overall picture is one of increased erythrocyte destruction followed by increased production and, in chronic cases, lymphoid atrophy, macrophage hyperplasia, hemosiderosis and secondary injury to parenchymal organs.*

Infectious hemolytic anemias

Equine infectious anemia

Equine infectious anemia virus (EIAV) is a member of the Lentivirinae subfamily of retroviruses that infects horses, mules, and donkeys. The disease has a worldwide distribution and since the development of the agar gel immunodiffusion test, which detects anti-EIAV antibody, has been subject to control measures in many countries. The location of outbreaks in marshy areas led to the common name of "*swamp fever*," and their occurrence during the summer led to the demonstration that the virus is *arthropod-borne*. The likely vectors are the stable fly (*Stomoxys calcitrans*), horse flies (*Tabanus* spp.), and *Anopheles* mosquitoes. *Transmission is mechanical not biological*, and may also occur accidentally by contaminated needles, syringes and tattoo equipment or experimentally by parenteral administration of blood or virus. The virus is stable in the environment, but infection appears always to arise by close contact with an infected animal.

Infection is lifelong and viremia is cyclic, resulting in a clinical course varying from asymptomatic to acutely fatal and which resembles the idiopathic hemolytic anemias of dogs. *The virus infects cells of the monocyte–macrophage system* but, in acute viremic states, unintegrated viral DNA is present at levels two orders of magnitude higher in liver than in leukocytes and at lower levels in nodes, marrow, spleen and kidney. The relationship between the cyclic viremia, viral antigenic variation and the immune response is complex. The gp90, gp45 and p26 antigens appear to be most apparent to the immune system and, while these antigens are bound in early disease, neutralizing antibody is not detected before 2 months of infection. Subsequently, there is rapid variation in the glycoprotein envelope antigens that indicates that the preparation of an effective vaccine will be difficult as for the other

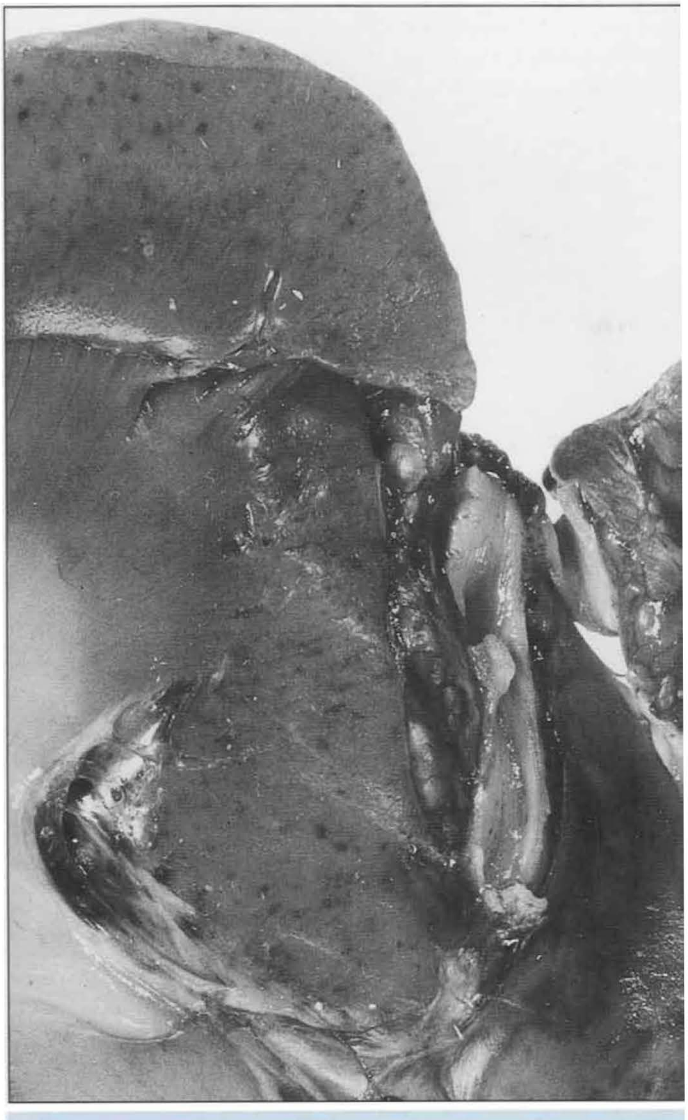

Figure 2.86 Equine infectious anemia. sagittal section of kidney. Prominent glomeruli with petechial hemorrhages.

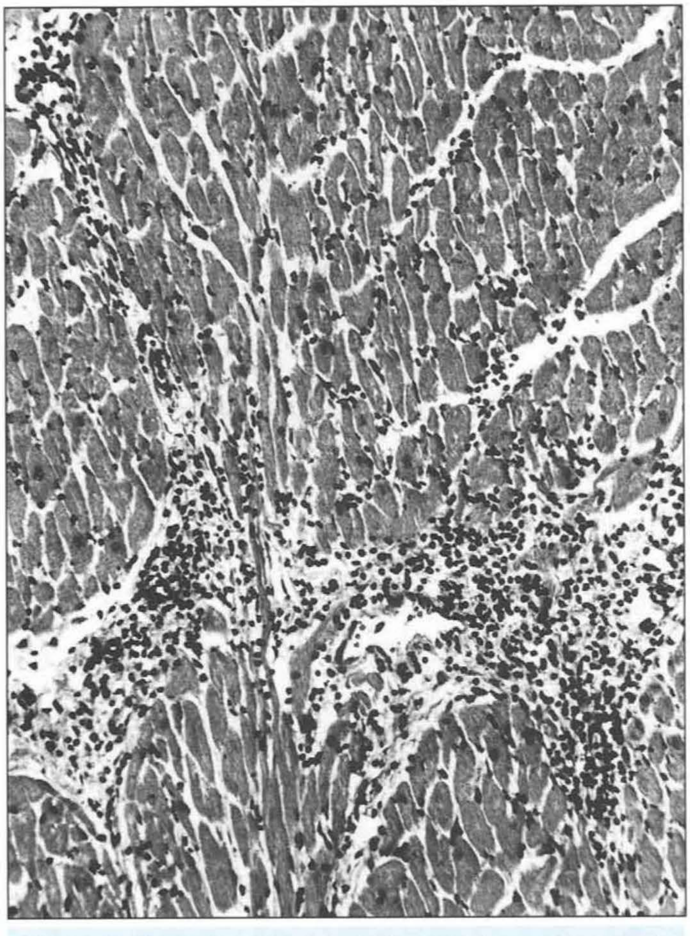

Figure 2.87 Equine infectious anemia. Lymphocytic interstitial myocarditis in acute disease.

retroviridae. The virus has both *cis*- and *trans*-acting response elements responding to viral regulatory proteins in controlling gene expression, and shares structural and sequence similarities with human immunodeficiency virus and simian immunodeficiency virus, and functional similarities with visna virus.

It has been suggested that the EIAV has little direct effect on tissues and that the pathogenesis of disease involves the indirect effects of the immune response. When foals with combined immunodeficiency (CID) and lacking functional B and T lymphocytes are infected with EIAV, the typical widespread inflammatory lesions of EIAV infection are not found, suggesting that the lesions in parenchymal organs are a function of the immune system. The foals develop anemia and, although they have a functional complement system, the characteristic fixation of C3 to red cells is not found. While CID foals are not able to clear virus from the blood, the level of viremia in these animals is no higher than that in infected conventional foals. Thus it appears that there may be NK cell or other factors operative in viral control besides antibody.

Following experimental infection of conventional horses, there is a variable incubation period of 5–7 days up to several weeks during which time there is asymptomatic viremia. All signs of disease correspond to the appearance of circulating antibody, which is complement-fixing but not initially virus-neutralizing. C3 appears on erythrocyte membranes, and this probably accounts for macrophage recognition and erythrophagocytosis. Antibodies of the IgG and IgM type are not found fixed to red cells, but it is believed that they have reacted specifically with virus adsorbed to erythrocytes, activated complement, and then been eluted off in the process of analysis. *Red cell destruction is thus of the "innocent bystander" type, with virus playing a similar role to compounds causing drug-induced immune hemolysis.* There is shortening of red cell lifespan to about 20–65% of normal. Hemolysis is largely intracellular, but in acute disease there is erythrocyte fragmentation due to microvascular injury, and decreased haptoglobin levels. The marrow is initially highly responsive with an upward shift in MCV and marked anisocytosis. Later the marrow becomes hypoproliferative. Evaluation of the erythroid response requires definition of the stage of the disease, and also the breed affected, since racing breeds tend to react differently than do ponies and heavy breeds.

The clinical disease is arbitrarily divided into *acute, subacute* and *chronic* forms, but death in the protracted cases results from acute exacerbation, so the signs are relatively constant. The acute disease is characterized by pyrexia and marked depression, with anorexia, weight loss and pitting, dependent edema. There are petechial hemorrhages most reliably seen on the ventral surface of the tongue but also present on ocular and vulvar mucosa. The tongue is most reliably examined by rotation in situ, since forced extraction tends to cause petechiation. Mild icterus develops after a short febrile period and is accompanied by pallor of mild-to-marked degree. The febrile periods may progress to death in less than a week, or

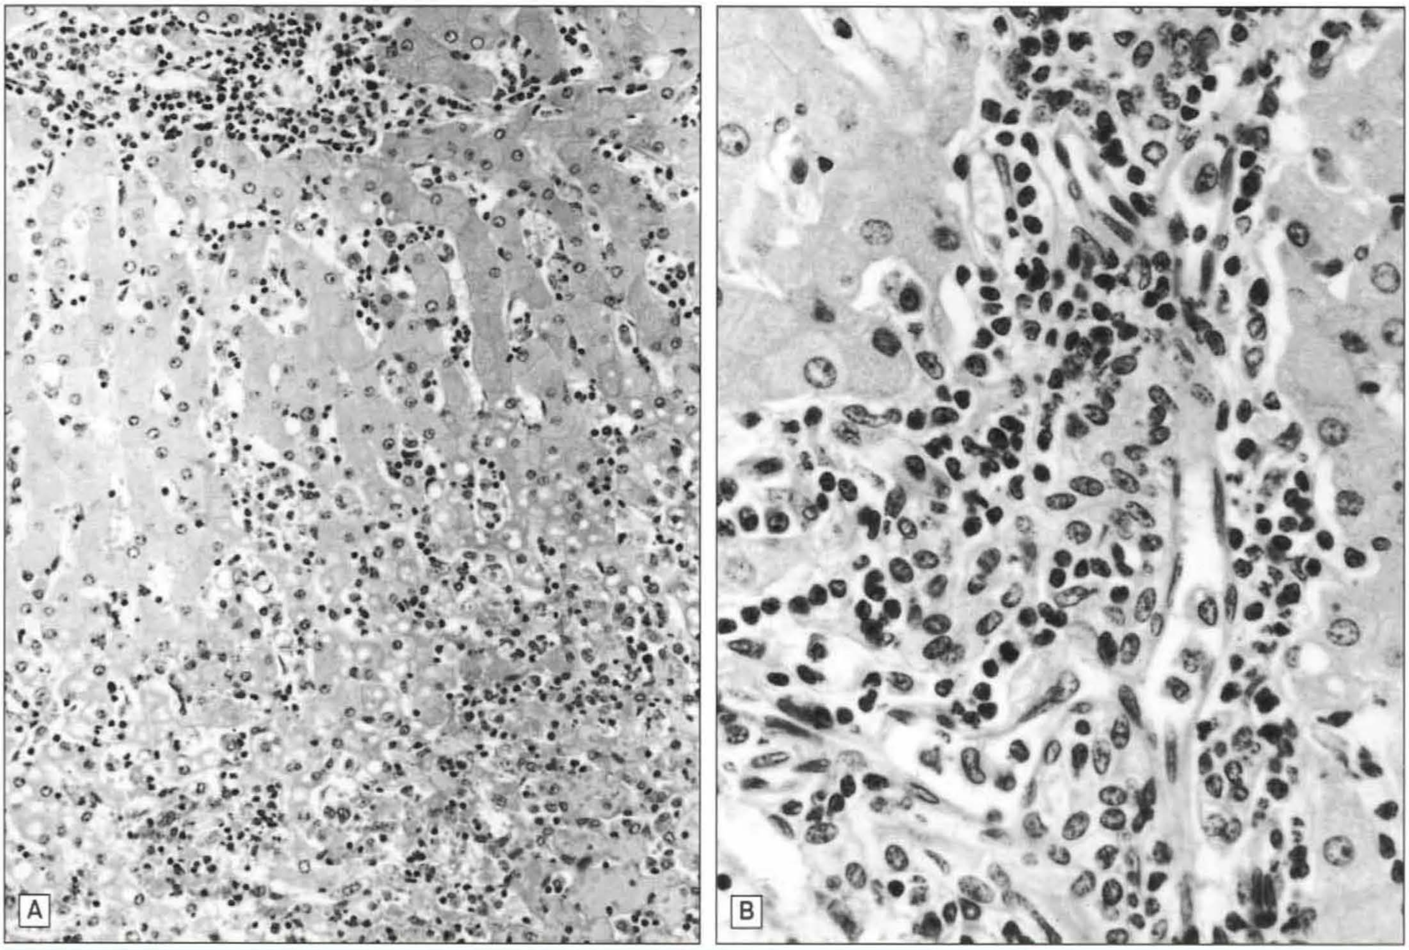

Figure 2.88 Equine infectious anemia. A. Hepatic portal and sinusoidal infiltrates of lymphocytes and plasma cells. Kupffer cell proliferation and periacinar necrosis in the chronic disease. **B.** Detail of portal area of (**A**).

regress and recur at irregular intervals. Rarely, an acute episode is followed by many years of an asymptomatic carrier state.

Anemia is severe and sufficient to cause death, with erythrocyte counts as low as 1×10^{12}/L, hemoglobin of 25–50 g/L, and hematocrits of 0.08–0.15 L/L. There is *consistent thrombocytopenia* during febrile periods with resulting petechiae. In the early stages of disease, there is anisocytosis, marked for the horse, with moderate poikilocytosis and, characteristically for the horse, no polychromatic red cells. Nucleated erythrocytes are not present in peripheral blood. In the early stage of an acute attack, there is macrocytosis, sometimes up to an MCV of 60 fL. Later the anemia is normochromic, normocytic and nonresponsive. There is accompanying leukopenia with neutropenia, minimal left shift, lymphopenia and at least a relative monocytosis. The monocytes often contain ingested red cells (*sideroleukocytes*), and stain positively for iron in buffy coat smears. Sideroleukocytes are specific not to equine infectious anemia but to intracellular hemolytic anemia but, prior to diagnosis by antibody, their presence at levels of 4/10 000 leukocytes or higher was considered a positive diagnosis. Sideroleukocytes are present in the blood within 2–3 days of a febrile episode and subside with the fever. The neutrophils have moderate toxic changes with vacuolation and azurophilic granulation, but not Doehle bodies. The mononuclear cells are large and basophilic and it is difficult to distinguish lymphocytes from young monocytes. The platelets are small and uniformly basophilic with a normal low level of granulation, and immature cells are rarely found. In the acute disease, the aspirated bone marrow is hypercellular with an erythroid shift, but cellularity and erythropoiesis are later reduced, and there is mild dyserythropoiesis and proliferation of macrophages and plasma cells.

Icterus is always present in febrile, anemic horses, and bilirubin is usually between 170 and 250 μmol/L; most is unconjugated. Lipemia is occasionally seen in the acute disease. With chronicity (30 days or more), there is a drop in albumin of around 10 g/L and a corresponding increase in gamma globulin so that the total protein is relatively unchanged but the albumin/globulin ratio is decreased. The serum iron rises in the acute disease and drops with chronicity, while the total iron-binding capacity remains normal or mildly elevated.

In horses dead of the acute disease, there is anemia, icterus and widespread foci of hemorrhage. In animals with protracted disease, there is anemia, emaciation and edema with serous atrophy of fat which is bilirubin-stained. In febrile disease, thrombocytopenia complicates minor trauma, and larger hemorrhages are found subcutaneously and around sites of parasitic migration. There is edema of the ventral abdominal wall and in the suspensory ligaments of the viscera. The spleen is enlarged, turgid and fleshy with capsular hemorrhages, a bulging but not oozing cut surface, and inapparent lymphoid follicles. The liver is enlarged, dark and turgid with a fine lobular pattern and focal capsular hemorrhages. Petechial hemorrhages are present on the renal capsules and in the perirenal tissues. On cut surface, there are multiple fine hemorrhages throughout the cortex and medulla (Fig. 2.86). The most significant gross lesions occur in bone marrow where the degree of reddening is in direct proportion to the duration of the disease. In acute cases, the conversion of fat to hematopoiesis in the femoral marrow occurs first in proximal cancellous and then subendosteal diaphyseal and distal cancellous areas. The red and yellow areas are initially firm and opaque, often with focal areas of hemorrhagic infarction. In chronic cases, the red conversion may include all of the medullary marrow and is alternately pink and translucent in areas of serous atrophy of fat, and cyanotic where congested sinuses have dilated as adjacent hematopoietic areas atrophy.

Microscopic lesions *occur in most tissues, but are most prominent in the heart, lungs, liver, spleen, kidney, marrow and lymph nodes.* Their severity varies with chronicity and they are described here in the fully developed state. The *myocardium* has fiber atrophy in chronic cases, and interstitial edema in acute cases, with perivascular lymphocytic aggregations that irregularly permeate the surrounding interstitium (Fig. 2.87). There is mild *pulmonary* alveolar thickening and an overall appearance of hypercellularity. Occasionally, hemosiderin-bearing macrophages are found in alveolar walls and are likely intravascular. The *liver* presents a spectrum of changes which varies from mild periportal lymphocytic infiltrates to atrophic cords with sinusoidal dilation, Kupffer cell hyperplasia, broad loosely arranged periportal lymphoid infiltrates, and increased interstitial connective tissue. As the disease progresses, hepatic hemosiderosis increases, largely in Kupffer cells. Generalized endothelial prominence, along with sinusoidal Kupffer cells and infiltrates, gives an overall picture of hypercellularity (Fig. 2.88A, B). In subacute cases there is periacinar fatty vacuolation, and in acute cases hemorrhage and necrosis. In animals in which the disease has been quiescent for some months, hepatocytes appear normal and lymphoplasmacytic infiltrates subside but sinusoidal hemosiderin-bearing macrophages remain as evidence of previous hemolysis.

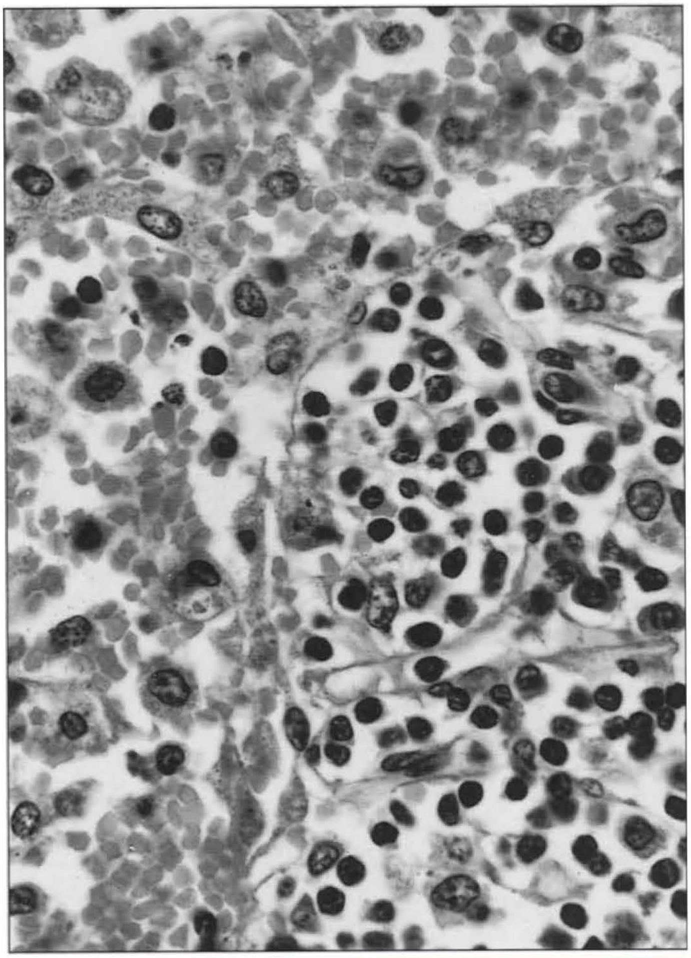

Figure 2.89 Equine infectious anemia, lymph node. Medullary cords contain few small lymphocytes and plasma cells. Active sinus histiocytes. Red cells in sinuses derived from thrombocytopenic bleeding.

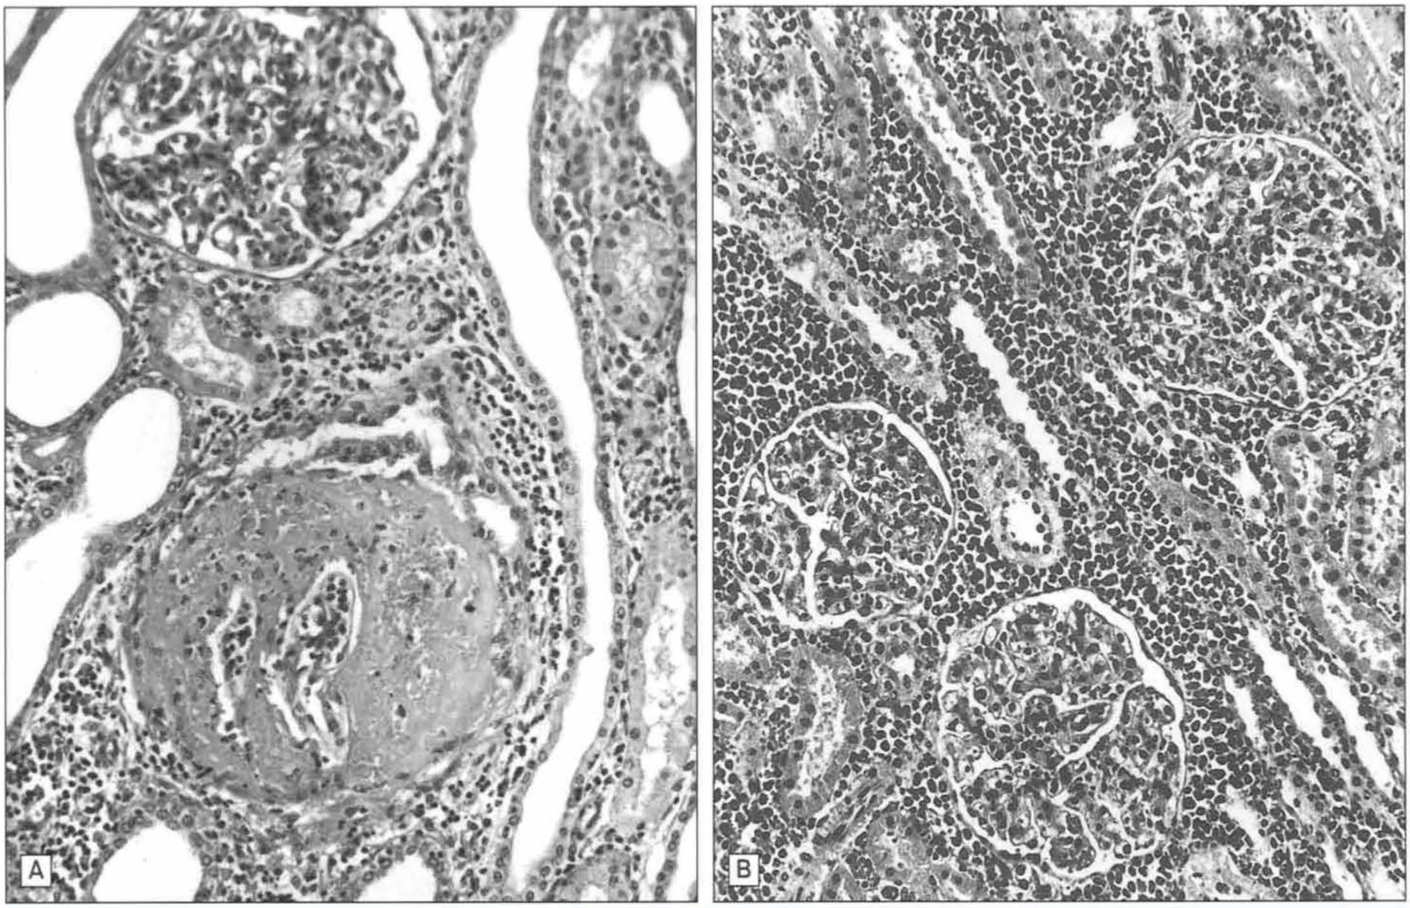

Figure 2.90 Equine infectious anemia, kidney. **A.** Periglomerular interstitial infiltrates of chronic disease, with glomerular hemorrhage from thrombocytopenia in acute exacerbation. **B.** Diffuse interstitial mononuclear cell infiltrate.

Splenic follicles are variably enlarged but hypocellular, often with a "bull's-eye" appearance due to a sharp distinction between the cells of the follicular center and the mantle and marginal layers, and a sharp transition to congestion in the surrounding sinusoids. In acute cases, the spleen is congested and, being largely composed of unsupported red cells, fractures on sectioning. Later there is sinus hyperplasia with stromal proliferation. The tissue is then cellular, fleshy and cohesive. Splenic hematopoiesis is never as prominent as in the dog with idiopathic immune hemolytic anemia, but hemosiderosis with macrophages and plasma cell proliferation is prominent. Lymph nodes are edematous and have medullary hemosiderosis with persistence of follicles and thin moth-eaten paracortical areas. In acute disease, the lymphoid tissue is highly reactive and there may be lymphocytic colonization of perinodal fat. Later there is sclerosis and lymphoid atrophy (Fig. 2.89).

Renal lesions in acute disease are largely hemorrhagic with some glomeruli obscured by erythrocytes and fibrin (Fig. 2.90A). Lymphocytic infiltrates may be intense and separate tubules in an irregular manner (Fig. 2.90B). There is some degree of epithelial atrophy and mild pigmentation that appears to be both bilirubin and hemosiderin.

The red *bone marrow* in acute disease has 40% or less of fatty areas and the hematopoietic cells are densely packed. There is an erythroid shift with synchronous maturation (Fig. 2.91), and a reduction in mature granulocytes, although eosinophils are prominent. Megakaryocytes are not increased, which may indicate that the thrombocytopenia may be at least partially due to ineffective production. With chronicity and repeated febrile periods, there is a progressive reduction of fat cells until the marrow is completely converted to hematopoiesis (Fig. 2.92A). At the same time, cellular packing decreases and sinusoidal expansion occurs so that marrow which appears red grossly can be seen histologically to be relatively hypoproliferative. Hemosiderin is prominent as is erythrophagocytosis (Fig. 2.92B). Large macrophages can be found which contain hemosiderin, red cells and rubricytes. This latter association does not appear to be a "nurse cell" relationship, but rather an extension of the peripheral disease to marrow with destruction of the precursors as well as the progeny. Dyserythropoiesis as evidenced by binucleated interphase rubricytes is present. Megakaryocyte cytoplasmic volume is normal or reduced but not increased, indicating that the response of this lineage is weakened and likely at least partially ineffective. Stromal cells are increased, endothelial nuclei are prominent, and there is a diffuse plasmacytosis. Hematopoiesis may regress from the central femoral cavity and leave fatty tissue with serous atrophy heavily laden with hemosiderin-bearing macrophages that indicate previous sites of production and hemolysis.

The disease is one of acute intracellular hemolysis followed by immunoproliferation and finally by hematopoietic and to a lesser extent immune exhaustion.

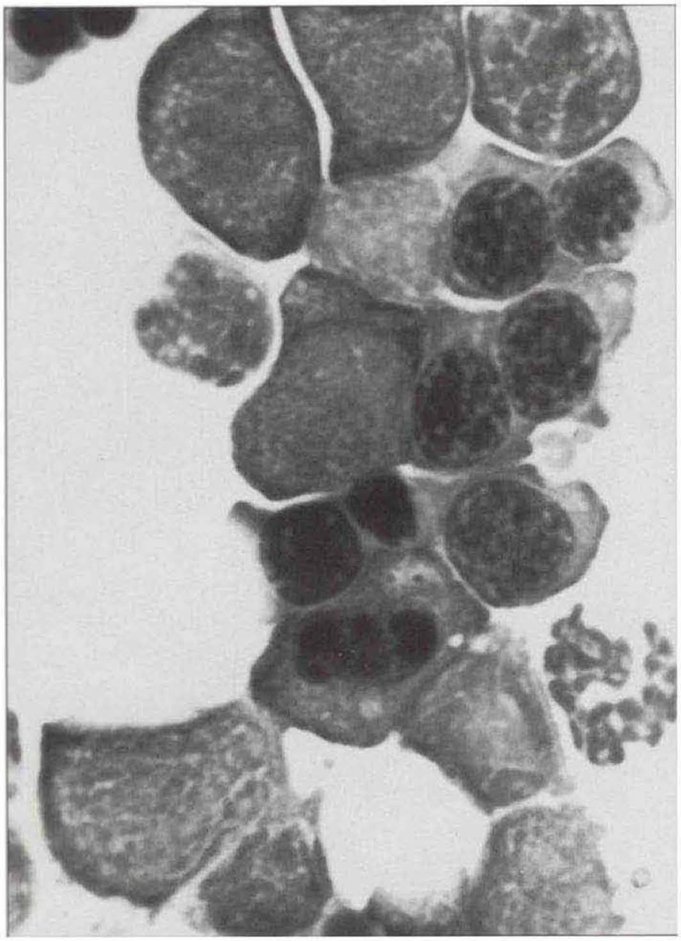

Figure 2.91 Equine infectious anemia. Marrow aspirate in acute disease. Productive synchronous erythroid hyperplasia.

Following the development of the agar gel immunodiffusion test, *steroid-responsive, idiopathic immune hemolytic anemia has been identified in the horse.* The lesions resemble those of immune hemolytic anemia of the dog, and lack the inflammatory reaction characteristic of equine infectious anemia. Horses with idiopathic immune hemolytic anemia are not usually thrombocytopenic and do not have cyclic fever.

Anemia of blood cell parasitism

Babesiosis

The protozoan *Babesia parasitizes the erythrocytes of a wide range of mammals* including humans, and there is normally *quite strict host specificity. The agent is transmitted by ticks.* Natural transmission is largely *transovarial*, that is, the adult female becomes infected, and, depending on the babesial and tick species, the ensuing larval or nymphal generation then transmits the infection to a susceptible host. Transtadial transmission occurs in three-host ticks, infection being carried through a molt off the host, permitting transmission to the next host encountered. There is no evidence for transmission by biting insects or contaminated instruments (in contrast to the situation with *Anaplasma* infection), but infection is readily transmitted by experimental blood inoculation.

The severity of the disease produced in the mammalian host depends more on the strain and species of infecting *Babesia* than on the number of organisms inoculated. Pathogenic effects are, in most infections, related directly to *lysis of red cells by emerging parasites* but other mechanisms, including sludging of infected red cells, hemoglobinuric nephrosis, and release of vasoactive peptides, contribute to the signs and are responsible for death.

Different tick species are vectors in different countries for what are apparently the same species of *Babesia*. Nomenclature is not dealt with here, but rather the pathology and pathogenesis of babesiosis and, in particular, those naturally occurring infections that cause the most severe and economically important disease. *The severity of many of the anemias caused by parasites of blood cells is enhanced by splenectomy*, and this technique is used commonly in pathogenetic studies. Splenectomy is often performed in dogs following abdominal trauma or for treatment of neoplastic disease, and this may activate latent infections by organisms such as *Haemobartonella canis*. In human babesiosis, splenectomy appears to be a major risk factor for infection, primarily with *B. microti*.

Bovine babesiosis

Babesia bovis *(=B. argentina, B. berbera, B. colchica) is probably the most important cause of the "tick fevers" of cattle*, with local exceptions in some countries. The fact that some *Bos indicus* cattle breeds are relatively resistant to the effects of this parasite has led to the suggestion that the organism evolved in these breeds. Young cattle have pronounced resistance to severe infection. Immunity passively acquired from colostrum by very young calves may persist for up to 9 months of age. *Strong acquired immunity follows overt infection*, and may persist indefinitely in the absence of latent infection, although the latter is usual. Infection with a single strain of the parasite protects against subsequent infection for at least 4 years. For these reasons, the disease is

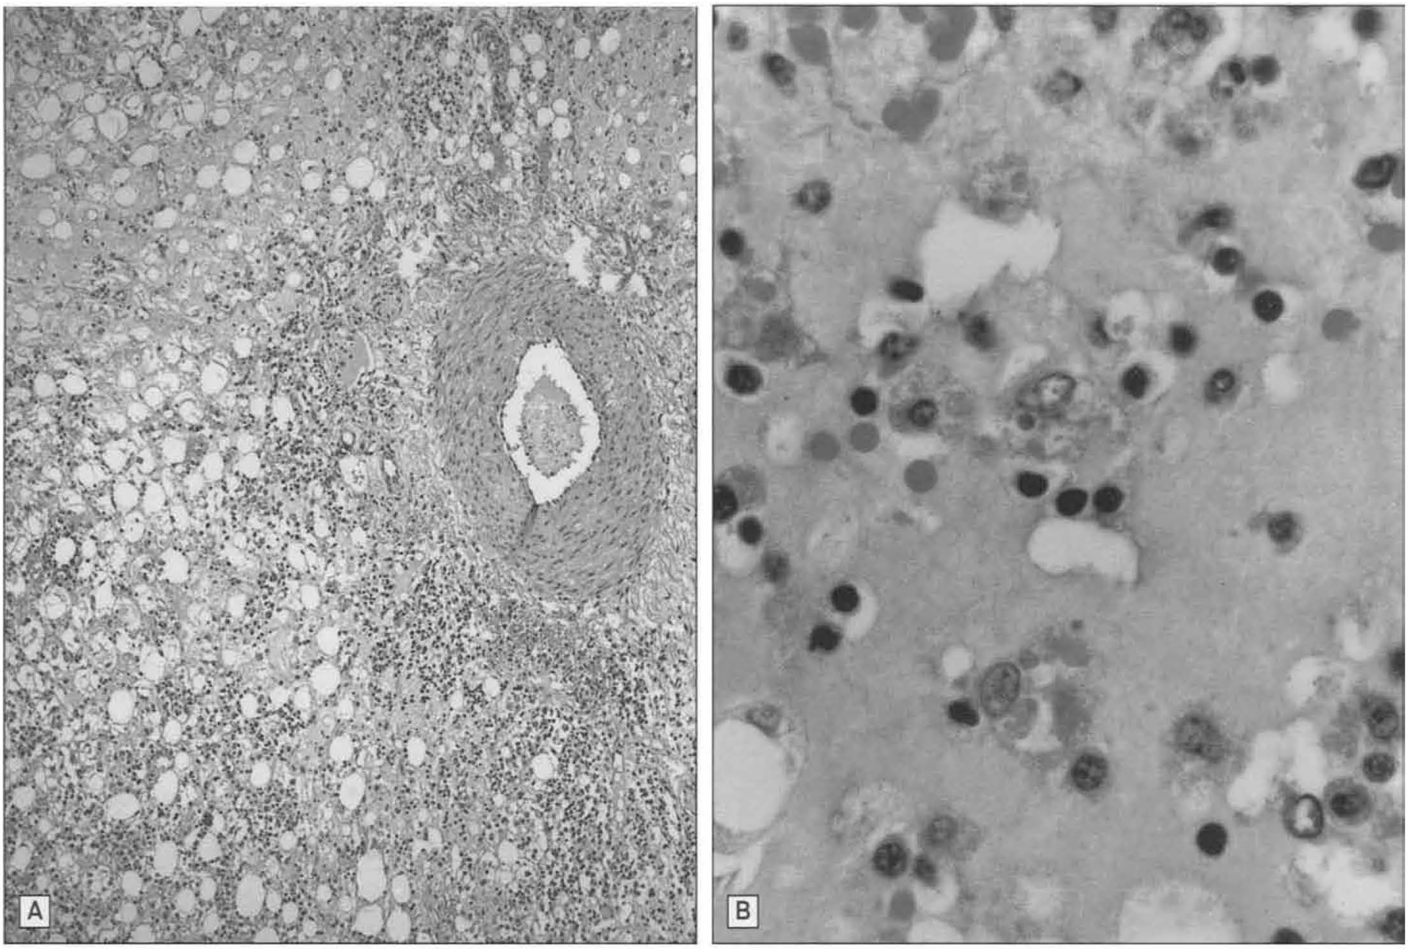

Figure 2.92 Equine infectious anemia. A. Central femoral marrow in chronic disease. Hypertrophy of marrow to occupy entire cavity followed by late reduced hematopoiesis and serous atrophy. **B.** Area of serous atrophy in marrow in chronic disease. Macrophages contain hemosiderin, indicating earlier hematopoiesis and erythrophagocytosis.

mostly seen in adult cattle recently introduced from tick-free areas, or in areas of greatly fluctuating tick populations.

Infection by *B. bovis* causes *severe febrile illness* which begins about 2 weeks after exposure to ticks. The animal may become extremely ill before severe anemia, parasitemia or hemoglobinuria are apparent, and sometimes the clinical picture is dominated by nervous derangement, likely associated with the tendency for parasitized red cells to sludge in cerebral capillaries as well as in the microvasculature of the adrenal and kidney of splenectomized animals. Usually, however, the clinical picture is characterized by *weakness, fever, hemoglobinuria, and anemia*; the latter is more severe in animals surviving more than a week. The parasite is never numerous in circulating blood, rarely being seen in more than 5% of circulating erythrocytes. Parasitized erythrocytes are much more likely to be found in smears of blood squeezed from cut skin capillaries than in routine blood samples from large veins. Recovery is usually fairly rapid in animals which survive the acute phase, although chronic ill-thrift has been described. Photosensitization may occur in the convalescent phase, probably due to overload of the phylloerythrin-conjugating sequence by bilirubin derived from hemolysis.

The most typical **postmortem findings** *are those to be expected of an acute intravascular hemolytic crisis.* There is anemia, variably severe jaundice and hemoglobinuria, and the kidneys are deep red-brown throughout as a result of hemoglobin staining and intense congestion of capillaries. There is capillary congestion of most organs, the spleen is always grossly swollen, soft and dark, and the liver is also acutely congested and may be heavily stained with bile pigment. The gallbladder is distended with thick, dark viscous bile.

In some acute cases, the lungs are congested and edematous and the larger airways contain stable foam. Recent hemorrhages are common in the thoracic serosal membranes. *The most characteristic macroscopic feature of B. bovis infections is striking, uniform congestion of the gray matter throughout the brain, imparting to it a dramatic, deep pink color (the cerebral flush)*, which contrasts strongly with the white matter; the latter is often stained a faint yellow by unconjugated bilirubin. In some peracute cases, there is minimal hemoglobinuria or jaundice, but the brain still shows the characteristic capillary congestion from which imprint preparations are usually diagnostic, with many intraerythrocytic organisms present.

Histologically, there is thickening and congestion of pulmonary capillaries with hemosiderin in intravascular macrophages. Kidneys and liver have the histological lesions to be expected of an acute hemolytic disease. There is variably severe hemoglobinuric nephrosis with severe congestion, focal hemorrhage and hemosiderin in tubular epithelium, and diffuse vacuolar degeneration with interstitial mixed mononuclear cell reaction. There is hepatic periacinar congestion

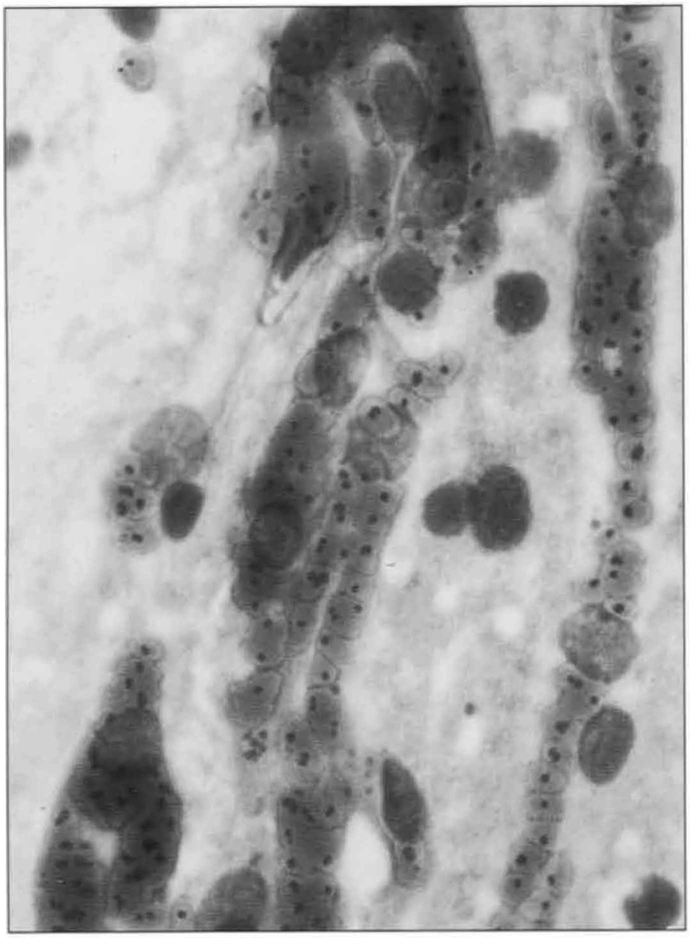

Figure 2.93 ***Babesia bovis***, ox. Giemsa stain. Sludging of parasitized red cells in cerebral capillaries. (Courtesy of HMD Hoyte.)

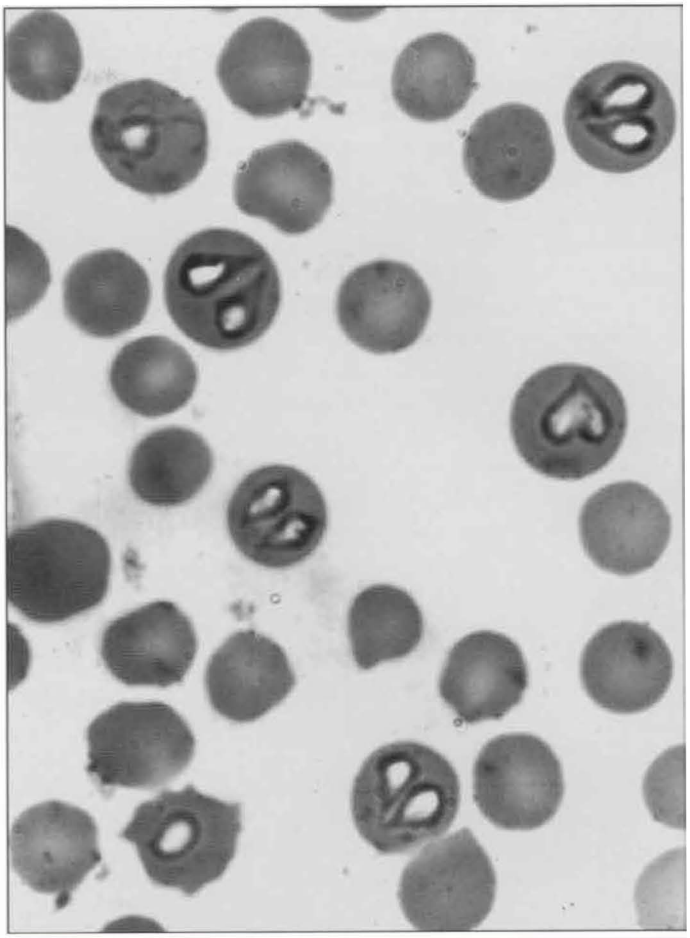

Figure 2.94 ***Babesia bigemina***, ox. Giemsa stain. Parasitized cells are large due to presence of parasites and selective parasitism of young cells.

with uninfected red cells, and vacuolar degeneration in midzone and periacinar hepatocytes, accompanied by canalicular cholestasis. There is hemosiderin accumulation in both hepatocytes and Kupffer cells, and the latter contain both infected and noninfected red cells. Lymphocytes and plasma cells accumulate in portal areas and around central veins. *Parasitized erythrocytes may be seen in vessels in all tissues*, but they are particularly common in interstitial capillaries in the kidney, in the gray matter of the brain, in the heart, and especially in skeletal muscle; in these locations, nearly every red cell packed into the distended capillaries appears to contain 1–2 parasites. *The organisms are faint blue in routine sections, and are best demonstrated in imprint preparations of fresh tissue.* In sections, Giemsa's stain demonstrates them as small paired or single spherical bodies with denser staining at one pole. In well-fixed fresh brain of acute cases, there may be edema of the neuropil around the clogged capillaries (Fig. 2.93).

Animals that die with peracute disease have necrosis of lymphocytes in germinal centers of node and spleen, while there may be some degree of recovery in animals surviving a week and general depletion of lymphocytes in those dying after protracted illness. Characteristic changes in the medullary region of nodes include sinus histiocytosis with extensive erythrophagocytosis. The histology of the spleen is often unhelpful, the organ being so suffused with intra- and extracorpuscular hemoglobin that evidence of erythrophagocytosis is obscured. There is little extramedullary hematopoiesis in liver or spleen. The bone marrow has an erythroid shift and, in animals that survive the acute stage, there is a strong reticulocytosis and slow recovery in red cell numbers. There is mild hemosiderin increase, suggesting that marrow is also a site of erythrolysis.

Babesiosis results in metabolic disease more complex than a simple syndrome of intravascular hemolysis. Severely affected animals may die before significant anemia has set in, and in these cattle the intense visceral congestion and pulmonary edema suggest that death may be at least partly due to circulatory shock. This has been supported by studies which have shown that the parasite is the source of proteases which activate plasma kallikrein which, as well as being a hypotensive agent, may activate bradykinin, another potent vasodilatory agent. Rather unexpectedly, metabolic alkalosis occurs in *B. bovis* infections, whereas acidosis is the rule in severe *B. canis* infections. *The result of these profound metabolic upsets is a syndrome of circulatory failure, likely due to extensive plugging of microvasculature by sequestered red cells.* The apparent anemia is therefore due in considerable measure to the vasodilatory effects of kallikrein and shift of red cells away from large veins. While plasmin activation occurs, the effects on the coagulation system are unlikely to be a significant factor in the pathogenesis since hemorrhage is not a major part of the morbid picture.

The actual mechanism of penetration of red cells by the merozoites of Babesia is as yet unclear, but complement is required and it appears that the organism causes activation by the alternative pathway, and by

C3b achieves adherence and later invasion. *The mechanism of hemolysis is also obscure.* It may be in large part spherocytic, and complicated by mechanical loss by fragmentation and exiting of parasites. Immune mechanisms do not appear to play a significant role in the early stages of the disease, but they may be a factor in delayed recovery. Osmotic fragility is markedly increased in nonparasitized cells, while the fragility of parasitized cells may actually decrease. Parasitized red cells form prominent stellate projections which appear to be the means by which they adhere to each other and to the endothelium. Fibrin may be involved in some of the sludging phenomena.

Babesia bigemina infection may be transmitted by the same tick as *B. bovis*, and both parasites may cause losses in the same geographic area. *Babesia bigemina*, however, usually causes a *much less severe syndrome*, notwithstanding the fact that parasitized erythrocytes circulate early (Fig. 2.94), sometimes before clinical signs are apparent, and in much greater numbers than they do in *B. bovis* infection. Like the latter parasite, *B. bigemina* causes *erythrocyte destruction*, but this appears to be directly proportional to the level of parasitemia, unlike *B. bovis* infection. There are few of the vasoactive and red cell adherence effects, so the disease is not attended by such profound shock-like signs. Thus the anemia in severe cases may be severe before the animal becomes ill and, as in any case of severe anemia, death may occur suddenly as a result of myocardial failure. Fever is not usually as severe as in *B. bovis* infection.

The pathology of *B. bigemina* and *B. bovis* infections is similar, except that in *B. bigemina* infection there is little capillary congestion of the viscera and none of the cerebral gray matter, *the presence or absence of the cerebral flush being the most reliable gross feature for differentiating the two infections.*

Pulmonary edema may be more often seen in fatal cases of *B. bigemina* infections, probably because the greater severity of anemia causes terminal left ventricular failure.

Babesia divergens and ***B. major*** are more or less restricted to northern and western Europe and Asiatic Russia and, for the most part, are of relatively minor importance to the cattle industries there, although significant outbreaks of disease and death may occur. Although *B. divergens* is small and resembles *B. bovis* in size, and *B. major* is as large as *B. bigemina*, the pathology and pathogenesis of the disease produced by these organisms is apparently very similar to that produced by *B. bigemina*. Thus there is intravascular hemolysis with little or no capillary agglutination of erythrocytes, and *death is due primarily to severe anemia*. Spontaneous splenic rupture has been reported in *B. major* infections, a complication rarely if ever reported in other bovine babesial infections.

Differential diagnosis of bovine babesial infections *in countries where more than one species of Babesia is present is important and at times difficult*, and may be complicated by dual infections and by the additional possibility of *Anaplasma* infection. *Babesia bovis* and *B. bigemina* may be distinguished from one another in *well-prepared blood smears* but erythrocytes parasitized by *B. bovis* are rare in jugular blood, or even in blood from deep skin punctures. They are best demonstrated in smears of blood expressed from a superficial skin scrape; this is most conveniently obtained from the *tailtip* in the live animal. *Babesia bigemina*-containing erythrocytes, on the other hand, are quite numerous in circulating blood while clinical signs are severe. The morphology of the parasites will usually be insufficiently preserved in postmortem material to allow distinction but the preference of *B. bovis* for capillaries of organs such as kidney, heart and brain will in most cases serve to distinguish the infections. It must be remembered that *Sarcocystis* spp. may be present in smears of myocardial blood. *Serological tests* are available for live animals and *direct fluorescent antibody techniques* may be used for differentiation in postmortem material. It is necessary to demonstrate a very heavy parasite burden in cerebral capillaries if brain smears are to be relied on as evidence of active *B. bovis* infection, as most clinically normal carriers of this organism can be shown to have some parasitized erythrocytes in this site.

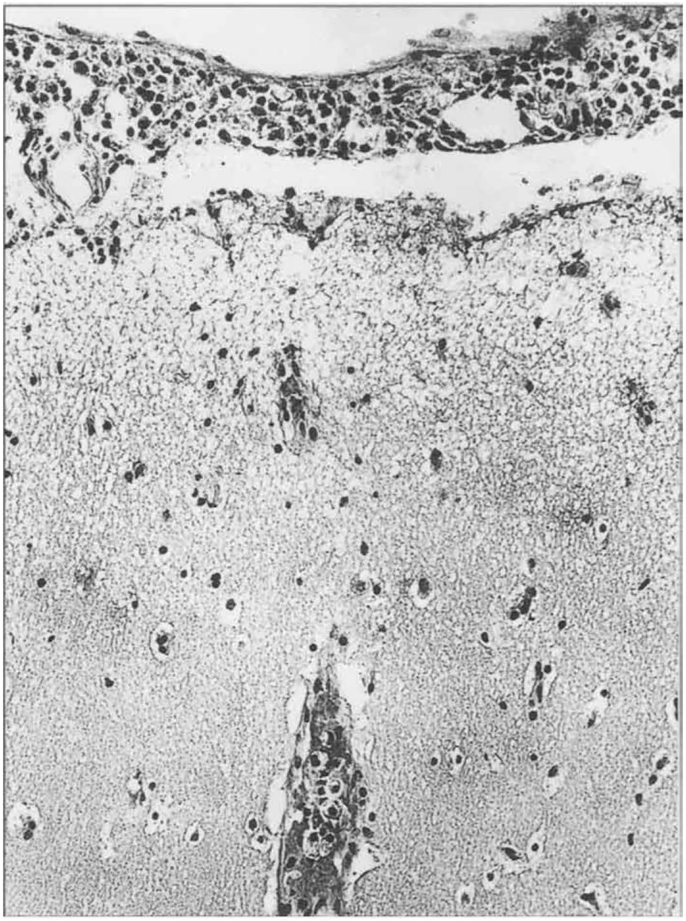

Figure 2.95 Sludging of red cells and meningeal infiltration in ***Babesia canis*** infection.

Blood smears should always be made from a peripheral site in a dead animal, particularly if fluorescent antibody techniques are available for diagnosis, because *such smears may be the only means of distinguishing an Anaplasma infection from one of the babesial infections.* Sterile immunity can be obtained with appropriately prepared antigens though these are not readily available.

Canine babesiosis

Babesia canis *is transmitted by different ticks in different countries*; it is not known if this is related to the apparent differences in virulence of the organism. The infection in dogs in Africa is severe and frequently causes death in all ages, whereas in Australia and in the United States the disease is relatively mild in mature animals. The disease is, however, *more severe in pups in all countries.* As distinct from bovine babesiosis, young dogs appear to be more susceptible than older animals.

Mildly affected animals develop *anemia and fever*, and are lethargic and have a poor appetite. Icterus and red urine are not seen and they recover after a clinical course of a few days. More severe cases show a wide variety of signs, including severe depression, drooling, vomiting, jaundice and hemoglobinuria, mucosal petechiae and congestion, ulcerative stomatitis, and angioneurotic edema of the head, legs and body. Anorexia and weight loss may be persistent. A few **dogs** may show nervous signs that are associated with erythrocyte sludging in cerebral capillaries and cellular infiltration of the meninges (Fig. 2.95). Acidosis is particularly important in this disease.

Grossly, there is staining of tissues both with bilirubin and hemoglobin. The kidneys are dark brown and there is copious thick bile in the gallbladder and splenomegaly. In addition, there is evidence of vascular injury in the form of hemorrhages and edema, which may be severe in the lung. Parasitized erythrocytes may be found plugging capillaries in smears and sections of cerebral cortex, reminiscent of *B. bovis* infection, but the phenomenon is never as severe as in that disease. *Disseminated intravascular coagulation* is a consistent occurrence in severe *B. canis* infection, and is presumably related to, and is likely to aggravate, the hemolysis and the vascular damage. Microthrombi can be demonstrated in many tissues.

Babesia canis and *B. bovis* infections clearly resemble one another in the severity of the syndromes and the involvement of pathogenetic mechanisms other than simple hemolysis.

Babesia gibsoni infection is apparently restricted to Asia, with the most severe losses in dogs imported into India. The pathogenesis of this infection seems to be analogous to that of *B. bigemina* in cattle, in that dogs may have heavy parasitemia and quite severe anemia without becoming very ill. The body temperature is not elevated as consistently as in the case of *B. canis* infection, and hemoglobinuria rarely if ever occurs. The pathogenesis of *B. gibsoni* infection appears to be related primarily to the intracellular destruction of erythrocytes, as the spleen becomes very large and there is no evidence of intravascular hemolysis. Death is due to anemia with PCVs dropping to less than 0.10 L/L.

Equine babesiosis

Babesiosis in horses is similar to that in dogs in that there are *two babesias of equids*, one larger than the other, but the larger (***B. caballi***) is usually considered less virulent than the smaller (***B. equi***). *Babesia caballi*, like *B. canis* and *B. bovis*, tends to accumulate in capillaries; thus these species have been referred to as "visceral," as distinct from *B. bigemina, B. equi*, and *B. gibsoni*, which are more evenly distributed throughout the circulation. There is, however, considerable overlap in virulence between all these species, all of which may cause death.

Babesia caballi infection is often mild and, if severe, the syndrome is characterized by fever, jaundice and anemia, but hemoglobinuria is unusual. *Babesia equi* infection produces severe anemia, often accompanied by hemoglobinuria, severe depression, lacrimation, and often ventral and periorbital edema and mucosal petechiae. Pelvic limb ataxia is not seen as frequently as in *B. caballi* infection. The lesions in both infections are very similar, and include generalized icterus, anemia and splenomegaly. More visceral edema and hemoglobinuric nephrosis is expected in *B. equi* infection. *Mixed infections are possible, and pathologic differentiation of equine babesiosis from equine infectious anemia may be difficult.*

Babesial infections of other species

These for the most part are mild or clinically inapparent, but severe reactions sometimes occur; the reasons for these are seldom obvious. The course of these diseases in general follows the pattern described for *B. bigemina* infection, in that there is quite severe parasitemia, anemia due to intravascular hemolysis, with hemoglobinuria in acute cases. At autopsy, there is splenomegaly and variably severe jaundice and, in some cases (notably *B. trautmanni* infection in pigs), edema and petechiae. *Babesia ovis* may cause cerebral congestion in sheep.

White-tailed deer may be infected by an organism resembling *B. divergens*, and mice may be infected with *B. rodhaini*, *B. hylomysci*, and *B. microti*. The latter infects other rodents as well. *Babesia hylomysci* causes severe hemoglobinuria and nephrosis.

Cytauxzoonosis

An intraerythrocytic apicomplexan protozoal hemoparasite piroplasm classified in the family Theileriidae *infects wild ungulate species in Africa*, including the kudu, eland and giraffe, as well as *domestic and wild Felidae in North America*. Unlike *Babesia*, which only infects red cells of the mammalian host, *Cytauxzoon organisms have a schizogenous phase in intravascular macrophages as well as in red cells*. The natural mode of transmission is unknown, but *ixodid ticks are believed to be the most likely vectors*. The disease is not spread by cage contact but can be experimentally transmitted by fresh blood or by cryopreserved blood or tissue homogenates from infected animals.

The *clinical signs of cytauxzoonosis in domestic cats* include depression, anorexia, pyrexia, dehydration, pallor, icterus, dark urine and occasionally dyspnea. Affected cats are markedly febrile (40.9°C) in the early stages of the disease, and the hematologic picture is characterized by *pancytopenia with nonregenerative anemia*. In the early hemolytic stages of the disease, the urine is highly concentrated, acidic with high levels of protein and large amounts of bile and blood, including intact red cells and bilirubin crystals. Blood for detection of the intraerythrocytic parasites is best collected from peripheral tissues such as ear or tail. The intraerythrocytic organisms are similar in appearance to *Mycoplasma haemofelis* (*Haemobartonella*) and signet-ring forms are frequent. Rarely, multiple organisms may be present in the same red cell in a tetrad or Maltese cross configuration. Morphologically, *Cytauxzoon felis* (*C. felis*) cannot be reliably distinguished from *Babesia felis* by light microscopy. However, *C. felis* generates a strong and persistent antibody response with titers as high as 1:300 15 weeks after recovery, as measured by microfluorometric immunoassay. Effective immunity against apicomplexan hemoparasites requires a specific response by cytotoxic T cells. The disease is peracute with most animals dying within 1–2 days after onset of clinical signs. Treatment is largely supportive and recovery is slow, requiring several weeks for the hemoglobin to reach normal levels. In acute stages of the disease, there is prolongation of the clotting time as well as the prothombin time and partial thromboplastin time. These findings might be expected with rapid intravascular hemolysis releasing red cell stroma which is procoagulant.

While the disease is unusual, most reported cases have been fatal, with death occurring within a few days after the onset of clinical signs. The level of parasitemia is low and the piroplasms are commonly found in 1–4% of peripheral blood erythrocytes. While a much higher level of parasitemia may occur, in some reported cases no parasitized red cells were identified. *The sporadic appearance of the disease and fatal course suggest that domestic cats are an unusual host for the organism and that a reservoir host exists in the wildlife population.* The bobcat (*Lynx rufus rufus*) given blood from an infected cat develops persistent parasitemia without signs of clinical illness, suggesting that it may be the reservoir for the acute disease in domestic cats. Remarkably, there appear to be two strains of the organism which are indigenous to either the eastern or western bobcat. Cats are susceptible to both, and bobcats are susceptible to their non-indigenous strain. This likely explains why cats recovered from the bobcat transmission are still fully susceptible to other strains from domestic cats. **Diagnosis** *is dependent upon detection in red cells of the irregularly pear-shaped organisms.* They are often paired and are larger than *Mycoplasma haemofelis (Haemobartonella)* organisms. *There are apparently no pathognomonic gross or histological findings.*

Hepatozoonosis

Hepatozoonosis caused by the protozoan parasite ***Hepatozoon canis*** occurs worldwide in dogs and is seen in the southeastern and the southwestern United States. There are two species of *Hepatozoon* that affect dogs: *Hepatozoon canis* is spread by a variety of ticks, principally the brown dog tick, *Rhipicephalus sanguineus*; and ***Hepatozoon americanum*** is spread by the tick *Amblyomma maculatum*. Ticks ingest *gametocytes* in blood while feeding on an infected animal. Gametocytes sporulate in the tick, and *oocysts* containing 12 to 24 *sporozoites* are produced in the body cavities of the tick. When dogs ingest infected ticks, the sporozoites penetrate the intestinal epithelium and travel in blood to liver and other tissues where *intracellular cysts* are formed. *Merozoites* released from these cysts form *gamonts* in peripheral blood leukocytes and are spread to form *schizonts* in other areas of the body.

The prime presenting signs in the dog are *fever and depression*, characterized by mild anemia with extreme neutrophilic leukocytosis generally in the range of $100 \times 10^9/L$. The gamonts of *H. americanum* are larger than a red cell and egg-shaped, displacing the nucleus and relatively unstained in routine blood preparations. The level of parasitemia in leukocytes is highly variable, and *examination of buffy coat smears may be required to identify the pale "ice-blue" gamonts in the cytoplasm of monocytes or neutrophils.* The gamonts of *H. canis* are similar in appearance. Dogs with hepatozoonosis suffer *generalized myositis* with subsequent periostitis and generalized lymphadenopathy. The animals show signs of pain on palpation and movement and the schizonts may be identified in muscle; merozoites are present within histiocytes involved in areas of pyogranulomatous inflammation. The disease may become chronic with dogs serving as carriers of the infection. Commonly, the disease follows a chronic course without full recovery and death occurring in one to two years. There is currently no effective treatment.

Anaplasmosis

There are three species of the genus ***Anaplasma***, order Rickettsiales: ***A. marginale*** and ***A. centrale*** are infectious for *cattle*; ***A. ovis*** infects *sheep and goats*. These parasites are now classified with the Rickettsiales notwithstanding that the disease produced, and its mode of transmission, have much in common with babesiosis. Division occurs by binary fission. The organisms are spherical or oval, from 0.3 to 1.0 μm in diameter, and situated in the erythrocytes (Fig. 2.96), usually near the margin (*A. marginale* and *A. ovis*).

Anaplasmosis in **cattle** is probably transmitted under field conditions by *Dermacentor* and other ticks, as well as by *Boophilus microplus*, and may be transmitted mechanically by blood-sucking flies. Mechanical transmission has resulted from the careless use of hypodermic needles during immunization procedures and bleeding, and by instruments used for dehorning, castration and ear tagging. The disease can be transmitted by blood from an infected animal, although in the chronic carrier state the level of parasitism is very low and organisms are difficult to find in the peripheral blood. Unlike *Babesia*, the intraerythrocytic antigens are relatively easily separated from red cells and form the basis of an *efficient diagnostic test based on complement fixation.*

Much of what has already been said of babesiosis is applicable to anaplasmosis. Young animals are susceptible to infection but relatively resistant to the disease; acquired infections in these are latent and endow the animals with resistance for the duration of the latent infection. *Carrier status and immunity are usual following recovery from infection.* This has epidemiological significance in that indigenous animals, wild ruminants as well as cattle, in enzootic areas acquire the infection early in life and, barring accidents, do not become diseased, but represent a source of infection for incoming animals and make eradication of the disease virtually impossible in many areas. Events that upset the balance between the organism and the host's immune system are not common, but include hemorrhage and especially other protozoan diseases that cause anemia. As in babesiosis, splenectomy is expected to lead to recrudescence. Acute disease can be regularly produced in splenectomized calves and infection appears to occur preferentially in older red cells.

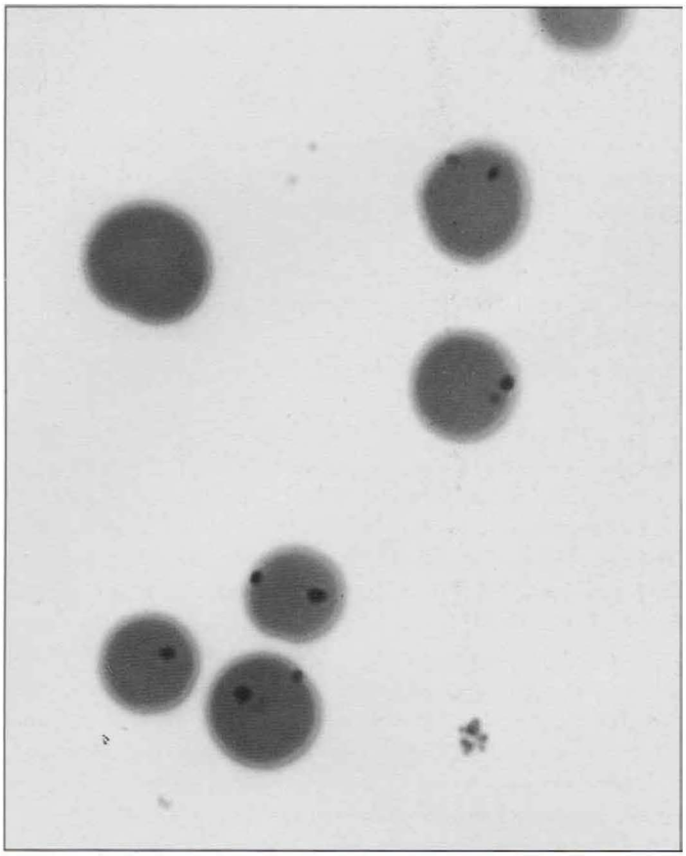

Figure 2.96 ***Anaplasma marginale*** in the peripheral blood of an ox.

The natural incubation period of anaplasmosis is 1–3 months or longer, and the disease which follows closely resembles babesiosis. One important distinction is that *hemoglobinuria does not occur in anaplasmosis* as the destruction of erythrocytes occurs intracellularly rather than intravascularly. While the mechanism of hemolysis is apparent, the means by which the phagocytic cells recognize injured or infected red cells is less clear. Serum factors sensitize erythrocytes to phagocytosis by the monocyte–macrophage system, and these opsonins increase in the circulation prior to the hemolytic crisis. Since the destruction of parasitized red cells seems to be selective, it is likely that the immune system identifies the erythrocytes containing parasites as abnormal and these are then removed by splenic and other macrophages. Spherocytosis may be prominent in the acute disease and is likely immune-mediated. Non-immune factors may be operative as well, and the decrease in plasma lipids with parasitemia may be related to the reduction in red cell numbers, and may contribute to that reduction by increasing membrane rigidity. Attempts to culture *Anaplasma* in vitro demonstrated that high magnesium levels were required to establish growth, and animals deficient in magnesium are refractory to clinical disease after experimental challenge. It appears that *Anaplasma* and other intracellular parasites require abundant ambient magnesium for their endogenous metabolism.

Animals with acute anaplasmosis have mucosal pallor, icterus, depression, and occasionally incoordination. The animals resist movement and have a rapid heart rate and increased respiratory rate. Urine may be deep brown but not red. *The clinical syndrome in cattle is usually subacute illness, with variable fever, anemia, weakness and ill-thrift.* The severity of the disease is related to the proportion of the erythrocyte mass destroyed, which may equal 70%.

At a variable period prior to the onset of clinical signs, usually 5–10 days, the *Anaplasma* organisms appear in red cells in the peripheral blood. Since the organisms continue to appear and increase in number, it is apparent that in the acute phase the parasitic multiplication proceeds more rapidly than removal of parasitized red cells in the monocyte–macrophage system. The erythrocyte count in acute disease drops to as low as 1×10^{12}/L and the hemoglobin to 30–40 g/L. The hematocrit tends to stabilize at 0.10–0.15 L/L, at which time there is rapid ongoing destruction with a competent marrow response resulting in a macrocytic, mildly hypochromic, anemia. At this time, as many as 50–60% of the red cells may be parasitized. *The strong erythroid response to anaplasmosis, which does not occur in babesiosis, is possibly due to the intracellular rather than intravascular destruction of erythrocytes*, thereby avoiding hemoglobinuria and allowing recycling of iron and proteins. Characteristically, anemia is accompanied by neutrophilic leukocytosis. Chronicity results in apparent recovery or chronic disease with debility and nonresponsive normochromic normocytic anemia in which the *Anaplasma* bodies are rarely observed in the peripheral blood. Biochemically, bilirubin, most of it unconjugated, is elevated in the acute disease.

There are no pathognomonic gross lesions of anaplasmosis. There is pallor of all tissues and mild icterus, with relatively good body condition in those animals dying acutely and cachexia in chronic cases. The lungs are pale and discolored and may have bullous emphysema if there has been severe terminal dyspnea. There are frequently ecchymotic hemorrhages on the epicardium, and the heart is flabby and dilated. The liver is anemic and icteric and the gallbladder is usually distended. The spleen is enlarged, turgid and congested in acute cases and firm, dark red and fleshy in chronic ones. The enteric tract is unremarkable and the bladder may contain deeply bilirubin-stained urine. The marrow cavity is variably expanded, depending on the stage of the disease, and may have serous atrophy with chronicity.

The tissue changes in anaplasmosis are similar to those in babesiosis, although hemosiderosis is much more marked in anaplasmosis.

Anaplasma centrale produces a natural infection of cattle, but is also employed, being a mild pathogen, as an immunizing agent against *A. marginale* in some areas of endemic infection. It usually produces a mild disease, although sometimes it can be severe, with fever and anemia but no icterus. *Anaplasma centrale*, too, causes a persistent infection.

Anaplasmosis in **sheep and goats** is caused by ***A. ovis***. Cattle are not susceptible to this parasite. On the other hand, sheep and goats develop a latent infection if inoculated with *A. marginale*. In the Mediterranean region, anaplasmosis occurs as a natural disease in sheep and goats, and is characterized by *progressive anemia and emaciation*, but with a relatively low mortality rate. In other regions in which the infection occurs, especially the United States and South Africa, the disease is milder unless the resistance of the animal is lowered by intercurrent disease, helminthiasis or inadequate nutrition. It is possible, however, that in endemic areas, ovine anaplasmosis of subclinical severity is responsible for unthriftiness of economic importance. Infected sheep develop complement-fixing antibodies.

Mycoplasma (Eperythrozoon) suis

Parasites of the genus *Mycoplasma* (family Mycoplasmataceae, class Mollicutes) are *found on the surface of erythrocytes and occasionally free in the plasma*, rather than within the cells, and thus differ from *Anaplasma*. This location of the parasites is typical of the Mycoplasmataceae (Haemobartonellae), but *Mycoplasma* (*Eperythrozoon*) *suis* is distinguished by being predominantly coccoid with multiple organisms in a single red cell and irregularly arranged over the concavity, unlike the Mycoplasmataceae which tend to have coccoid and rod-shaped forms which typically appear in chains around the red cell periphery. This distinction is somewhat artificial since the round bodies of *Mycoplasma suis* when viewed on the periphery of the red cell membrane also appear rod-like. The ring-shaped structures frequently observed in Romanovsky-stained blood films are apparently artefactual alterations.

"*Eperythrozoonosis*" is, among domestic animals, *a disease of sheep, cattle, swine, and llamas, which is characterized by anemia and icterus*. Hemoglobinuria does not occur, and in **sheep** the red cells in clinical disease are Coombs-positive, which *suggests that the anemia is due to intracellular destruction of parasitized erythrocytes*. The disease in sheep has a seasonal incidence which suggests that infection may be associated with changes in the population of *Melophagus* and other blood-sucking insects. Infection can be transmitted artificially by inoculation of blood from a carrier animal, and clinical disease is most easily established in splenectomized recipients.

Mycoplasma (Eperythrozoon) ovis is parasitic in sheep in the form of ring-shaped, bacillary or coccobacillary forms, from 0.3 to 1.0 μm in diameter, attached to the surface of erythrocytes. Organisms are found free in the plasma, probably being dislodged from the erythrocytes during preparation of the smear. These parasites can cause disease in nonsplenectomized sheep, and relapses occur following splenectomy of carrier animals. The incubation period of the disease is approximately a week, after which parasitemia develops. The parasites multiply rapidly and in the course of a week far outnumber the erythrocytes, after which their relative numbers decline as anemia develops. In severe infections, icterus occurs. The mortality rate is insignificant, but repeated relapses can occur and can be induced by intercurrent disease. The erythrocyte count may drop to 1×10^{12}/L and there is concurrent monocytosis with lymphocyte counts up to 20×10^{9}/L.

Although *M. ovis* is widespread and ordinarily insignificant as a pathogen, a 10% mortality rate has been reported in naturally infected lambs that died with profound anemia. This suggests that the infection, either alone or as a complicating disease, may be responsible for more widespread anemia and unthriftiness than is usually recognized. Summer epizootics of the disease without mortality have been observed in which anemia was profound and affected animals developed edema of the head while grazing by day.

The pathological picture in clinical or fatal ovine eperythrozoonosis is principally that of anemia and serous effusions, in some cases with modest icterus. The anemia is hemolytic and, while hemoglobinuria is of unusual occurrence, bilirubin levels may be increased several-fold. The bone marrow has subendosteal reddening and shows evidence of regeneration. The kidneys may appear normal or be the blue color associated with hemoglobin, or more usually a rusty brown color that is due to large deposits of hemosiderin iron in the proximal tubules. The spleen is enlarged and soft and the enlargement may persist for some time after clinical recovery. There is lymphoid hyperplasia in the Malpighian corpuscles which are very prominent to the naked eye.

Mycoplasma (Eperythrozoon) wenyonii is the **bovine** parasite. It is of wide geographical distribution, and in most species resembles *M. ovis* but is host specific. It is not an important infection, and its potential for causing anemia and icterus is realized only during severe intercurrent disease and after splenectomy. The disease was believed to occur in outbreak form in first-calf dairy heifers following calving, and was characterized by edema of the teats and hind limbs believed due to vasculitis. *Eperythrozoon teganodes* is also a parasite of cattle. It is not pathogenic and is distinctive in that it is confined to plasma and not attached to red cells.

Mycoplasma suis and *E. parvum* are immunologically distinct, host-specific species in **swine**. The species *E. parvum* is usually coccoid with occasional ring forms less than 0.5 μm in diameter, and is benign. The natural disease in swine, which has been known as "icteroanemia," is caused by *M. suis*, an organism usually ring-shaped and about 0.8 μm in diameter, although in acute disease it may be up to 2.5 μm in diameter. Both parasites are enzootic in South Africa and the United States and probably elsewhere. The mode of natural transmission is not known, but *an arthropod is probably implicated*; the highest incidence of infection occurs during the summer months.

The morbidity in porcine haemotrophic *Mycoplasma* infection (eperythrozoonosis) is low, and pigs that acquire the infection remain as carriers. The disease is characterized by fever and anemia, which may be profound and in cold climates there may be necrosis of extremities. Icterus occurs only in the most severe cases. The usual manifestation of porcine hemotrophic *Mycoplasma* infection is the sudden death of a few pigs in a herd. Grossly, there is icterus, watery blood, serous effusions, and enlargement of the spleen. In the examination of smears of blood, precipitated stain should not be confused with the parasites. *The disease in all species is diagnosed by finding the organism in blood in conjunction with anemia, by serology, and by PCR techniques.*

Hemotrophic *Mycoplasma* infection (hemobartonellosis)

The genus formerly known as *Haemobartonella* is closely related to the genus formerly called *Eperythrozoon* with nucleotide sequence data indicating that these organisms are part of the family Mycoplasmataceae, class Mollicutes, genus *Mycoplasma*. The organisms are attached to the surface of erythrocytes, principally as minute coccoid or bacillary forms that stain blue with Giemsa stain.

Hemotrophic mycoplasma are found in cattle, goats, cats and dogs, and in each species they are capable of causing hemolytic anemia. Geographically they are widespread, but they are unlikely to be seen unless looked for specifically. ***Mycoplasma haemocanis*** (*Haemobartonella canis*) is an opportunistic agent in **dogs** that is capable of causing hemolytic anemia in splenectomized animals, or those immunosuppressed by therapy or other disease. The sequence of the 16S ribosomal RNA gene of the dog appears to be almost completely similar to that of *M. haemofelis* permitting a PCR assay to be developed for detection of infection of hemotrophic *Mycoplasma* infection (hemobartonellosis) in both cats and dogs.

The type species is *candidatus M. haemomuris*, an ubiquitous parasite of the rat transmitted by lice. Rats harbor latent infections that can be activated by splenectomy, hemolytic poisons and intercurrent trypanosomiasis; anemia and parasitemia then develop rapidly and can be fatal. *M. haemocanis* of dogs has not been shown to have pathogenic significance, except that latent infections can be activated by splenectomy. Susceptible dogs develop acute hemolytic anemia that resembles idiopathic immune-mediated hemolytic anemia except for the presence of the organisms. ***Haemobartonella bovis*** of **cattle** is of no economic significance, but hemobartonellosis may complicate research on *Babesia* or *Anaplasma* where splenectomy has been carried out and dual infections occur. ***M. haemofelis*** is responsible for the natural disease "*feline infectious anemia*." The organism is ubiquitous, but the uncomplicated disease is unusual. Most often some other disease process has caused a reduction in resistance of the animal, and hemotrophic *Mycoplasma* is an opportunistic infection. One of the most common causes of reduced resistance in the cat is an occult lymphoma.

Hemotrophic *Mycoplasma* infection is presumably spread by fleas and other biting insects and is an important infection in **cats**. Males are at twice the risk of females of developing the clinical disease, and the risk of infection increases with age and in the spring. Direct contact is thought to be important in transmission. The anemia in cats may be Coombs-positive, and it is likely that either an antiparasitic antibody cross-reacts with normal red cell antigens, or parasitic antigen adsorbs to red cells and sensitizes them to the phagocytic system and selective removal by the spleen and marrow macrophages. The antibody in experimentally infected cats is of the cold-reacting type, which could be a factor in the development of clinical disease, since cats if permitted are regularly nocturnal. The red cell lifespan is halved in clinical disease.

The most common signs in cats are *lethargy and anorexia* for a short period of time. Often there is some other history of stress including transport or trauma resulting in sepsis. The *anemia is severe* and appears suddenly; the erythrocyte count may drop as low as 2×10^9/L with hemoglobin levels of 20–60 g/L and hematocrit of 0.06–0.23 L/L. Since the disease is characteristically secondary to other processes, the response to the anemia is highly variable, but in the rare uncomplicated case, the anemia is responsive and macrocytic and mildly hypochromic. **Diagnosis** *is dependent on identification of the rod- and ring-shaped organisms that are characteristically arranged in chains around the periphery of the erythrocyte membrane* (Fig. 2.97). The leukocyte count is

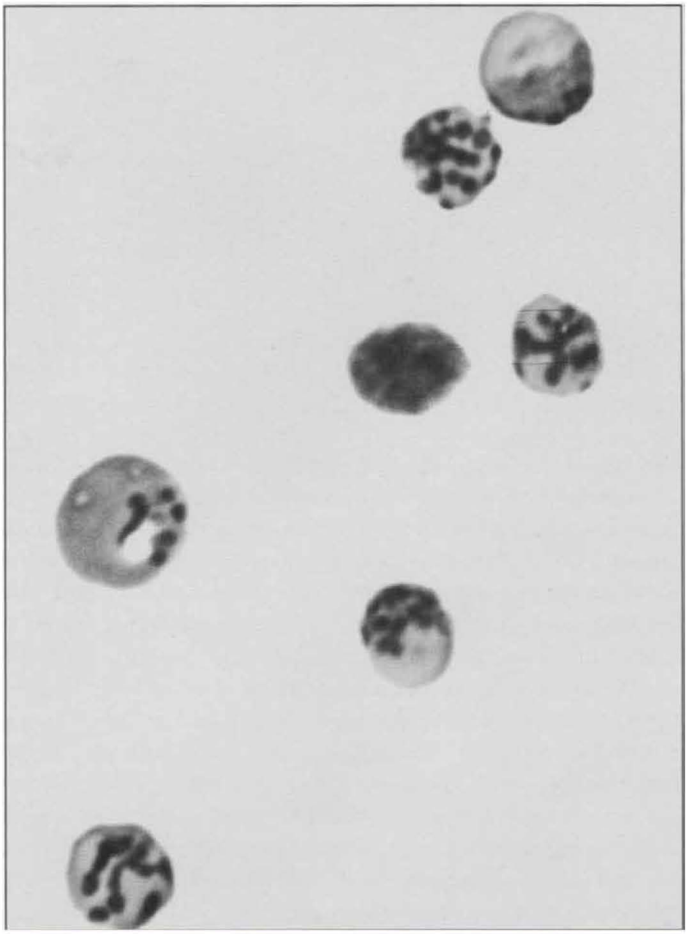

Figure 2.97 Hemotrophic *Mycoplasma haemofelis* (*Haemobartonella felis*) infection in the peripheral blood of a cat.

highly variable and there may be leukopenia due to marrow failure, or neutrophilic leukocytosis due to intercurrent sepsis, or leukocytosis of leukemia. Icterus is inconstant and generally mild. Since hemolysis is largely intracellular and not intravascular, the urine may be dark if the animal is icteric but hemoglobinuria is not a feature of the disease and the retention of iron and proteins resulting from hemolysis contributes to a degenerative response by the bone marrow in cats that are otherwise in good health.

The gross examination is dominated by pallor with or without mild icterus, and usually splenomegaly and mild generalized lymphoid hypertrophy. There is usually reddening of the femoral marrow. Histologically there is splenic sinus hyperplasia and moderate generalized follicular hyperplasia. In uncomplicated cases, the marrow is hypercellular with an erythroid shift. Not infrequently, the marrow and nodes are involved with a primary myeloproliferative or lymphoproliferative disorder that has reduced the efficiency of the monocyte–macrophage system in controlling the level of parasitism.

Ehrlichiosis

Ehrlichieae of the family Rickettsiaeceae includes three species, ***Ehrlichia canis*, *E. bovis*** and ***E. ovina***, which produce disease in dogs, cattle and sheep respectively. A similar agent has been described (***E. equi***) which causes disease in the horse. The agent infecting the horse causes cytoplasmic morulae in granulocytes, whereas that infecting the dog causes inclusions in lymphocytes and monocytes. It appears that the equine agent occasionally also causes disease in the dog. A tick-borne anemia of dogs caused by *Rickettsia canis* has been known for many years. Subsequently a disease which occurred among introduced breeds in Southeast Asia became known as **canine tropical pancytopenia**. Unlike the disease in horses, which is self-limiting, the disease in dogs is characterized by fatal or protracted course in dogs of all ages. Although included here with the infectious hemolytic diseases, *canine ehrlichiosis when fully expressed is a symptomatic aplastic pancytopenia* with identification of the leukocyte inclusions giving specificity to the disease syndrome.

Ehrlichiosis in German Shepherd **Dogs** often produces a *severe hemorrhagic syndrome* that is less common in other breeds and in experimental infections. The disease is characterized by an incubation period of 10–20 days followed by a febrile phase with variable pyrexia, anorexia, weight loss, depression and weakness. Some animals die at this acute stage, but most enter a subclinical stage that is of variable duration but generally ends in about 90 days with either epistaxis and generalized hemorrhage or pancytopenia with progressive renal failure.

Typically, the most severe hematologic changes occur in platelets which are depleted by about the tenth day, with slow recovery over the next 30 days then fall progressively over 2 months or so as marrow aplasia develops. The erythrocyte numbers parallel proportionately with the changes in thrombocytes. The leukocyte count fluctuates until 80–90 days postinfection when there is *progressive and severe panleukopenia*. The anemia is characterized by moderate anisocytosis and polychromasia, with increasing poikilocytosis and loss of polychromasia as marrow failure progresses. There is marked variation of platelet size following the first attack of thrombocytopenia, but signs of production decrease terminally. The neutrophils and lymphocytes, though markedly decreased, retain relatively normal proportions and there is usually eosinopenia and some degree of monocytosis. **Diagnosis** *is based on hematological changes and the presence of the rickettsial inclusion bodies in the cytoplasm of lymphocytes and monocytes.* Typically the morulae of *E. canis* appear rounded and one-third to one-half the diameter of a red cell, with a granular internal structure consisting of basophilic elementary bodies each 0.5–1.0 μm in diameter. In the dog, the inclusions are typically in the cytoplasm of lymphocytes and monocytes, and a predominance of inclusions in the neutrophils associated with a milder disease syndrome suggests infection with *E. equi*. There is an increased erythrocyte sedimentation rate throughout the disease, progressive reduction in serum albumin with increased gamma globulin occasionally with polyclonal gammopathy and a much prolonged bleeding time. The late onset of marrow aplasia that becomes limiting as the globulin level peaks suggests that the marrow inhibition may have an immune rather than a direct infectious origin.

Grossly, there is *emaciation with subcutaneous and interstitial edema.* A consistent finding is epistaxis with petechial hemorrhages on gingiva and conjunctiva. Large subcutaneous hemorrhages are present and there are hemorrhages on the serosa and mucosa of the intestinal tract and on the bladder mucosa. There is mesenteric lymphadenopathy with irregular enlargement of other nodes and medullary discoloration due to hemorrhage. The liver is of normal size and consistency with pallor, focal areas of hemorrhage and an anemic periacinar pattern. The spleen is of normal size, or slightly enlarged and firm with congestion and obscured splenic corpuscles. Typically hemorrhages are found on the surface of the heart and in the myocardium, and the lungs are edematous and mottled, often with focal areas of hemorrhage associated with sepsis. *The* **postmortem diagnosis** *is best made by demonstration of morulae in the cytoplasm of pulmonary macrophages obtained from direct imprints of the cut surface of fresh lung.* There are focal subcapsular hemorrhages on the kidney with mild yellowing of the medulla.

Histologically, there is lymphoplasmacytic cuffing of veins in the central nervous system and around many vessels in other organs. The liver has panlobular atrophy of cords with sinusoidal dilation, focal plasmacytic cuffing in portal areas, and ischemic periacinar degeneration. There is mild alveolar septal thickening with hypercellularity and mononuclear cuffing around pulmonary vessels. In lymph nodes, the germinal centers are depleted, the paracortical areas are atrophic and there is marked medullary cord plasmacytosis and sinus histiocytosis, often with prominent erythrophagocytosis. Glomeruli are often ringed with aggregates of lymphocytes and plasma cells, and there are focal interstitial infiltrates of mononuclear cells. The bone marrow is hyperplastic early in the disease, with few fat cells and dense cellular packing, and aplastic terminally with dilated sinusoids and foci of hemorrhagic infarction. The disease in the dog has been called *radiomimetic* because of the prominent destruction of proliferating cell populations. The prominent plasmacytosis that persists in many organs should, however, alert the diagnostician that these lesions are more inflammatory in nature than those associated with idiopathic or drug-induced marrow aplasia.

Ehrlichiosis in **horses** is similar to that in dogs but less severe. In experimental disease, the incubation period varies from 1–9 days with the onset characterized by pyrexia, depression and complete anorexia. Edema of the ventral midline, limbs and prepuce persists for 1–2 weeks. There is leukopenia, thrombocytopenia, elevated plasma bilirubin and granular inclusion bodies, which are circular and 2–3 μm in diameter, in the cytoplasm of the neutrophils. The inclusions in granulocytes parallel the febrile period and are maximal on the third to fourth day and present for up to 15 days after infection. A rise in lymphocyte numbers heralds recovery, and a rise in platelets precedes the disappearance of ventral edema.

Gross lesions include petechial hemorrhage, ecchymoses and edema, particularly in subcutaneous tissues and on the ventral abdominal wall. There is often increased fluid in serous cavities as well as icterus, emaciation, and secondary bacterial infections, including bronchopneumonia, arthritis, lymphadenitis and cellulitis. Histologically there is vasculitis in the areas of edema and hemorrhage.

Potomac horse fever caused by *Ehrlichia risticii* is described in Vol. 1, Alimentary system.

Anemias of vascular parasitism: trypanosomiasis

Trypanosomes are unicellular organisms, uniform in type but varying in morphologic details of taxonomic importance. Some species are morphologically stable while others are polymorphic, and the differentiation of species requires the familiarity of long acquaintance.

The important trypanosomes to human and animal health are *transmitted by arthropods* that carry the metacyclic stages in either the oral or anal tracts. Thus, ***Trypanosoma cruzi***, the cause of *Chagas' disease* in humans and animals in South America, is known as a *stercorarian parasite* because it is spread by passage in the feces of the reduviid insects (*Triatominae* spp.); after the insects bite (often around the mouth or eye), they defecate and the trypanosomes gain entry to the host through the bite wound, often assisted by the host scratching. The important African trypanosomiases of animals (***T. congolense***, ***T. vivax***, ***T. brucei brucei***) and of humans (*T. brucei rhodesiense* and *T. brucei gambiense*) are called *salivarian parasites* because of their transmission through the salivary glands of the tsetse fly. Other biting and sucking insects, such as tabanids, stable flies or fleas, and vampire bats may transmit trypanosomes mechanically. Infection of the definitive host, the tsetse fly, is probably lifelong. Some researchers feel that the disease resulting from fly transmission is more typical of field cases than that resulting from trypanosomes delivered by hypodermic needle.

Trypanosoma equiperdum, the cause of dourine, does not require a vector host but is transmissible by direct contact with mucous membranes. It is described in Vol. 3, Female genital system.

Not all species of *Trypanosoma* of mammals are pathogenic, and among the common nonpathogenic species of veterinary interest are ***T. melophagium***, ubiquitous in sheep and transmitted by the ked, *Melophagus ovinus*; ***T. theileri***, which is widespread in cattle and transmitted by several types of biting flies, including Tabanidae; ***T. theodori***, which occurs in goats in the Middle East, transmitted by the hippoboscid fly, *Lipoptena caprina*, and probably synonymous with *T. melophagium*; and ***T. lewisi*** of rats, which is of much interest as a convenient subject for research on the genus. ***Trypanosoma rangeli*** of South American cats, dogs and humans is also apparently nonpathogenic to the vertebrate hosts but differs from the above in that it can be transmitted by inoculation or contamination, the vector being the triatomine, *Rhodnius prolixus*. The species of trypanosomes listed above, although widespread in their hosts, are ordinarily sparse in blood and seldom observed unless specifically looked for in thick smears, after splenectomy, or by artificial culture. Occasionally, however, *T. melophagium* and *T. theileri* are found in very large numbers in the blood of cattle and sheep suffering from a primary and usually an immunosuppressive disease. It is not clear whether or not *T. theileri* may become pathogenic in the compromised host; however, its increase in number in association with other diseases suggests that it may be of secondary importance.

In endemic areas, the incidence of infection by pathogenic species varies depending on such factors as the availability of mammalian reservoirs, the density of vector tsetse flies, and the systems of husbandry adopted, but, *as a rule, domestic animals and trypanosomes cannot coexist.* Trypanosomiasis prohibits domestication of livestock in perhaps one-quarter of the total land surface of Africa. Knowledge of host–parasite relationships is not fully understood, either for the vector or the mammalian hosts. Within a species of the organism, local strains may be distinct in their basic and predominant antigens, but within the host in the course of chronic infections, a series of *genetically regulated antigenic variants* appears in succession so that the animal exhausts itself without clearing the infection. Successive waves of parasite and antibody dominance account for the characteristic recrudescences of the infection and for the known difficulty in producing an effective vaccine.

The pathogenic trypanosomes differ widely in virulence and are apparently nonpathogenic in mammalian reservoir hosts. Most of them are parasites of a variety of domestic and wild animals, in some of which they produce fulminating disease, in some chronic disease, and in others mild or unapparent infections. Strains within a species of the parasite also differ greatly in virulence, some strains producing rapidly fatal infections, some producing chronic infections with premunition, and some allowing complete recovery and acquired immunity. Much of the knowledge of trypanosomiasis has been gained by studies of *T. brucei* which conveniently infects dogs, rabbits, rats and mice and poses little problem of dissemination in developed countries where it has served as a research model. In terms of the overall problem, *T. brucei* is not nearly as important as *T. vivax* and *T. congolense* and the pathogenic trypanosomes of humans. Of the latter organisms, only *T. congolense* is studied with any frequency outside their natural habitats because the other trypanosomes are thought to constitute too great a hazard of dissemination even under conditions of laboratory restraint. Most of the research on *T. vivax* and *T. congolense* has been directed at defining the disease in British breeds of cattle. Efforts are now being made to understand the host–parasite relationship in indigenous species of animals, such as the Thomson's gazelle, wildebeest, cape buffalo and eland, which are heavily exposed and apparently carry the organisms, but rarely if ever have clinical disease.

The components of pathogenicity of trypanosomes are largely unknown. Their effects vary with their tissue tropism. The edema and interstitial reactions caused by *T. brucei* are due to the fact that this parasite resides in perivascular tissues, in contrast to the more serious pathogens of humans and animals which are obligate intravascular parasites. In many respects, bovine trypanosomiasis is similar clinically and pathogenetically to equine infectious anemia in that infection is followed by an asymptomatic period until antibody develops. There is then anemia and generalized compensatory hyperplasia of the mononuclear phagocyte system, which ultimately results in cachexia and hematopoietic and lymphoid exhaustion.

Bovine trypanosomiasis

In cattle, parasitemia regularly occurs a week after inoculation with 10^5 or more organisms that have been passed in rats and column-separated. By the second week of infection, there is a sharp drop in the red cell count and hemoglobin levels, accompanied by an erythroid shift and macrocytosis, *anemia being the predominant aspect of the disease.* There is *concurrent thrombocytopenia* of moderate degree and *hypocomplementemia*, with irregular appearance of immunoglobulin and complement on red cell membranes. Fibrinogen is reduced to about half of normal levels, and there is irregular appearance of fibrin split-products as animals go through febrile periods. Kinetically, the red cell lifespan is reduced to a half or less of normal, and iron utilization is initially rapidly increased, but slows down with cachexia and inhibition of the erythroid response due to inflammatory changes. The platelet lifespan is not shortened in infections with *Trypanosoma congolense*, although it may be with *T. vivax*. In the former, the truncation appears to be due to a proliferation of marrow megakaryocytes that are impaired in their maturation and produce fewer platelets that survive normally, thus constituting an ineffective response. The disease tends to stabilize at about 4–6 weeks in well-fed animals under laboratory conditions, and to proceed to death due to secondary causes in animals that are forced to forage for feed as well as maintain their immune defenses.

Red cells are destroyed in an "innocent bystander" fashion by adsorbing toxic and metabolic products of the trypanosomes, as well as suffering direct injury from a parasite-derived phospholipase. *There is competition between the stem cells for erythroid and myeloid proliferation in in vitro studies, which may explain the clinical finding that animals with severe anemia are more susceptible to secondary infection by bacteria and viruses.* A dilutional component to the anemia has been suggested, but no increase in blood volume has been detected. Calves infected during the first week of life have less severe hematologic disease than calves infected at 6 months or older. Some of these animals become cachectic and die, although it appears that infection at an early age results in a more tolerant host–parasite relationship that is less injurious to the host. *Trypanosoma vivax* and *T. congolense* differ in that *T. vivax* tends to circulate relatively freely and uniformly in the vascular system, and, in this respect, the level of parasitemia gives a reasonable estimate of the total parasitic burden. In contrast, *T. congolense* "homes" to the microvasculature of the brain and skeletal muscle, and the paucity of organisms in the peripheral blood makes diagnosis and estimates of total burden difficult. It appears that the tissue tropism of *T. congolense* is a response to developing immunity and is antibody-mediated. It is not known why brain and muscle are selectively parasitized, but the phenomenon may be related to trypanosomal energy requirements, since the endothelial cells in these areas tend to have more mitochondria than in other tissues.

Trypanosoma vivax is more virulent than T. congolense. Whereas both cause anemia and cachexia, infection with *T. congolense* regularly results in chronic disease, while in a high percentage of animals infected with *T. vivax* there is sudden death due to salmonellosis or other infections. Infected animals are moderately stunted in growth although this effect is less apparent on body weight than on dressed weight (the part of the carcass that is edible). This disparity is due to the fact that infected animals pool fluid in the intestinal tract and become pot-bellied while failing to deposit muscle and fat. When viewed from behind, infected animals have poorly covered bony prominences, poor "spring of rib," and a deep and pendulous abdomen. The skin is scurfy and rough, particularly about the head, ears and hind quarters. There is chronic low-grade pyrexia with intermittent temperature increases, and periodic watery diarrhea with passage of poorly digested ingesta of normal color. There is irregular oculonasal discharge, but no loss of appetite and the animals continue to eat. There is mild mucosal pallor without petechial hemorrhages, and the urine may be dark but never blood-tinged. The heart and respiratory rates are not remarkably altered under laboratory conditions but are increased in nonspecific response to anemia under field conditions, and animals may show open-mouth breathing on forced exercise. In the absence of secondary infection, there is little or no depression or abnormal behavior despite high levels of cerebral parasitism (Fig. 2.98A).

Anemia is of moderate degree, generally between 50 and 80 g/L, which is initially macrocytic and normochromic, and later becomes normochromic, normocytic and poorly responsive (Fig. 2.98B). In the well-developed disease, there are always some hypochromic red cells and at least mild poikilocytosis. In the early stages of infection, the radioiron uptake time is reduced from a normal of about 3 hours to about half that figure but in chronic disease is only mildly reduced. There is increased osmotic fragility of red cells without spherocytosis. The platelets are 100–200 × 10^9/L and are often lower during intercurrent infection. The leukocyte count is reduced to about half of normal (5–6 × 10^9/L) due to an absolute reduction in both neutrophils and lymphocytes. Changes are less severe in neonatally infected animals. Biochemical changes consist of a reduction in total protein, largely due to reduced albumin, but there are no consistent changes in transaminases or bilirubin. There is a consistent reduction in total serum lipids, cholesterol and triglyceride, and erythrocyte phospholipid levels are consistently elevated which may indicate that there is an acquired injury to red cell membranes which contributes to shortened lifespan. Aspirated marrow is hypercellular with an erythroid shift that drops the myeloid:erythroid ratio to 0.4 or lower in animals infected with *T. congolense*. There is a less marked erythroid response in *T. vivax* infection.

There are no pathognomonic **gross lesions** *of trypanosomiasis*. Chronically affected animals are cachectic and have a rough haircoat, and there is increased clear fluid in body cavities. There is generalized lymph node enlargement to 2–4 times normal, and the hemal nodes become prominent in subcutaneous areas and in association with the para-aortic and pelvic nodes where they may reach 1 cm in diameter or larger. The lungs are heavy and have increased density on palpation, and may show intercurrent cranioventral bronchopneumonia. The heart is generally flabby, with serous atrophy of pericardial fat, and there may be white foci 1–2 mm in diameter on the epicardium and on the cut surface. The liver and kidneys are symmetrically enlarged and constitute a greater than normal percentage of body weight. The liver is unusually firm and not easily penetrated by digital pressure, and there is a fine lobular pattern visible through the capsule and on cut surface. Renal medullary fat has serous atrophy. There are fine focal, raised, reddened areas 1–2 mm in diameter throughout both layers of the omentum. The enteric tract is unremarkable, except that the small intestine is atonic and contains an excessive amount of normal-appearing fluid content. *The most remarkable*

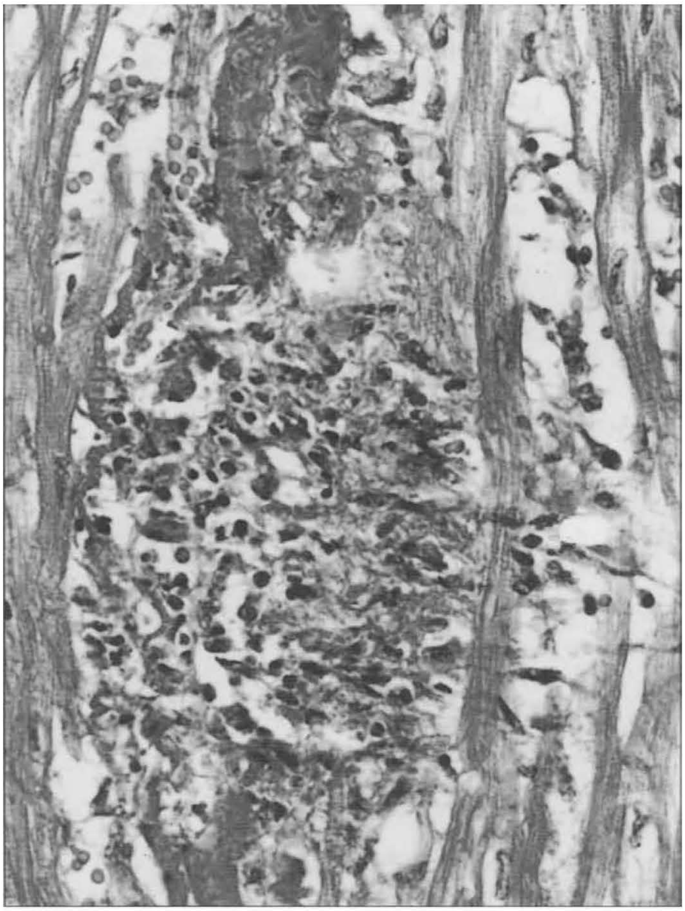

Figure 2.99 Trypanosomiasis in an ox. Lysis of myocardial fibers and myocarditis.

changes occur in lymph nodes, which have generalized medullary pigmentation, *and in bone marrow* where there is a regular increase in hematopoietic areas, which may occupy all of the cancellous and diaphyseal fatty areas in animals which have been infected 6 months or more. The spleen is uniformly enlarged and bulges, but does not ooze blood, on cut surface. The Malpighian corpuscles are generally visible grossly.

Microscopically, there is a generalized increase in septal width in the *lungs* and accumulation of intravascular hemosiderin-bearing macrophages. There are multifocal areas of fiber atrophy with sclerosis and lymphoplasmacytic proliferation in the *myocardium* (Fig. 2.99), most prominently in those animals which have succumbed to the disease. The *bone marrow* goes through a cycle of changes similar to those in equine infectious anemia. There is early conversion of fatty to hematopoietic marrow with high cell density, erythroid shift and plasmacytosis, followed by a reduction in cellular packing and dilation of sinusoids, and ultimately by reduction in hematopoiesis and serous atrophy of the remaining tissue. The rubricytes are increased in number and are relatively synchronous in maturation with numerous mature cells, suggesting late asynchrony associated with poor availability of iron. There is a variable degree of hemosiderosis, depending on the duration of the disease, and erythrophagocytosis may be observed in the marrow. Marrow granulocyte reserves are reduced, and, as a result, there is mild early asynchrony, although it is likely that with the expanded volume of hematopoeitic marrow there is a normal volume of granulopoietic tissue. Megakaryocytes are increased in number to about twice the normal level, and the nuclei are increased in diameter, but the cytoplasmic volume is reduced, indicating ineffective thrombopoiesis. There is a mild generalized increase in endothelial and true reticular cells in bone marrow, but myelofibrosis is not severe. Trypanosomes may be found free and phagocytosed in small vessels throughout the body, but are most commonly observed in the liver and cerebral cortex. *Hepatic changes* are constant, and consist of atrophy of hepatocellular cords with sinusoidal dilation and periportal lymphoplasmacytic proliferation. There is increased interstitial stroma, without change in lobular organization, and generalized Kupffer cell hyperplasia.

Changes in the lymphoid tissue are remarkable and constant in all areas of the body. There is first follicular hyperplasia (Fig. 2.100A), with a competent response and the formation of large and densely cellular germinal centers. These changes are accompanied by variable paracortical hyperplasia, and the paracortex has a moth-eaten appearance due to the many large lymphoblasts and tingible body macrophages. At this time, the lymph nodes are physically enlarged and there is thinning of the capsules with focal colonization of perinodal fat and a histologically compressed peripheral sinus. In chronic disease, the nodes remain enlarged but this is due, at least in part, to a marked increase in capsular and intranodal stroma with numerous collagenous septa extending from the medulla to the capsule. The medullary follicles remain, but their cellularity is reduced and there is marked atrophy of paracortical areas. Concurrently there is sinus histiocytosis and at least some degree of hemosiderosis without medullary cord hyperplasia. *The changes are thus those of continuing stimulation with an initial competent response followed by hyperplasia, then atrophy and sclerosis* (Fig. 2.100B).

Concurrent with the changes in lymph nodes, there is *remarkable atrophy of the thymus*, with the reduction most prominently affecting cortical regions. With the loss of cortical volume, there is a reduction in cell density and an increase in size of nuclei in cortical thymocytes. The *splenic lymphoid changes* reflect those in other areas of the body, with atrophy of periarteriolar cuffs and the formation of large hypocellular follicles, occasionally with "target" ringing of mantle cell and marginal zone layers. The number of follicles is not increased. The most marked splenic change is sinus hyperplasia characterized by a marked increase in fixed cells in the Billroth cord areas, which contain within their interstices many macrophages and plasma cells, with increased hemosiderin and an irregular appearance of extramedullary thrombopoiesis and erythropoiesis. *Renal changes* consist of a moderate generalized increase in interstitial connective tissue with mild epithelial atrophy and the appearance of large lymphoid cuffs around arterioles at the corticomedullary junction. Glomeruli are regularly increased in diameter and in cellularity and occasionally contain hemosiderin-laden macrophages. There are focal adhesions between the visceral and parietal layers of Bowman's capsule, and a mild epithelioid appearance to the central areas of the tuft. The nuclei of the juxtaglomerular cells are unusually prominent, and there is mild pigmentation by both iron and bilirubin in the proximal epithelium. The overall changes in glomeruli are compatible with *membranoproliferative glomerulonephritis*.

Subtle changes are consistently present in *skeletal musculature* and consist of an overall hypercellularity with a mild reduction in fiber diameter and increased perivascular lymphocytes. The

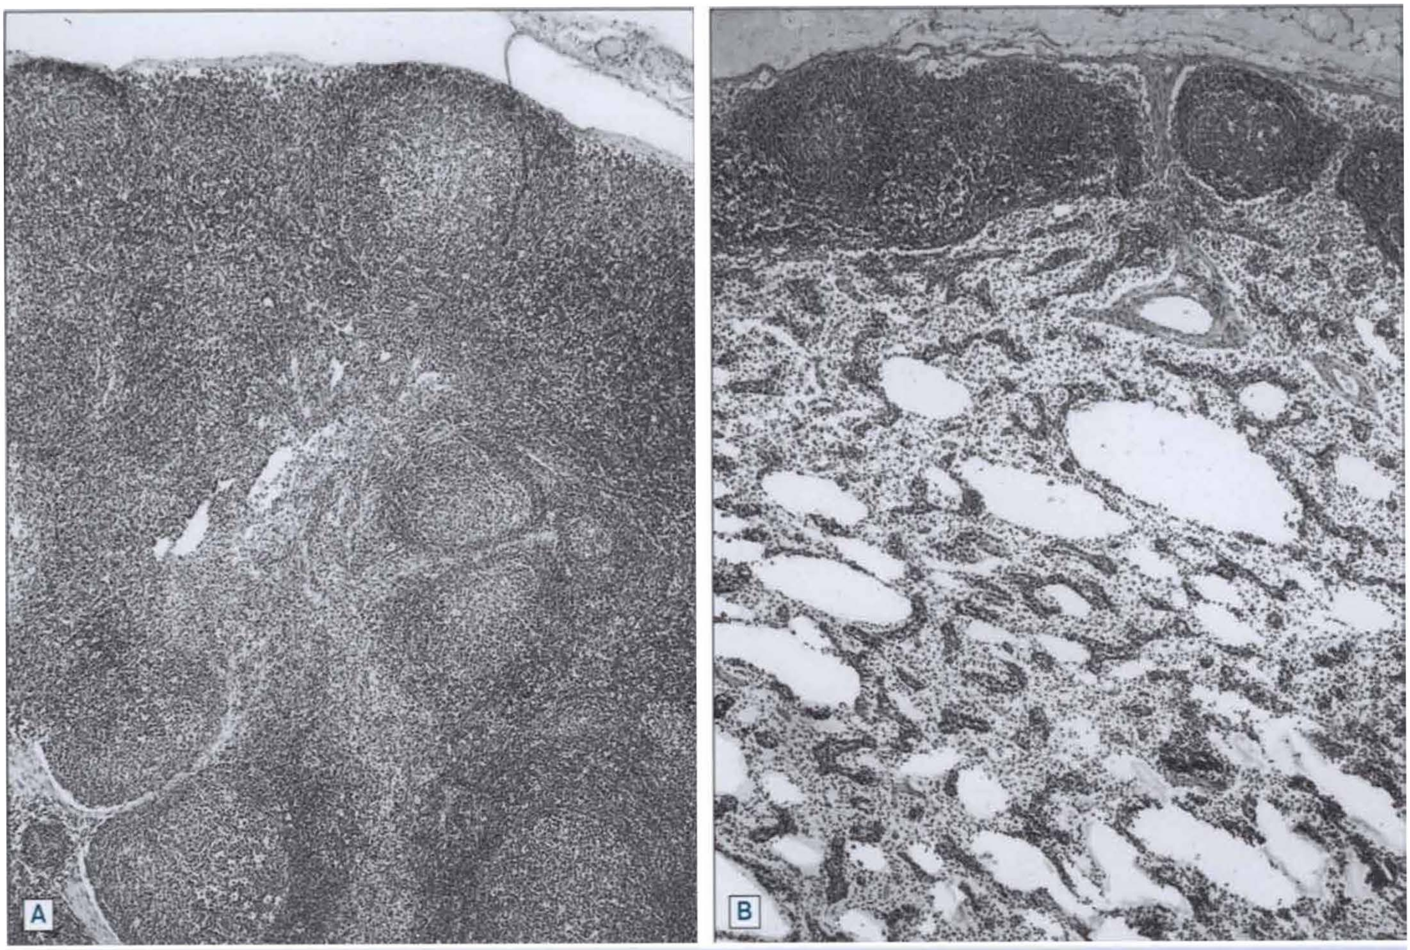

Figure 2.100 Trypanosomiasis in lymph nodes from cattle. **A.** Follicular hyperplasia. **B.** Paracortical atrophy, medullary sinus hyperplasia and histiocytosis, dilation of lymphatics in chronic disease.

reddened foci in the *omentum* consist of focal venous ectasia with mild interstitial sclerosis and perivascular lymphoplasmacytic reaction.

Trypanosomiasis in other species

Trypanosoma brucei rhodesiense and *T. b. gambiense* are human pathogens causing African sleeping sickness and are not important in domestic animals, although *T. gambiense* has produced meningoencephalitis in experimental goats and cats. These trypanosomes are morphologically indistinguishable from each other and from *T. brucei*, from which they are presumed to have evolved.

Trypanosoma brucei brucei is a cause of **nagana** in most domestic species in Africa, but in humans is refractory. Transmission is by *Glossina* spp. or mechanical. Equidae, small ruminants, camels and dogs are very susceptible, the disease is more chronic in cattle, and pigs may recover. Incoordination and spinal paralysis are reported in horses and dogs. Dogs may also develop parasitism and inflammation of the anterior segments of the eye. The neurological signs are undoubtedly due to invasion of cerebrospinal fluid and to inflammation of meninges, brain and cord. Diagnosis depends on demonstration of the organism in blood in acute or relapsing febrile cases, or otherwise in lymph nodes by direct smear, inoculation into the very susceptible laboratory mouse, or cultivation.

Trypanosoma evansi was originally shown to be the cause of **surra** in horses and camels, but it is pathogenic for most domestic species and distributed in North Africa, Asia, and Central and South America. Transmission is mechanical, chiefly by Tabanidae, but also by other blood-sucking flies, and apparently by vampire bats in the Americas. The disease in horses and dogs is severe, and probably uniformly fatal in the absence of adequate treatment. Cattle are mildly affected and act as reservoirs, although acute disease may occur in susceptible cattle introduced to endemic areas.

Trypanosoma equinum occurs in South America as the cause of **mal de caderas** of horses, a disease that resembles surra. The parasite is transmitted mechanically by tabanids. It is probably a stable variant of *T. evansi*.

Trypanosoma suis is a West African species transmitted by tsetse flies. It produces a nagana-like disease in pigs but is apparently nonpathogenic for other domestic animals.

Trypanosoma simiae was originally isolated from African monkeys. Although its pathogenicity for pigs is unpredictable, it is ordinarily highly virulent and causes death in a few days. Pathogenicity for other domestic species is insignificant. Transmission is cyclical in tsetse flies. Trypanosomes of the species *T. congolense*, *T. dimorphon*, *T. vivax*, and *T. uniforme* are causes of nagana in Africa. Most domestic species are susceptible to infection, although dogs are resistant to *T. vivax*. There is considerable variation in the pathogenicity of different strains, especially of *T. congolense*.

Trypanosoma cruzi is the cause of American trypanosomiasis (**Chagas' disease**), which is an uncommon illness of children, although infection of human adults and animals is apparently common. The reservoir hosts are chiefly wild species, but cats, dogs and pigs can be infected and act as reservoirs. Sheep and goats are susceptible to experimental infections. This trypanosome is of zoological interest because, both in the tissues of the vertebrate host and in the alimentary canal of the vector, it forms developmental phases resembling the other genera *Leptomonas, Crithidia*, and *Leishmania* of the Trypanosomidae.

Whereas some of the manifestations of *T. cruzi* infection may be attributable to parasitemia with the trypanosomal form, the disease is characterized by invasion of mesodermal tissues, and the growth therein of the leishmanial forms of the organism, which show a *preference for cardiac and skeletal muscle*. It has been suggested that, since the cysts are focal and the interstitial reaction may be widespread and diffuse, there may be an autoimmune component to the myocarditis associated with release of fiber proteins associated with parasitic injury.

Hemolysis due to physical and chemical agents

Heinz-body hemolytic anemia

Hemolytic anemia due to denaturation of globin occurs in cattle, horses and dogs fed *onions*, and in cattle and sheep fed *rape or kale*. The same mechanism is operative in the anemia of horses with hemolysis after receiving *phenothiazine*, and in cats given *methylene blue* as a urine acidifier. Heinz-body anemia also occurs in horses that eat the leaves of *red (swamp) maple* (*Acer rubrum*). Heinz-body hemolytic anemia occurs as an *inherited deficiency of the glucose-6-phosphate dehydrogenase* (G-6-PD) enzyme in humans, and also rarely in sheep and dogs. In inherited deficiency, the level of G-6-PD may be 70–75% of normal, and low levels are associated with hemolysis on exposure to oxidants that may be dietary, such as *fava beans* or pharmaceuticals, such as the *primaquine* antimalarials. Cats appear particularly susceptible to Heinz-body formation, and Heinz bodies may be found in as many as 5% of apparently normal cats. The inclusions in cats were formerly called *erythrocyte refractile bodies*. Unstable hemoglobins resulting from inherited substitutions in the amino acids of the globin chains may have reduced avidity for the heme molecule, the loss of which is followed by globin denaturation and Heinz body formation. The latter pathogenesis is not of importance in domestic animals. Globin injury is involved to some degree in *postparturient hemoglobinuria in cattle* and in *chronic copper poisoning* in sheep. Heinz bodies or *intraerythrocytic globin precipitates*, when stained supravitally, appear as dense round structures 1–2 μm in diameter at the margin of the red cell.

Oxidizing agents which deplete red cell G-6-PD, the rate-limiting enzyme of the pentose shunt, diminish the protective biological antioxidant glutathione. Reduced glutathione is a hydrogen donor in the process catalyzed by glutathione peroxidase, a selenium-containing enzyme. *Selenium deficiency* alone may result in Heinz-body anemia. Failure to reduce oxidized glutathione results in formation of mixed disulfide linkages between glutathione and globin chains. These linked proteins, having lost the elasticity essential to the molecular shape change associated with reversible oxygenation, precipitate within the cell and aggregate to form Heinz bodies. *If the oxidizing attack is mild, the Heinz bodies are selectively removed by splenic phagocytes*, and the red cells return to the circulation with a slightly reduced volume. *If the reaction is severe, the Heinz bodies appear free in plasma* (Fig. 2.101), complicate platelet counts, and are removed by the spleen and liver. Hemoglobinemia, hemoglobinuria, and icterus occur in severe cases. Since young red cells have a higher G-6-PD enzyme level, *Heinz-body anemia is usually self-limiting and nonfatal*, as new red cells added to the circulation are more resistant to episodic toxic exposure. If the exposure to the toxic compound is dietary or continuous, the anemia may be progressive. The anemia may be moderate to severe, normochromic and moderately macrocytic, and responsive, with Heinz bodies free and projecting from the outer edge of red cells. Heinz bodies are unstained with Wright's stain, or stain similarly to hemoglobin. With supravital stains, such as new methylene blue, they are dark blue against red cells that are unstained. The level of red cell G-6-PD will be less than 25% of normal.

Copper poisoning

Copper poisoning may be acute or chronic, but the syndromes differ markedly, and the terms are misleading because *chronic copper poisoning is an acute and catastrophic syndrome*. The terms acute and chronic as applied to copper poisoning are not illogical since acute poisoning follows more or less immediately the acquisition of an overdose, whereas the chronic form represents cumulative poisoning which may, sooner or later, result in acute disease. *Chronic copper poisoning is a sporadic and enzootic disease of sheep, and a sporadic disease of cattle and swine.*

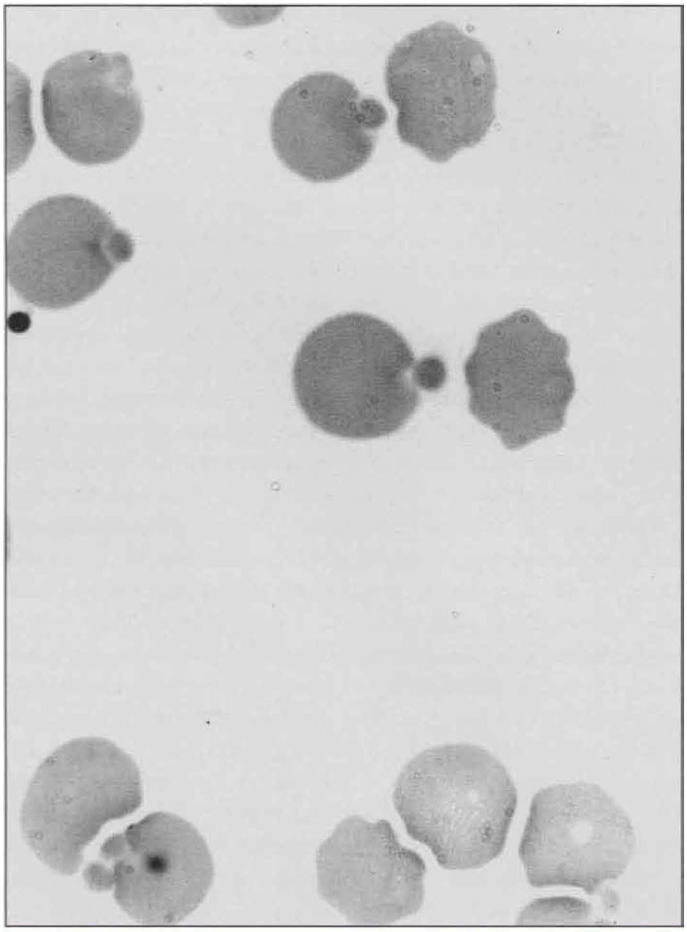

Figure 2.101 Phenothiazine toxicity. Heinz bodies in peripheral blood of a horse. Aggregates of denatured globin budding from red cell membranes.

Acute copper poisoning is characterized by *gastroenteritis* caused directly by the irritative effects of copper salts. The sole distinguishing feature is the passage of *bright blue-green fluid feces* accompanied by severe shock and rapid prostration. Grossly, there is *hemorrhagic and edematous abomasitis*. The copper salts are obtained by ingestion or by accidental therapeutic, chiefly anthelmintic, overdosage. The toxic dose of $CuSO_4$ for a sheep is ~20 mg/kg of live weight. Oral treatment at an appropriate level may precipitate the chronic syndrome if tissue stores of copper are high.

Chronic copper poisoning as defined here is an *acute episode of intravascular hemolysis caused by the release from hepatic storage into the blood of excessive amounts of copper*, until then stored by labile binding. The accumulation and release of copper may occur in a variety of ways, some being quite circuitous (see Vol. 2, Liver and biliary system).

Copper is an hepatotoxin, and during the period of copper accumulation there are progressive histologic, histochemical and ultrastructural changes in the liver, associated with an increase of hepatic enzymes in plasma. *The hemolytic crisis may be precipitated by stress; hepatocellular overload and lysosomal injury release toxic levels of copper into the blood.* As the capacity of carrier proteins is exceeded, excess copper rapidly enters the red cells, presumably exhausts the red cells' antioxidant system, and results in the denaturation of globin and the formation of Heinz bodies. Hemolysis lasts 2–6 days, with Heinz-body formation, hemoglobinemia and hemoglobinuria. If the animal does not die acutely, the new young red cells produced have higher enzyme levels and are more resistant to lysis than are older cells.

Coombs-positive red cells occur in sheep in the recovery stage of chronic copper poisoning. This is presumably the result of autosensitization by circulating red cell stroma and not a prior pathogenetic mechanism.

Hematologically, the hemolytic phase is characterized by a sharp increase in hematocrit to 0.60 L/L or higher in the hours preceding the onset of the hemolytic crisis, and is likely due to *dehydration*. The hemoglobin drops from a normal level of 100–110 g/L to 40–50 g/L in survivors. Since both free and cellular hemoglobin are measured by standard techniques, the massive hemoglobinemia will mask the actual amount of hemoglobin contained within intact erythrocytes. The erythrocyte count drops sharply to 2×10^{12}/L or less. There is neutrophilic leukocytosis during and following hemolysis. Morphologically, during hemolysis there is marked anisocytosis and poikilocytosis with moderate polychromasia and the appearance of Howell-Jolly bodies and rubricytes, with Heinz bodies budding from up to 15% of erythrocytes. *Reticulocytosis heralds the onset of recovery*. Serum bilirubin rises after the appearance of hemoglobinuria. Blood urea rises in parallel with bilirubin and then drops sharply in survivors, but does not return to normal. Levels of ceruloplasmin rise to 2–3 times normal during the hemolytic crisis, while red cell copper increases 15–20 times, plasma copper increases 3–6 times, and whole blood copper increases up to 10 times normal levels.

Cold hemoglobinuria

Hemoglobinuria after the ingestion of cold water occurs in calves and occasionally older cattle, principally as a disease of winter, and is seen in cattle which are housed in warm barns and given water at near-freezing temperature. It occurs also, but rarely, in calves which are maintained in hot barns in the summertime, and it can be readily reproduced by forcing them to drink cold water. The temperature of the water relative to the animals' environmental temperature is important since the disease rarely, if ever, occurs in cattle kept in cooler, open barns. *Hemolysis occurs most often in penned animals which are watered at irregular intervals and which therefore tend to drink large volumes when allowed access.* The disease is common although *rarely fatal.* The clinical signs consist of dyspnea with open-mouth breathing, followed by the passage of port-wine colored urine within 1–2 hours of drinking. Hemoglobinuria associated with the ingestion of cold water has also been observed in dogs and swine, but apparently is rare. The mechanism for the hemolysis in calves has been suggested to be osmotic lysis of red cells caused by the rapid ingestion of water, but this explanation is unconvincing since the osmotic effects of water should not be temperature dependent. The activity of cold agglutinins has been suggested as a cause of the hemolysis, but this seems even more unlikely since they are probably not widespread in cattle. The sporadic and ephemeral nature of the disease has not been conducive to study of the cause of the hemolysis.

Postparturient hemoglobinuria

The syndrome of postparturient hemoglobinuria occurs primarily in dairy cows and typically is seen within 2–6 weeks after parturition. The earlier the onset the more severe the disease. The name, however, is too restrictive because *the same disease, although slower in development, occurs before parturition, at other periods of the lactational cycle, and in males.* Most cases are, however, postparturient and severe. In North America, postparturient hemoglobinuria is a sporadic disease of multiparous high-producing dairy cattle, and is characterized by *intravascular hemolysis, hemoglobinuria, and anemia.* The disease is usually seen between the third and sixth lactation and tends to occur in the winter, particularly when preceded by a dry growing season. In New Zealand, the disease occurs in mid and late summer and in younger cows in first and second lactations. Like chronic copper poisoning of sheep, the disease may be precipitated by stress such as forced exercise.

The pathogenesis of erythrocyte destruction leading to intravascular hemolysis is not clear and may vary with geographic distribution. It is generally accepted, however, that *the disease is associated with severe hypophosphatemia*, and it has been produced when diets deficient in phosphorus are fed for long periods. Severe hypophosphatemia of the order observed with postparturient hemolysis is associated with depletion of red cell ATP and loss of membrane plasticity with formation of spherocytes and rigid, easily fragmented red cells. The latter syndrome is often recognized in humans on hyperalimentation or dialysis, and has been reproduced in dogs. In grazing cattle, an inverse relationship between the incidence of the disease and the fertility of the soil has been observed, and there is a direct relationship to use of beet pulp and cruciferous pastures as forage. In New Zealand, *copper deficiency* has been suggested as a possible factor in postparturient hemoglobinuria, possibly associated with the use of fertilizers containing molybdenum. Since copper is essential for the red cell superoxide dismutase antioxidant system, it is possible that cruciferous forage and copper deficiency work together to produce a Heinz-body type of hemolysis. While the dietary associations are varied, hypophosphatemia appears to be a significant part of the overall disease. The phosphorus levels in the blood, despite hemolysis, range from 0.45–0.59 mmol/L.

The signs of phosphorus deficiency which may accompany hemolytic anemia include *severe and shifting lameness, allotriophagia, decreased productivity, lordosis, and retention of long hair.* The animals may be emaciated. Usually there are no accompanying signs of phosphorus deficiency, however, and the disease occurs in well-fleshed animals at the peak of their productivity.

It is usual for hemoglobinuria to draw attention to the disease. Hemoglobinuria may not occur in all cases, and weakness with increased respiratory rates and mucosal pallor may be the initiating sign. The disease may progress to death in a day or in 4–5 days. The early mucosal pallor is, with time, replaced by jaundice, and milk production is sharply reduced and the secretion discolored with bile pigment.

Anemia is frequently severe, with erythrocyte counts dropping to 1×10^{12}/L or less. It is moderately responsive in animals which survive, and there is concurrent neutrophilic leukocytosis. Biochemical changes consist of hypophosphatemia and hyperbilirubinemia. The urine may contain high levels of hemoglobin that rapidly turns dark on conversion to methemoglobin with standing. There is concurrent albuminuria, characteristic of intravascular hemolysis and hemoglobinuric nephrosis, and the urine forms a stable froth on passage.

Grossly, *the principal changes are icterus, pallor, thin watery blood which is dark, and red-to-brown discoloration of the urine.* There is fluid accumulation in the serous cavities, and subcutaneous and interfascial edema. There are extensive ecchymotic hemorrhages on the cardiac surfaces, and the liver is slightly enlarged, turgid and pale with an ischemic nutmeg appearance caused by periacinar necrosis. The gallbladder is distended. The spleen is enlarged and congested in peracute cases but, in those that survive several days, it is of normal appearance. In spite of the frequent association of hemoglobinuria and death, it is unusual to find the blue-black pigmentation of kidneys characteristic of chronic copper poisoning in sheep. Icterus is often severe with canalicular cholestasis, which indicates extensive intracellular as well as intravascular hemolysis where the pigment is not lost in urine. Kidneys may be swollen, pale and soft, without hemoglobin pigmentation. The lungs are edematous and there is frequently interstitial and subcutaneous emphysema associated with terminal dyspnea.

Microscopic changes *are characteristic of intravascular and, to a lesser extent, intracellular hemolysis, and are not indicative of the cause.* There is panlobular hepatocellular swelling with ischemic periacinar coagulation necrosis. If animals survive for some hours with profound anemia, the margin of necrotic tissues within the functional lobules becomes progressively sharpened with a zone of fatty vacuolation separating viable and necrotic hepatocytes. Hypertrophy of Kupffer cells with hemosiderin accumulation becomes distinct in animals that survive for 3–4 days. There is congestion of splenic sinuses. Renal lesions are variable, usually with fatty degeneration of tubular epithelium, bile and hemosiderin pigmentation, and hyaline, granular and hemoglobin casts in the lower nephron. In more severely affected kidneys, there is patchy necrosis of the proximal tubular epithelium with desquamation, and interstitial edema.

Postparturient hemoglobinuria closely resembles the syndrome of hemolytic anemia produced in animals that are fed plants of *Brassica* spp. or *onions*. An unusual amino acid, S-methyl cysteine sulfoxide, is produced in these plants and is degraded in the rumen or colon to dimethyl disulfide. The sulfide causes the production of Heinz bodies in the red cells of all exposed species, but the resulting hemolytic anemia is most important in pregnant or parturient animals, especially those which are exposed to diets deficient in phosphorus. An intake by cattle of 10 g/100 kg body weight per day of the amino acid will produce low-grade anemia, and an intake of 15 g/100 kg body weight per day can produce severe fatal anemia.

Hemolytic anemia due to mechanical damage to red cells

Microangiopathic or fragmentation hemolysis *occurs as a consequence of disseminated intravascular coagulation* and, like that syndrome, is secondary to primary disease involving microvascular injury. **Microangiopathic hemolytic anemia** (MHA) is characterized by severe poikilocytosis with intravascular hemolysis and hemoglobinuria (Fig. 2.102).

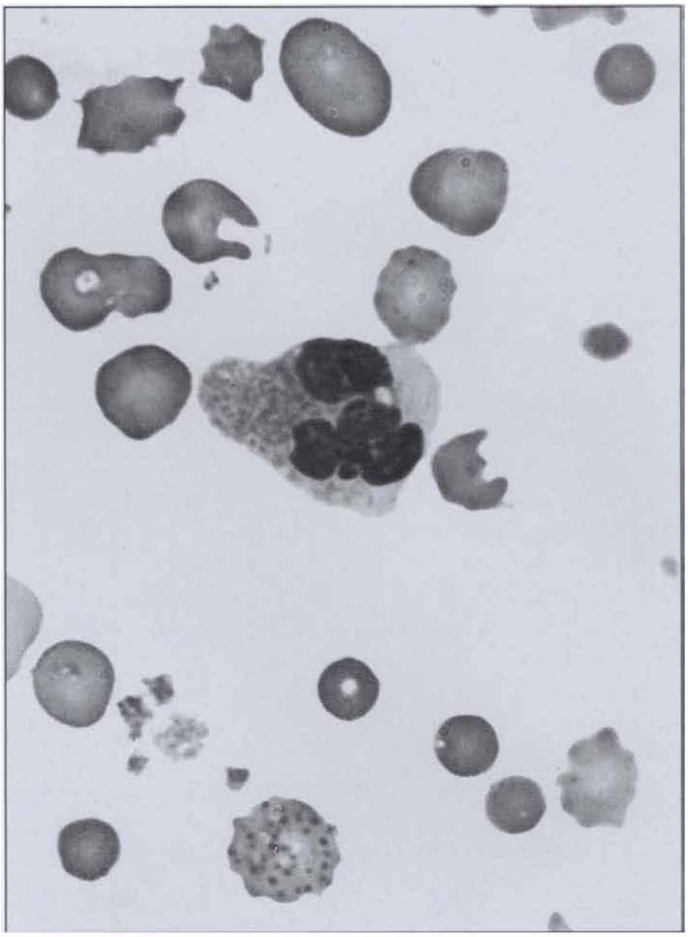

Figure 2.102 Microangiopathic hemolytic anemia, peripheral blood, in a calf with hemolytic-uremic syndrome. Nonresponsive anemia, microcytosis, poikilocytosis and basophilic stippling.

The basic mechanism underlying fragmentation hemolysis is the application of high shear forces to red cells moving at high velocity across a sharp drop in pressure. These conditions are most often met when *erythrocytes moving rapidly in small arterioles impinge on intraluminal fibrin strands and are fragmented*, usually with a characteristic "bite" out of the cell periphery. Thus, inflammatory lesions of capillaries and veins do not result in significant fragmentation, since the rate of flow in these vessels is too low. Fragmentation may occur as a result of arteriovenous fistulae when there is high turbulence and flow rates across a small orifice.

Fragmentation anemia occurs most often in association with infectious diseases which cause severe endothelial injury. Mild fragmentation occurs in animals with *salmonellosis* and with *fibrinous pneumonia*, but in these cases the degree of hemolysis is usually insignificant compared to the injury to the primary organ. Mild fragmentation also occurs in horses with colic in association with *verminous arteritis*. Since alterations in red cell shape in the horse are relatively rare, their presence in stained blood films is significant. Fragmentation anemia is seen in association with *somatic migration of parasites* and is prominent in animals affected by tissue phases of *Strongyloides stercoralis* and in dogs with *dirofilariasis*. Because of high renal blood flow and juxtaglomerular flow regulation, vascular lesions are prone to develop in the kidney, and fragmentation may occur there in association with a variety of renal diseases. Mild fragmentation occurs in association with *vegetative endocarditis*, particularly of the aortic and pulmonary valves, but is rarely seen in septal defects where the openings are usually large and the flow rate relatively low. In contrast, fragmentation occurs regularly in *patent ductus arteriosus* where the conduit is small and the pressure drop is high. Fragmentation of erythrocytes occurs during the development of *vitamin E/selenium deficiency of swine*, whereas marked poikilocytosis is seen in iron-deficiency anemia, and in lambs and, to a lesser extent, calves with nutritional myopathy. Presumably in the latter diseases, the hemolysis is largely due to intrinsic defects in erythrocyte membranes rather than to primary endothelial injury. Mild fragmentation occurs in *thrombocytopenia* in all species, presumably as a result of widespread endothelial deterioration, some of which involves small arteries. *Hemangiomas* cause focal coagulation and fragmentation in humans and animals, but the rate of destruction seldom results in anemia or red urine. Fragmentation of red cells may be significant in *widely metastatic carcinoma* and may be the presenting sign or may herald an accelerated phase of the disease in animals being treated. Hemoglobinuria occurs in event horses on *protracted exercise*, often in association with exertional myopathy and with a pathogenesis probably similar to that of "march hemoglobinuria" of humans. Markedly distorted red cells may be seen in hepatic failure in association with *severe anemia*. The major defect appears to be intrinsic to the red cell membrane as a result of low plasma lipid ("Zieve's syndrome"). The abnormal shapes and loss of membrane plasticity predispose these cells to fragmentation despite only minor vascular injury.

Hemolytic anemia due to splenic hyperfunction

Increased erythrophagocytic activity results from any condition that causes enlargement of the spleen (**splenomegaly**). Splenomegaly may be the result of an immunoproliferative reaction due to infection, autoimmune disease, myeloid metaplasia, neoplasia or simply chronic congestion. Portal hypertension can cause congestive splenomegaly, but does so very rarely in animals. The stretching of the splenic reticulum in an enlarged spleen, regardless of the cause, is a specific stimulus to stromal hyperplasia. This increased sinus volume rapidly becomes populated with macrophages and, therefore, *splenic enlargement by definition leads to increased phagocytic function*. In the short term, conditions which cause splenomegaly with stretching, but not proliferation of the sinus stroma, are reversible. Blood pooled in an enlarged spleen is subjected to areas of slow flow and is biochemically characterized by low glucose, cholesterol and pH, which collectively cause premature aging and subsequent spherocytosis of erythrocytes, rendering them subject to phagocytic destruction. *The clinical disease resulting from hypersplenism may, therefore, be thrombocytopenic purpura, hemolytic anemia, neutropenia, or any combination of these*. If immune factors are added to the congestive pathogenesis, the disease is more severe.

Specific examples of conditions involving splenomegaly and hypersplenism include most if not all of the *infectious anemias*, but particularly those caused by protozoan agents such as *malaria, leishmaniasis and trypanosomiasis*. Generalized splenomegaly occurs in storage diseases in all species, but the effects in the nervous system and other organs are usually of more clinical importance than an enlarged and hyperfunctional spleen. Salers calves with β-mannosidosis have splenic involvement that is incidental to the impairment of the nervous system. Occasionally localized disease in the spleen will cause clinical anemia, as in *plasmacytoma of the spleen in the dog*. Occasionally, a focal area of splenic enlargement, such as might occur with *nodular hyperplasia*, or *marginal zone or mantle cell lymphoma*, will result in cellular deficits in the peripheral blood. Focal splenic lesions tend not to cause anemia but may cause thrombocytopenia due to slow and stagnant flow in irregularly dilated sinuses adjacent to a focal area of lymphoid proliferation. Clinical thrombocytopenia in the dog sufficient to result in petechial hemorrhages has resulted from a splenic lesion less than 2 cm in diameter that resolved on surgical removal. Histologically, there was apparent platelet sequestration in sinus "lakes" adjacent to the advancing margin of a *mantle cell lymphoma*. The latter conditions are not usually a diagnostic problem due to the efficiency of ultrasound in identifying focal lesions in body cavities of the dog and cat. In the horse, a type of *lymphoma* occurs as a localized splenic mass that may weigh as much as 15 kg. The animals are presented with a responsive hemolytic anemia that is usually suspected to be due to equine infectious anemia until proven serologically negative. Since the spleen is not palpable even with this size of mass, a clinical diagnosis depends on recognition of a nonimmunologic hemolytic process. It would be expected that lesions of this type would be evident on abdominal sonograms.

Hemorrhagic anemia

Hemorrhage represents the simplest means of blood loss, although the pathogenesis may be most intricate. (The hemorrhagic diseases are given separate consideration later.) The causes of hemorrhage are very diverse with equally diverse results depending on the cause, the tissues directly involved, and on the rate of blood loss. Bleeding may be *acute* and the anemia of sudden onset, or *continuous* with loss of small amounts of blood over prolonged periods. The syndromes representing these two extremes are different, and therefore are discussed separately; however, between the extremes, the various signs form a continuous spectrum. The manifestations also vary depending on whether the hemorrhage is external with the blood lost from the

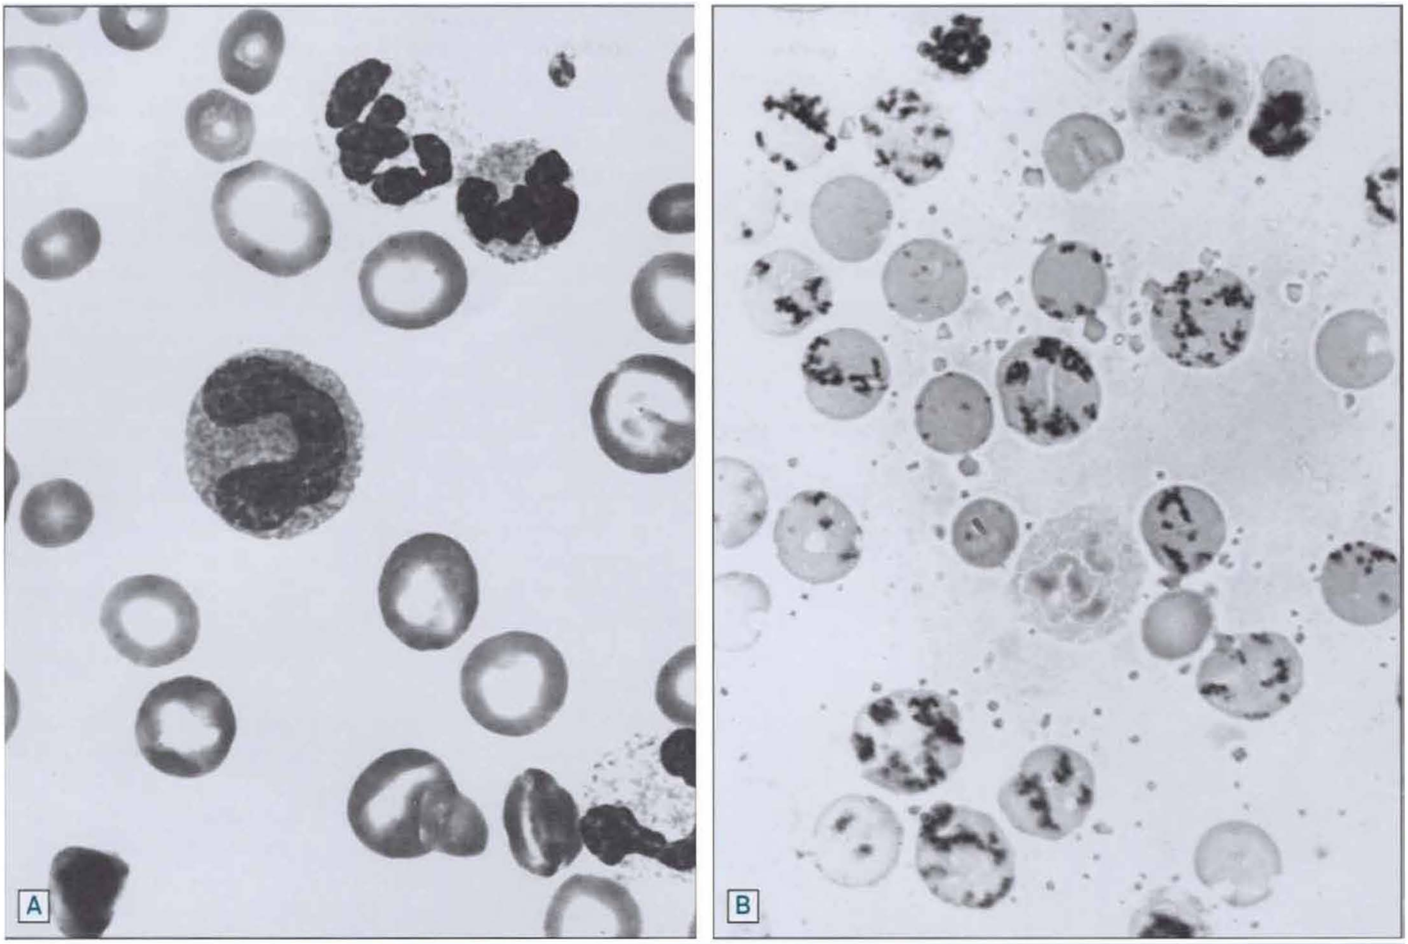

Figure 2.103 Hemorrhagic anemia of 1 week duration in an ox. **A.** Anisocytosis, hypochromia and poor response due to rate-limiting effects of iron utilization. **B.** Same case: reticulocyte preparation 2 days after parenteral iron administration.

body, or internal with the essential components of hemoglobin available for reutilization. These differences depend largely on the availability of iron and, to a lesser extent, on protein and essential amino acids (Fig. 2.103A, B).

Acute posthemorrhagic anemia with bleeding to the exterior has a number of possible causes, of which a common one is *trauma*. Rupture of blood vessels by *pathological processes* also occurs and is exemplified by massive hemorrhage from the nasal cavities, lungs and the female reproductive tract. *Esophagogastric ulceration of the porcine stomach* is a relatively common cause of acute anemia, as are *bleeding abomasal ulcers* in cattle. Hemorrhage into the stomach and intestines is accompanied by a moderate elevation of nonprotein nitrogen in blood. Parasitism, especially *hemonchosis, ancylostomiasis and coccidiosis*, may cause acute posthemorrhagic anemia. *Enzootic hematuria* of cattle is recognized as a cause of anemia in certain geographical areas.

In *acute hemorrhage*, immediate examination of the blood may reveal no change since all elements including plasma are proportionately reduced. Very shortly, however, there is an increase in the number of circulating platelets and of leukocytes, particularly neutrophils, which are largely mature. The leukocytosis is initially due to a redistribution of leukocytes from organs such as the spleen, splanchnic vessels and lung, in which there are normally sequestered a number equal in mass to the cohort normally in circulation. This neutrophilia and thrombocytosis persist as a reflection of increased marrow output directed principally to the production of red cells. As fluid is withdrawn from the tissues and alimentary tract to restore the plasma volume, the anemia becomes evident and it is, for the first 2 days or so, normocytic, after which the arrival of new red cells made macrocytic by the action of increased levels of erythropoietin add to the PCV, MCV and apparent anisocytosis. *Thus, the anemia of hemorrhage will be briefly macrocytic, and then scattered hypochromia will be seen, followed by a general reduction in red cell size and saturation as iron becomes limiting.* These changes appear to a greater or lesser degree regardless of the level of storage iron, since demand far outstrips mobilization, and the response will be increased incrementally by the addition of iron by both oral and parenteral means. The reticulocyte count, normally at 1% or 60 × 10^9/L in the dog and 0% in the cow will rise to 200–300 × 10^9/L depending on the iron supply and whether the blood was lost from the body. *In no case will the response equal that for hemolytic anemia.* As an example, a typical dog from a group of 36 with enteric bleeding from overdose of sulfa for coccidiosis had a PCV of 0.15 L/L and a reticulocyte count of 3.2 × 10^9/L, and a dog with factor VIII deficiency and an equivalent PCV had a similar level of response. Calves with blood loss anemia are even less responsive than dogs. Horses, which do not release reticulocytes into the circulation, will have an upward shift in MCV of 6 fL in response to removal of half the red cell mass, while in response to a similar loss due to Heinz-body hemolytic anemia the MCV rises 12 fL. Horses with roughly the same degree of anemia recovered their normal hemoglobin level in 42 days when made anemic by Heinz-body hemolysis, and in 84 days when made anemic by bleeding. Horses made anemic by bleeding increased their rate of hemoglobin production 1.5 to 2.5 times normal, while horses made anemic by hemolysis increased their hemoglobin production by 4.4 times normal. The red cells produced in response to hemolytic or hemorrhagic anemia had virtually normal lifespans. The response to anemia caused by a single episode of hemorrhage can be expected to restore a normal PCV in about 30 days, if not complicated by infection.

Following severe hemorrhage, rubricytes appear in the blood of most species except the horse. Their number, even when prominent by leukocyte standards, will only be in the $5–10 \times 10^9/L$ range and give no indication of response, as can be seen when their numbers are compared to the level of reticulocytes required to raise the PCV. *Reticulocytosis that persists longer than 1–2 weeks points to the probability that bleeding is continuing.* Significant red cell production can occur without apparent reticulocytosis, particularly in cattle, whose response is always subdued in comparison to dogs.

Marrow hyperplasia is evident grossly by an expansion of the hematopoietic areas along the endosteal surfaces of the long bones, and microscopically by an increase in proportion of hematopoietic to fat cells in red areas to nearly 100% from a normal proportion of about 50%. If iron deficiency is present, which it is likely to be in blood-loss anemia, there will be erythroid hyperplasia with late asynchrony or a predominance of late-stage rubricytes.

The immediate causes of chronic, posthemorrhagic anemia are, in general, likely to be enteric, occult and due to parasitism. Alternatively, the loss may be caused by external parasitism, as in *heavy flea infestation* of kittens and puppies. In the case of ulceration of the gastric squamous mucosa of swine, the loss may occur as recurrent acute episodes or continuous slight bleeding. By arbitrary but accepted definition, *chronic posthemorrhagic anemia is caused not only by loss of blood, but also by inadequate formation*, since continued bleeding depletes the body of hematopoietic substrates, principally iron. Under normal circumstances, 65–75% of the body iron is in the red cell mass, so severe hemorrhage represents a significant and irretrievable loss unless supplemental iron is given. Depending on the severity and duration of hemorrhage, the syndrome may be complicated by hypoproteinemia resulting from chronic loss of plasma proteins. *The anemia is hypochromic, microcytic, nonresponsive, and accompanied by thrombocytosis of small platelets.* Since, with deficiency of iron, hemoglobin synthesis lags behind the production of red cells, the hypochromia is more significant than the microcytosis. An indication of hypochromia can be obtained from a stained blood film in which the erythrocytes will be pale with increased central pallor in dogs, and show pallor in ruminants where it is not normally present. In addition, as part of the syndrome of iron-deficiency anemia, there will be poikilocytosis whose severity will vary directly with the degree of anemia. When the deficiencies are resolved, the response of the bone marrow is evident in prompt reticulocytosis. When anemia is excessively prolonged and severe, there may be some degree of extramedullary hematopoiesis by the liver and spleen. The spleen is enlarged and rather meaty, and microscopically there is increased sinus stroma.

Internal hemorrhage differs somewhat in its course from external hemorrhage. When acute, the main manifestations are the same but, in addition, there will be some increase in bilirubin even to the level of clinical icterus. Many cases, however, are too rapidly fatal for signs of degradation of the extravasated blood to become manifest. The principal causes of internal hemorrhage of a degree adequate to produce clinical anemia are *poisoning by sweet clover, Melilotus alba*, and *spontaneous or traumatic rupture of a viscus*, usually the liver or spleen as often occurs in dogs with hemangiosarcoma. Much of the blood lost into the peritoneal cavity is returned via the lymphatics to the circulation. In the latter disease in the dog, the previously extravasated red cells are apparent on the blood film as a second population of crenated cells in addition to the few acanthocytes characteristic of hemangiosarcoma. In any event of internal hemorrhage, most of the extravasated blood can be reutilized in hematopoiesis after its degradation by the monocyte–macrophage system. Hemosiderosis may therefore be a conspicuous feature in the liver, spleen, bone marrow and other organs in cases of internal destruction of blood but, as indicated earlier, hemosiderin iron is not readily available for reutilization.

Disorders of hemoglobin

Congenital abnormalities of the synthesis of heme and of the molecular structure of hemoglobin are not known in animals, except for porphyria of cattle, pigs, and cats. The porphyrins are photodynamic, but otherwise appear to be inert (see Vol. 1, Skin and appendages). *Acquired disorders of hemoglobin are, however, rather common.* Increased protoporphyrins are associated with a number of diseases including lead poisoning, *iron deficiency*, and the porphyrias. Most hemoglobin disorders result in the formation of *methemoglobin*. *Carboxyhemoglobin* formation is rare unless poisoning is intentional.

Methemoglobinemia

Methemoglobin *is derived from hemoglobin by conversion of iron from the ferrous and functional state to the ferric form, where it is incapable of transporting oxygen.* A small amount of methemoglobin is normally present in blood, especially of herbivorous animals, and methemoglobin is probably formed at a steady rate but maintained at low concentration by an equilibrium with hemoglobin. Excessive concentrations of methemoglobin in the blood must then be due to increased production or to a defect in the mechanisms which reduce methemoglobin to hemoglobin. Methemoglobin reductase deficiencies have been described in the dog, but in the majority of cases the formation of methemoglobinemia in animals is due either to increased production of the pigment, under the influence of oxidizing poisons, or to irreversible oxidation of free hemoglobin in hemolytic diseases.

Many drugs and poisons are known to cause the oxidation of intracellular hemoglobin to methemoglobin, but the most important of these are the *nitrates, chlorates, phenacetin, and acetanilid.*

Nitrate poisoning and nitrite poisoning are often used synonymously, especially in relation to herbivores, in which reduction of nitrate to nitrite may occur in the alimentary tract. Reduction may also occur in forage before ingestion. Nitrate is, however, toxic as the nitrate radical and, although uncommon, poisoning has been observed in dogs and horses following ingestion of excessive amounts of *potassium nitrate.* Potassium nitrate is an irritant to the alimentary mucosa, and a diuretic, and signs of poisoning are referable to the alimentary and urinary systems but there are no specific lesions. Excessive dosage results in severe hemolytic anemia and icterus. The reduction of nitrate to nitrite is frequently insignificant in these circumstances and methemoglobinemia does not occur.

When *herbivores ingest nitrate,* it is reduced in the alimentary tract to nitrite and ultimately to ammonia. Since the amount of ammonia produced is rate-limiting, toxicosis by ammonia does not occur. Depending on a number of factors, including the initial concentration of nitrate, the flora of the rumen, and the diet of the animal, the conversion of nitrite to ammonia may be inadequate, in which case nitrite is absorbed and causes methemoglobinemia. The capacity of the rumen microflora to detoxify nitrate, or the nitrite derived from it, is energy-dependent and therefore progressively reduced under conditions of poor feeding. The conversion of nitrate to nitrite can and does occur externally as, for example, in hay stacked with a high moisture content.

The sources of nitrite for grazing animals are varied. *Agricultural fertilizers* which contain large amounts of nitrate or nitrite are frequently responsible for outbreaks of nitrate poisoning. In addition, a number of *plants* accumulate toxic levels of nitrate under natural conditions. The plants which are most frequently incriminated include the cereal crops, either green or as hay, the leaves of sugar beets and turnips and other Brassicaceae, *Sorghum* spp., and a number of *weeds*, especially variegated thistle (*Silybum marianum*), redroot pigweed (*Amaranthus retroflexus*), capeweed (*Cryptostemma calandulacium*), and *Tribulus* spp. The nitrate content of these and other plants is extremely variable and is influenced by the species of plant, the availability of the nitrogen of soil, the amount of shading, and the stage of growth of the plant. The application of herbicides may lead to an accumulation of nitrates in plants, especially sugar beet and wheat, and it is probable that a deficiency of other essential nutrients, such as sulfur, may result in metabolic disturbances in the plant and the accumulation of nitrate. Levels of nitrate, expressed as potassium nitrate, of less than 2% in plants are unlikely to result in toxicity. Outbreaks of nitrate poisoning are usually recorded on forage which contains 3–7% potassium nitrate.

Stagnant waters, especially *well water*, in areas of high fertility of soils tend to accumulate toxic levels of nitrate, and poisoning has been recorded in cattle and pigs which have ingested such water.

The pathogenesis of nitrate (nitrite) poisoning depends upon the oxidation of ferrous to ferric hemoglobin iron. It is likely that there are additional factors, including the oxidation of iron-containing respiratory enzymes and, since nitrates dilate blood vessels, a drop in blood pressure is to be anticipated. The blood vessels that are most sensitive to the dilatory effects of nitrite are those of the head, brain, meninges, and coronary vessels, with the visceral vessels being less sensitive. It is likely that the rapid collapse seen with nitrite poisoning is due to hemodynamic disturbances as well as to the inability of the oxidized hemoglobin to transport oxygen.

Cattle are more susceptible to poisoning than are sheep or horses. Clinically, nitrite poisoning is characterized by weakness, staggering gait, collapse, dyspnea, cyanosis, and rapid pulse. Death occurs in coma. Animals that are less severely affected urinate frequently. Grossly, there is little to see except for *cyanosis of mucous membranes and light brown discoloration of the blood and tissues.* An excess of blood-stained fluid is commonly present in the pericardial sac. Methemoglobin levels decrease rapidly after death.

Sodium chlorate is used as a herbicide and is occasionally responsible for death of cattle and sheep. It is a powerful but rather slow oxidizing agent, and its principal toxic effect is to cause methemoglobinemia. At high dosage, chlorate also causes intravascular hemolysis, so that hemolytic anemia and hemoglobinuria may accompany methemoglobinemia. When applied to plants, sodium chlorate is progressively converted to sodium chloride so that pastures are most hazardous immediately following spraying. The salt is palatable to livestock especially in areas of marginal deficiency of sodium chloride and this no doubt contributes to the likelihood of poisoning.

Carboxyhemoglobinemia

Carbon monoxide *is formed by incomplete oxidation of combustible carbonaceous materials.* It is a common cause of poisoning in humans, *uncommon in most animals, even pets, but still occurs in housed pigs.* The usual sources of the carbon monoxide are illuminating gas and exhaust fumes from petroleum fuels that accumulate in tightly closed, heated barns. *Carbon monoxide has an affinity for hemoglobin that is 200–300 times the affinity of oxygen for hemoglobin, and the conjugated carboxyhemoglobin is incapable of carrying oxygen*; the conjugation is, for practical purposes, irreversible. Apart from the bright redness of the blood, which is directly due to carboxyhemoglobin, *the signs and lesions of carbon monoxide poisoning are those of anoxia.* The anoxia affects the brain most profoundly, and in acute poisoning the brain is congested and edematous and contains punctate hemorrhages. Degeneration of neurons may be widespread, and there is a tendency for foci of softening to develop. Recovery results in residual nervous defects in some cases.

Lymphoreticular tissues

THYMUS

The thymus is a composite organ of epithelial and lymphoid tissues, with the epithelial part derived from the third pharyngeal pouch of the foregut endoderm. This epithelial anlagen is colonized by lymphocytes from the blood islands of the primordial yolk sac following migration of the epithelial component to the cranial mediastinal area. The epithelial components are derived bilaterally from the middle series of branchial pouches, which by epithelial outgrowths meet in the midline and are then displaced caudally in the neck.

There are *two streams of epithelial migration*, with that from the uppermost part of the pharyngeal pouch forming the *thymic duct epithelium* and later the *Hassall's corpuscles*, and that from the lower part of the pouch forming the *reticular epithelial component* of the cortex and medulla of the adult thymic lobule. Embryologically, the reticular epithelial component first invades the mediastinal interstitium with irregular, solid, rosette-like buds that enlarge to form the primordial lobules. This reticular epithelium forms loose cuffs around small vessels that persist in adult life and become obvious following lymphoid atrophy. The second component migrates as a system of branching ducts that ramify in the interlobular stroma and penetrate the lobules to form a central cord that broadly communicates between the lobules of a single lobe. In early development, this tubular system has a basement membrane and layered epithelium that becomes solid and cystic and loses the outer membrane in the mature medullary corpuscle. These relationships are pertinent to the histological interpretation of the thymus in pathologic states, as *in dysplasia, atrophy, regeneration, and hyperplasia, these components recapitulate their embryologic relationships*. Thus a thymoma with diffuse architecture and medullary predominance can be differentiated from hyperplasia by the presence of the reticular cuffs around the vessels of a thymoma. In terms of induction, it appears that these medullary ducts are essential to colonization of the anlagen by lymphocytes, and are the source of trophic thymic hormones. They are also the source of the cysts lined by ciliated epithelium found in the thymus and cranial mediastinum in many species and which, if large, may be of clinical significance as a cause of dyspnea. *A further cell type, which resembles striated muscle fibers*, is of indefinite origin, but has importance in the pathogenesis of myasthenia gravis.

In most species, the thymus reaches maximum development about the time of puberty. It can become hyperplastic, and in calves given repeated injections of endotoxin can extend from the rami of the mandibles to the base of the heart. Normally, *the thymus regresses in adult life*, and this regression may be accelerated during severe or chronic illness, but it never entirely disappears. Even a very small organ weighing less than 10 g can be immunologically potent in autoimmune dysfunction.

Thymic cortical lymphocytes are small cells with nuclei slightly larger than erythrocytes, little internal nuclear detail, and minimal cytoplasm. Despite their small size and lack of nucleoli, there is intense lymphopoiesis in the peripheral thymic cortex and continual migration of cells to the periphery from this area. Most (99%) of this proliferation is ineffective and balanced by a high rate of cell death, apparently in a process of immunologic selection. In normal states, cortical lymphocytes are closely packed so that the cortex appears uniformly dark histologically. In conditions of stress and atrophy, cortical epithelial cells and phagocytes become prominent and these larger cells with ingested nuclear debris give the cortex a moth-eaten appearance.

Thymic medullary lymphocytes are larger than their cortical precursors and have a more vesicular nucleus with small nucleoli and more cytoplasm. They appear less tightly packed than the cortical cells and, with the higher density of epithelial cells and the greater variability in nuclear size and shape, cause the medullary areas to appear lighter histologically, giving the thymus its *characteristic corticomedullary differentiation*. In many disease states where the animal is faring poorly, this corticomedullary boundary is indistinct and blurred by dilution of the cortical cells and an increase in macrophages in both regions. In normal states, the squamous ductal epithelium is obvious in central medullary areas, but the reticular epithelium of the cortex and medulla is not; the latter background of cells is only apparent following atrophy of the normal lymphocyte population.

Physiologically, *prothymocytes from bone marrow colonize the outer cortex of the thymus where they proliferate and are selected and trained by the cortical epithelium*. In this region, the epithelial cells form large membrane-lined cavities called *caveolae* in which the marrow-derived lymphocytes divide and undergo phenotypic development. On release from the marrow, prothymocytes have the ability to home selectively to the thymus but they lack helper, suppressor, or killer functions. In contrast, peripheral T lymphocytes are characterized phenotypically by CD4 (cluster derived, helper) or CD8 (suppressor) expression, functionally by the MHC determinants they recognize, and by their collective inability to react against normal self-antigens. The naive T cells arriving in the thymus from the bone marrow express CD34 and CD7 and are pluripotent in their ability to become types of T cells as well as dendritic or NK cells. They undergo a sequential pattern of antigen expression as a function of orderly gene rearrangements encoding the T-cell receptor (TCR). The earliest T-cell development occurs in the outer cortex with the expression of CD2 and CD44 and are termed "triple-negative" cells as they do not yet express CD3, CD4, or CD8. Most T cells develop a TCR heterodimer composed of α and β chains, a much smaller proportion develop the $\gamma\delta$ TCR configuration, and fewer still become intrathymic dendritic cells. Besides becoming CD3-positive with this level of maturation, the young thymocytes expressing the $\alpha\beta$ form of TCR also express CD4 and CD8 molecules and are known as double-positive cells during the time they express both molecules. Those cells that recognize antigen in association with class II MHC gain additional CD4 expression and lose CD8. Similarly, those cells that recognize antigen in association with class I MHC persist as CD8-positive cells. A much smaller population of $\gamma\delta$ T cells form a cytotoxic T-cell population as mature cells.

Prothymocyte development is believed to occur within the caveolae of the large epithelial "nurse cells." Nurse cells tend to express either MHC II, primarily in the cells of the outer cortex and dendritic cells of the inner cortex, or, in association with the more flattened reticular epithelium of the medulla, expressing both type I and II determinants. This close apposition of epithelium and young lymphocytes permits the transmission of inductive signals for proliferation and development, or for death of the great majority of the cells produced. The thymic nurse cells themselves produce interleukin-1 (IL-1), which drives lymphoproliferation, and in the course of maturation the T cells acquire receptor and production capability for IL-2, as well as other reactive lymphokines.

The progeny of this system are the recognition and regulation specialists of the adult immune system. They identify antigens presented to them by other cells as having either the MHC I or II determinants, and determine the presence or absence of foreign antigen, which is handled by killing or by stimulation of antibody development. T-cell development involves the rearrangement of the T-cell receptor genes analogous to the same process by which the B cells gain antibody diversity. *Whereas B cells recognize antigen on the basis of molecular shape, T-cell recognition is on the basis of peptides.* Since antigen is presented to the T cell by antigen processing phages and dendritic cells, denaturation of antigen is of no consequence since it is the amino acid sequence that is detected as foreign. In nonhematopoietic cells, internal antigen is displayed within a groove in the MHC-I molecule on cell membranes so that viral infection or tumor antigen are available for recognition by T lymphocytes. This process of cell recognition is accomplished by intracellular transporter pumps that display all of the proteins (self or foreign) produced within the cell on the cell surface. The diversity of T-cell recognition appears to be a function of receptor diversity and permits survival of cells with acceptable recognition of self to avoid "holes" in antigen detection. Thus, most NK (natural killer) cells recognize targets without MHC restriction, while the CD8+ cytotoxic cells with appropriate antibody mediate antibody-dependent cytotoxicity (ADCC). *Cytotoxic T cells and NK cells can induce apoptosis in adjacent cells by releasing cytotoxic granules called perforins or granzymes, both of which act in a Ca^{2+}*-dependent manner.

Cells exiting the thymus have not only managerial receptors but also *"homing" receptors* to guide them to appropriate areas in the peripheral nodes and Peyer's patches. Only 1–3% of thymocytes bear homing receptors, all of which are in the cortex and all of which are phenotypically mature. Thus, it appears that the homing direction is added last, with most of the cortical cells homed to nodes and likely medullary cells homed to Peyer's patches.

It appears that the thymic epithelium, besides making trophic hormone for the immune system, also makes the peptides *oxytocin and vasopressin* in common with the pituitary, thus indicating a mechanism for the interaction of the nervous, endocrine and immune systems.

In terms of ontogeny, lymphocytes first appear in the thymus of the fetal lamb at day 43, nodes at day 45, spleen at day 54, and Peyer's patches at day 65. These relationships are altered by fetal infection (see Vol. 3, Female genital system). In the dog, thymic epithelial enlagen are present by gestational age 23 days, lymphopoiesis begins by day 33 and corticomedullary differentiation with formation of Hassall's corpuscles is first evident at about 38 days.

Developmental diseases of the thymus

Congenital immunodeficiency

Immunodeficiency is defined as an absence or defect in a class or subclass of the lymphocytes derived either from bone marrow or thymus. Problems not included in this discussion are congenital defects of phagocytic cells or of complement, and the failure to passively transfer immunoglobulin from dam to offspring. Immunodeficiency disease may be partial or complete. In individuals, the deficiency may affect bone marrow derived cells and be recognized by hypogammaglobulinemia, or involve thymus-dependent cells and be expressed as lymphopenia and deficient cell-mediated immunity. When the deficiencies involve both B- and T- derived classes of lymphocytes, they are called **combined immunodeficiency states**. Since deficiencies of the B and T lymphocytes tend to occur together, they are considered here under the thymus.

Agammaglobulinemia

Immunoglobulin deficiencies occur in human males, foals and probably in other species. The disease in **foals** resembles X-linked agammaglobulinemia of human infants in both expression and progression. A selective deficiency of immunoglobulin M occurs in foals of Quarter Horse and Arabian breeding and both sexes are affected. Immunoglobulin levels vary from undetectable to 10% of normal, and the lymphocyte counts are normal, with normal proportions of B and T derived classes. These animals have neutrophilic leukocytosis without anemia and are presented for examination at 4–8 months of age with febrile disease involving the respiratory tract.

Combined immunodeficiency (SCID)

Combined immunodeficiency occurs in humans, foals primarily of the Arabian breed, Jack Russell Terrier dogs, and in an inbred strain of the C.B-17 mouse. Both sexes are affected and the disease is due to an *autosomal recessive trait expressed as an absence of both B and T lymphocyte functions*. The syndrome is heterogeneous with a number of entities that differ in severity; however, since the disease is usually fatal in early life, *the acronym SCID is used to indicate* **severe combined immunodeficiency**. In mice, Arabian foals, and Jack Russell Terriers, SCID has been ascribed to defects in expression of DNA-PKcs (DNA-protein kinase catalytic subunit), which normally acts as a tumor suppressor. In the fully developed disease, there is extreme susceptibility to infectious agents, and in affected human infants, vaccination with smallpox and bacillus Calmette-Guerin is uniformly fatal. Affected foals survive about 2–5 months and infants 2 years, while SCID mice if maintained in microisolators will survive 40–80 weeks, or about three-quarters of a normal life span.

The disease occurs in some 2% of *Arabian bred foals* but the incidence of phenotypically normal heterozygotes will be much higher. Affected foals are normal at birth, but at about 10 days of age develop a range of diseases including pneumonia and diarrhea with which adenoviruses are peculiarly associated. In spite of intensive therapy, affected foals die at about 3 months of age. Hematologically, the animals are profoundly lymphopenic. There is hypoplasia of all lymphoid tissue including thymus, nodes and spleen, with histologic hypocellularity (Fig. 2.104A–D). Reduced lymphocyte levels in blood are usually more than compensated by neutrophilia, so that total leukocyte counts are usually in the normal range. *The mechanism of disease appears to be a defect in prolymphocytic stem cells at a hierarchical level that involves both bone marrow-derived and thymus-dependent systems.* Affected foals develop bilateral nasal discharge that becomes sufficiently profuse to impair suckling. There is progressive loss of weight and intermittent pyrexia with coughing, depression and rough haircoat. *Intractable respiratory disease is the most common clinical sign*, but diarrhea and swollen joints are also observed. There is severe lymphopenia, and *it is suggested that counts of less than* 1×10^9*/L are diagnostic for the disease.* Lymphopenia is present from birth and is constant throughout life. Since IgM is synthesized by the normal equine fetus, *absence of IgM from serum of foals that have not suckled supports a diagnosis of severe combined immunodeficiency disease*. In animals from 1 to 100 days of age, the serum IgM and IgA levels are low and remain between 0.2 and 0.6 g/L. The IgG, which is maternally derived, progressively drops from 8.0 g/L shortly after birth to 2.0 g/L in foals which approach 100 days of age. There is usually mild anemia that increases in severity with resistant and repeated infections, but is often masked by dehydration. Leukocyte counts are highly variable, being primarily dependent on the numbers of neutrophils.

The characteristic lesions associated with severe combined immunodeficiency in foals are *bilateral cranioventral bronchopneumonia in association with small spleen, lymph nodes and thymus.* The latter organ is identified only as a thin mediastinal raphe cranial to the heart. The bone marrow is unusually reactive for the age of the animal, and hematopoiesis persists in cancellous bone and partially occupies the central femoral cavity. Terminally, areas of marrow that appear red grossly may be hypoplastic with dilated sinusoids (Fig. 2.105A).

Histologically, *basophilic adenoviral inclusion bodies* are usually present in the epithelial nuclei of bronchi, bronchioles (Fig. 2.105B) and pancreatic ducts. The spleen is remarkable in that sinus areas are moderately cellular with macrophages and extramedullary hematopoiesis, while the small arterioles are devoid of lymphocytic cuffs. Architecturally, the nodes consist of a stromal framework that is essentially an unoccupied superstructure. Node capsules are delicate, with the peripheral sinus often heavily colonized by macrophages and granulocytes. Some nodes, particularly from the mediastinal area, may have cortical microabscesses. Follicles are absent, and the cortex consists of a reticular framework in which there are small foci of lymphocytes around small arterioles. Postcapillary venules have high vesicular endothelium and are usually well demonstrated because of the lack of perivascular and intramural lymphocytes. Medullary cords are collapsed, and medullary sinuses are dilated and contain neutrophils and macrophages. If thymus can be identified, it consists of small lobules of 1–2 mm in diameter surrounded by normal fat. The lobules have normal stromal capsulation and consist almost entirely of medullary structures with central Hassall's corpuscles and a vesicular reticular network with a very low lymphocyte population.

The presence of the **Hassall's corpuscles** is worthy of note since, besides identifying the tissue as thymus, their presence also indicates that there has been successful embryological migration of the epithelial duct system. In human infants, the corpuscles are present only in that variant with adenosine deaminase deficiency; however, this enzyme is not deficient in foals. In contrast, Hassall's corpuscles are not found in SCID mice, including the beige strain that also lacks NK cells. In the latter species, thymus can only be distinguished from mediastinal node by the presence of a peripheral sinus in the latter. Long-term survivors of the SCID mouse strain have a remarkable incidence of some 15% thymic lymphomas. Thymic hormone is not deficient in the SCID syndrome, and possibly the persistent high levels of interleukin-1 acting on a deficient target induce autonomous lymphoproliferation. The cellular defect is not well defined. There is failure of the lymphocytes to mature and, in the mouse, a defective recombinase system may prevent gene rearrangement both for immunoglobulin production and formation of the T-cell receptor. A variant of the SCID

syndrome in infants is termed the "bare lymphocyte syndrome," as the T cells lack HLA expression. It appears that some of the variability in these diseases may be due to the level of maternal cells in circulation that are functionally competent by standard tests. The SCID syndrome can be successfully treated in infants and foals by marrow transplant. Graft-versus-host disease follows transplantation of unmatched precursors.

Acquired immune deficiency

Loss of normal immune reactivity occurs in a number of circumstances, most often as a result of therapeutic intervention, either specifically to combat autoimmune disease or indirectly as a result of antineoplastic chemotherapy. An unexpected cause of immune suppression is the *transfusion of otherwise compatible allogeneic blood*. The mechanism is apparently a blanking of the immune system by the massive introduction of antigen which, despite the beneficial hematologic effects to postsurgical patients, has a number of undesirable immune effects including a reduction in natural killer cell activity. *Normal pregnancy* induces a mild immune suppression which is usually only of significance in the face of epidemic viral disease, such as occurs with human influenza. The effect of pregnancy on the immune system is readily demonstrated experimentally in animals by alteration of the course of infection with viral, protozoal and helminthic agents. For example, in Uganda during an outbreak of lumpy skin disease, nonpregnant dairy cattle developed lymphadenopathy and high fevers of short duration followed by complete recovery, while pregnant cattle failed to develop severe lymphadenopathy and fever but subsequently developed skin lesions and protracted disease.

Inflammatory diseases of the thymus

Immune inflammation of the thymus: myasthenia gravis

Myasthenia gravis is an autoimmune disorder of humans, dogs, and cats, characterized by muscle weakness and reduced exercise tolerance. All of the physiologic features of the disease can be accounted for by *reduction in acetylcholine receptors of neuromuscular junctions* (see Vol. 1, Muscle and tendon).

The disease arises as an immune-mediated phenomenon whereby a cellular and antibody reaction is developed against the thymic myoid cells which express acetylcholine receptors. The disease is mediated by the attachment of antibody to peripheral neuromuscular junctions. In dogs the syndrome occurs as an inherited disease of Smooth Fox Terriers, Springer Spaniels and Jack Russell Terriers, and spontaneously, often associated with thymoma. A possible role of bacteria in the pathogenesis of the spontaneous disease has been suggested because antibody against acetylcholine receptor cross-reacts with proteins found in *Escherichia*, *Klebsiella*, and *Proteus* spp. The thymus in myasthenia gravis of animals has not been well described, other than in the recognition of thymoma. In myasthenia gravis of humans, there are three characteristic types of non-neoplastic thymic histology, consisting of B-cell infiltration in a *follicular* or *diffuse* pattern, and *thymic atrophy*. The follicular type is most common and associated with the greatest density of thymic myoid cells with the diffuse lesion having an intermediate number and the atrophic type the fewest. The myoid cells tend to be associated with Hassall's corpuscles and the germinal centers, which resemble those of antigen-activated lymph nodes, and diffuse areas of B-cell proliferation are centered on the medullary areas with sparing of the cortex, which is often reduced in volume.

Myasthenia gravis in the dog is characterized by progressive weakness and is exacerbated by exercise, with only partial recovery on rest. Specific areas of involvement include the facial and extraocular muscles with the development of megaesophagus associated with difficult swallowing, regurgitation and aspiration pneumonia. Myasthenia gravis is characterized by sterile thymitis and the intrathymic production of acetylcholine-specific autoantibodies. It appears to arise completely within the thymus and appears to involve acetylcholine receptors on the myoid cells as a triggering antigen. The development of autoantibodies against acetylcholine and abnormal neurofilaments related to striated muscle, called *titin*, appear to result from aberrant T-cell selection and proliferation. It has been suggested that the acetylcholine receptor which is fully expressed in neonatal thymus abnormally persists and is amplified in cases of myasthenia gravis, and that this development may be the inciting antigen inducing the autoimmune reaction to peripheral acetylcholine receptors.

The association of myasthenia gravis with *thymoma* may not be related to the immunological role of the thymus. Some cases may be expressions of paraneoplastic autoimmunity associated with tumor-derived antigens not necessarily related to the acetylcholine receptors.

Infectious inflammation of the thymus

Inflammation associated with some degree of atrophy of the thymus gland occurs frequently in infectious diseases. Thymic atrophy occurs in dogs with *canine distemper*, the changes being largely due to net emigration of lymphocytes rather than to lysis. Marked lymphocytolysis with involution occurs in foals aborted due to infection with *Equid herpesvirus 1* and in cats with *Feline panleukopenia virus*. In calves with *epizootic bovine abortion* and dogs with *salmon poisoning* (rickettsiosis), there is both lymphocytolysis and infiltration with other inflammatory cells. Chronic classical swine fever is characterized by progressive lymphoid depletion and death with complete thymic atrophy.

In foals aborted due to ***Equid herpesvirus 1*** infection, the thymus is grossly normal or of reduced size with edema. There is lack of distinction between cortical and medullary areas due to loss of cortical cells. Cytologically, there is extensive lymphocytolysis in the subcapsular areas, with pyknotic nuclear debris persisting in these areas (Fig. 2.106). The necrotic lesions tend to be patchy, but there is an overall reduction in cell density with edema of the lobules and separation of lymphocytes by clear fluid. Hassall's corpuscles may be surrounded by relatively clear acellular spaces, and viral inclusion bodies are often present in reticular epithelial cells. There is, in addition, a mild increase in monocytes and granulocytes in the interlobular connective tissue. The presence of nuclear debris in the outer cortices indicates acute lympholysis. Foals that survive 1–2

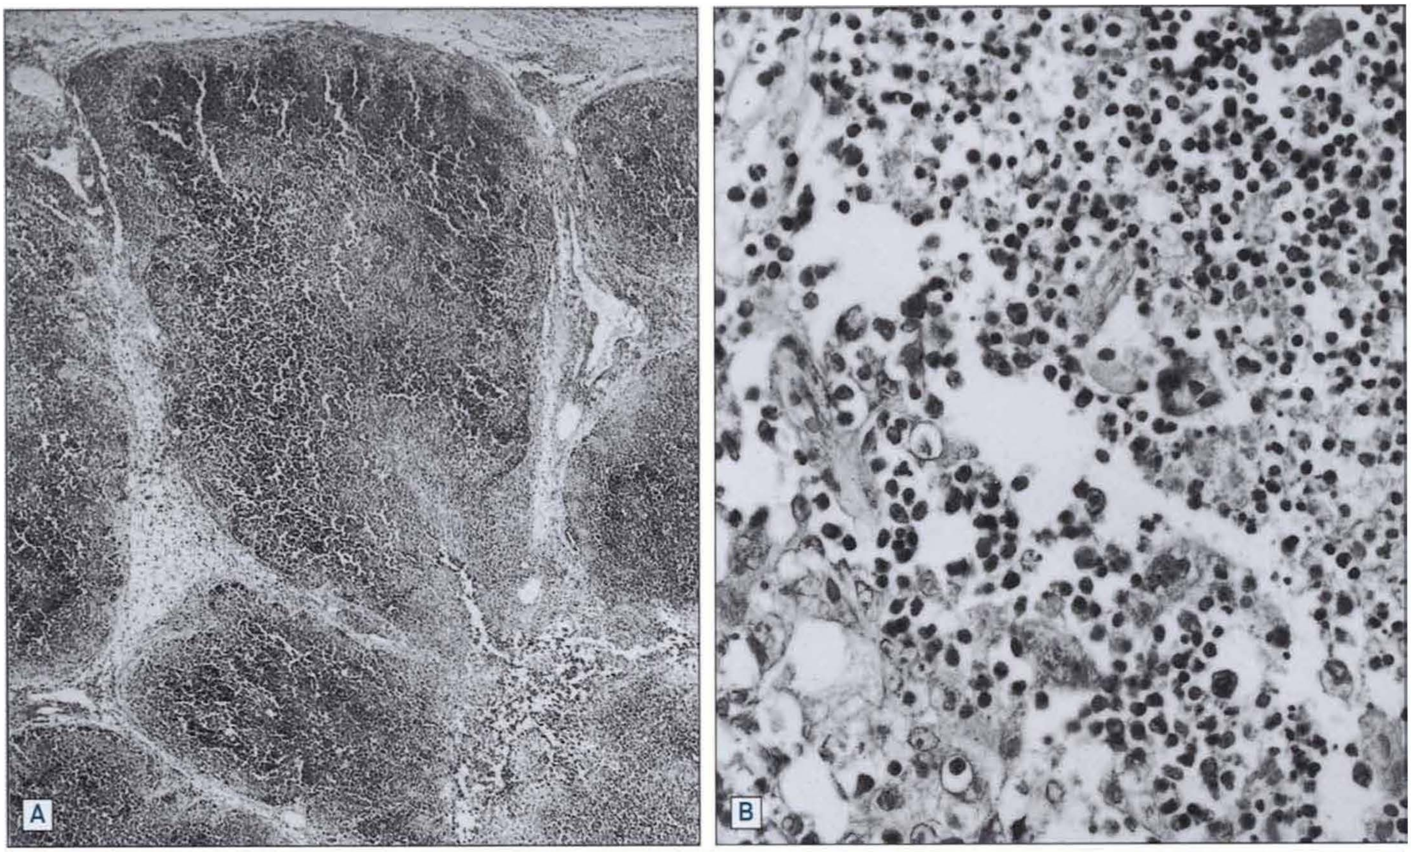

Figure 2.106 Thymitis caused by *Equid herpesvirus 1* in a fetal foal. **A.** Lobules are reduced in size and lack corticomedullary differentiation. The dark areas are viable lymphocytes. **B.** Detail of **A** to show extensive cell necrosis.

days may remove the cellular debris, and the cortices are then characterized by hypocellularity alone.

Cats which succumb to **feline parvoviral** infection (panleukopenia) have *marked thymic atrophy* (Fig. 2.107A–D) to the extent that the organ may not be identifiable grossly, and can only be examined histologically by systematically sampling the cranial mediastinal tissues. Microscopically, the thymus is characterized by collapsed lobules with angular facets to the lobes that become flattened and triangular. The changes are uniform in each lobule and consist of complete thymic atrophy (Fig. 2.108A, B), with only a very narrow rim of small lymphocytes 1–2 cells thick beneath the capsule. Hassall's corpuscles are prominent, and the lobules in effect consist of a condensation of medullary tissue and a prominent epithelial/stromal background that contains a few large lymphoblasts. Small lymphocytes typical of cortical cells are virtually absent from the medullary areas.

Cats infected with ***Feline leukemia virus*** (FeLV) suffer *thymic cortical atrophy of variable degree,* and a reduction in functional capability of neutrophils that may persist for a year after viremia is cleared. The p15E envelope protein appears to be the major factor in impaired T-cell function, apparently by inhibition of interleukin-2 production and responses. Gamma interferon production is inhibited and NK cell cytolytic function is impaired, but binding to target cells is unaffected. Circulating immune complexes contribute to the impairment of defenses and some improvement in condition can be achieved by their removal. There is a an age-related response to infection, with cats infected at under 8 weeks of age surviving about 3 months, and cats 4 months of age at infection surviving about a year. There is an early stage of lymphoid hyperplasia accompanied by weight loss, and followed by lymphoid depletion, lymphopenia, reduced lymphocyte response to lectins, hypogammaglobulinemia, ulcerative stomatitis, diarrhea with necrosis of crypt epithelium, and death. Thymic atrophy occurs in all cats that die, and terminally there is marrow hypoplasia.

The lesions associated with ***Feline immunodeficiency virus*** (FIV) appear, like the human disease, to be largely those of *secondary invaders*, and the most specific changes are largely in tests of immune cell number and function. Infected cats maintained in a clean environment survive indefinitely but have reduced numbers of CD4 lymphocytes and reversal of the CD4/CD8 ratio, suggesting specific infection of the helper cell population. Lymphocyte response to lectins is reduced and there is reduced interleukin-2 production by cells from infected cats. The disease process is likely accelerated when FeLV and FIV coexist, which occurs in about 1% of sick cats. Both viruses may be present in cats with lymphoma. It is remarkable how infrequently the thymus is examined in these diseases even when the focus of the investigation is on immunosuppression.

Bovine immunodeficiency virus (BIV) is an agent of wide distribution and low pathogenicity. In a proportion of infected cattle, there is a moderate lymphocytosis in the 10–15 × 10^9/L range, and mild generalized lymphadenopathy. The disease is very slowly progressive. Specific tests for this virus do not cross-react with *Bovine leukemia virus* or *Bovine syncytial virus*. The BIV agent will infect sheep and rabbits,

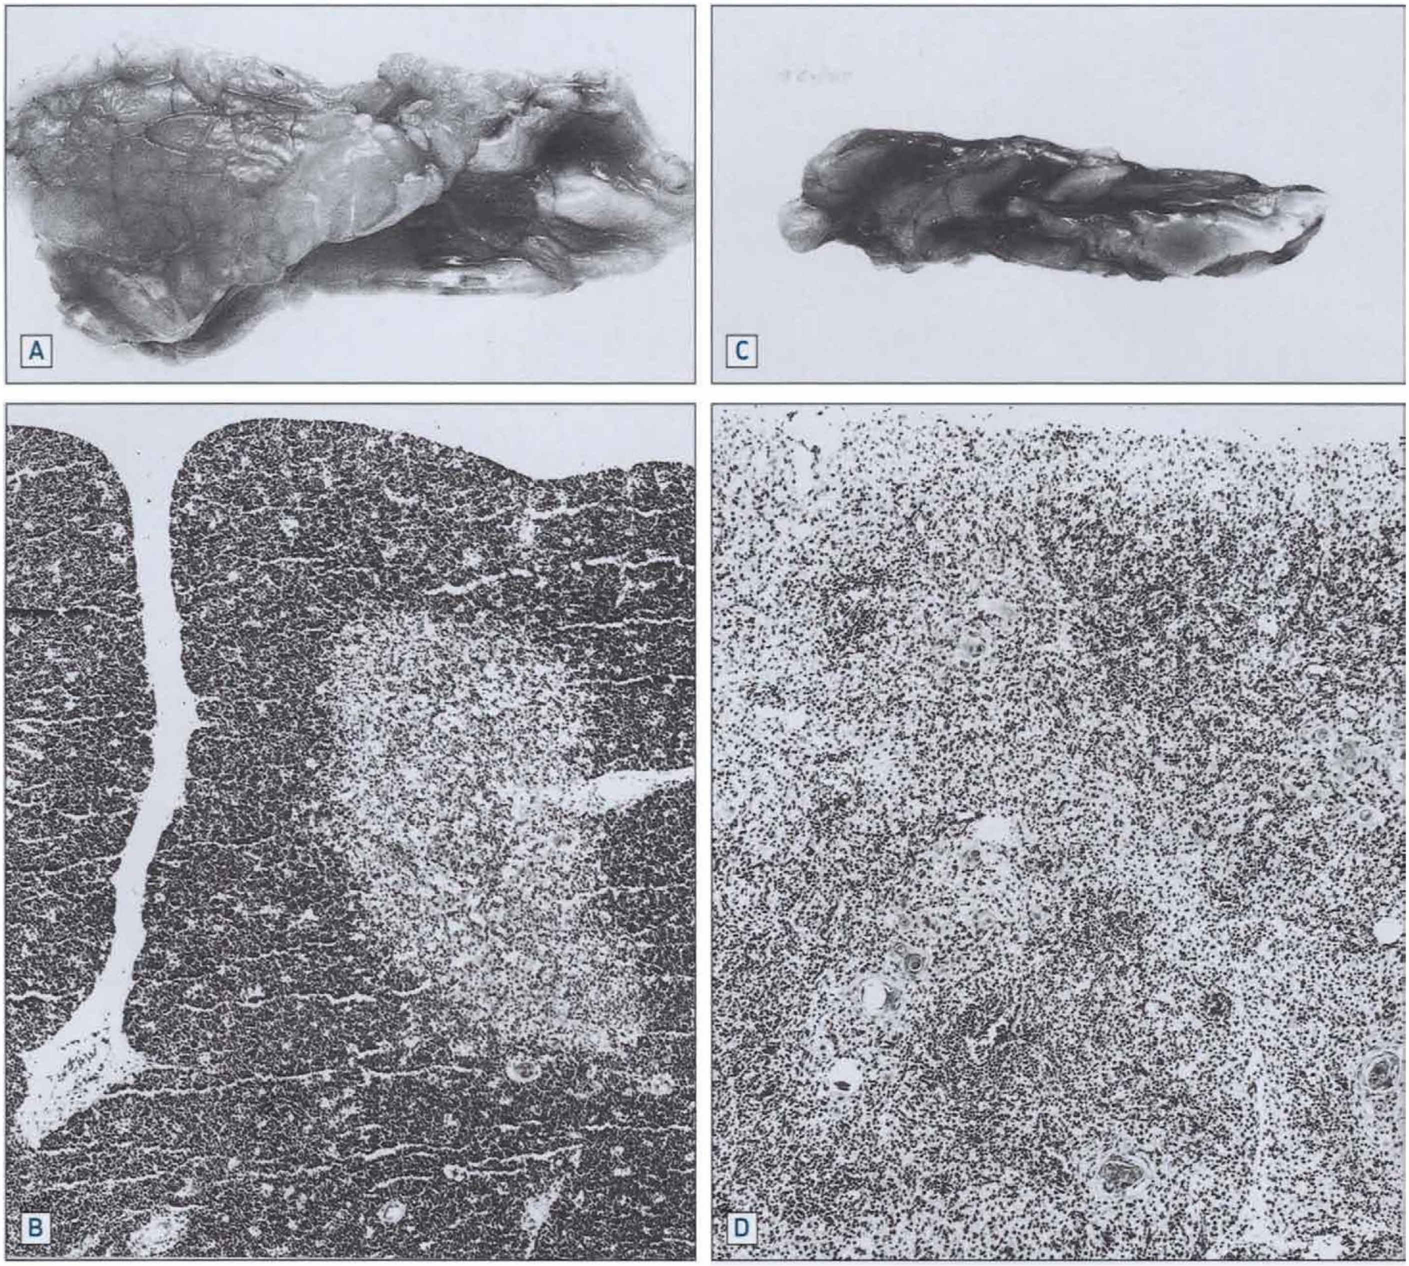

Figure 2.107 A, B. Normal thymus, gross and microscopic, of kitten at 8 weeks of age. **C, D. Degeneration of thymus** in panleukopenia in kitten at 8 weeks of age.

and they may be appropriate hosts for characterization of the virus and development of detection systems.

Infection with ***Bovine leukemia virus*** (BLV) is lifelong but, unlike infection with FeLV, there is no viremia after infection is established, the provirus persisting in the genome of B lymphocytes and macrophages. Chronic infection is characterized by the production of an ever-increasing array of antibodies against the various viral antigens, suggesting that the infection is not stable but continues to evolve with the development of lymphocytosis. An increased cull-rate has been shown for BLV-infected dairy cattle, which suggests that, while the cattle are outwardly normal, the anti-BLV immune response is at some cost to the animal.

A variety of **dietary constituents** can markedly affect thymic form and function, most often as a matter of deficiency. Animals that are *protein- and carbohydrate-deficient* during the adolescent phase have reduced thymic volume and fewer peripheral CD4-positive/CD8-positive T cells. Mice that were *protein- but not calorie-deficient* suffered thymic involution with elevated levels of endogenous steroid, which appeared to be the major mechanism in thymic involution. A number of trace elements including copper, zinc and selenium appear required for maintenance of an adequate immune system. Rats fed a *copper-deficient* diet developed hepatomegaly and increased heart weights with decreased thymus weights and reduction in production of immunoglobulin production and of cytotoxic NK cells.

Infection with *Human immunodeficiency virus* (HIV) causing AIDS is the major pandemic affecting this era. Infection with HIV induces thymic involution, as does infection with SIV in nonhuman primates. In the latter case where serial studies can be carried out,

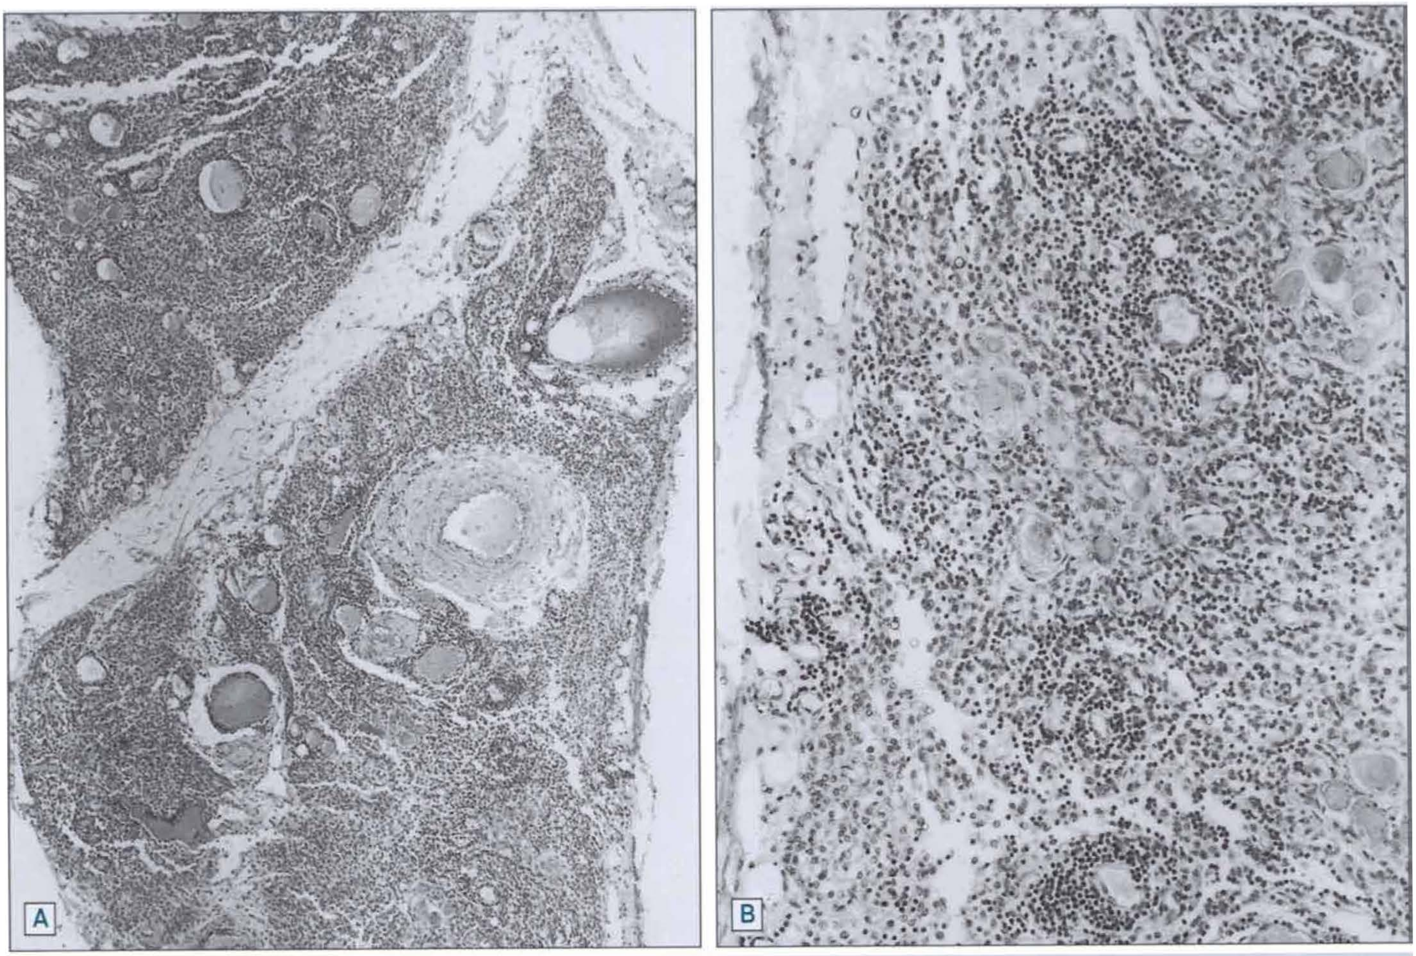

Figure 2.108 Thymic atrophy in feline panleukopenia. **A.** Lobules reduced in number and size. **B.** Proximity of Hassall's corpuscles to capsule indicates degree of cortical atrophy.

thymic involution associated with SIV infection was compared to the effects of normal aging and of stress and social deprivation (orphaned offspring) during the neonatal and adolescent periods. *Normal aging* was found to be associated with retention of the physical size of the thymic capsule with symmetrical atrophy of thymic cortex and medulla with the intervening space replaced by fatty tissue. The definition of the cortical and medullary regions was maintained, but cell division and apoptosis were decreased and there were no changes in general cell types. In contrast, the thymus in an orphaned monkey had severe thymic involution with loss of corticomedullary stratification. The overall thymus was reduced in size with collapse of the capsule and reduction in cellular density in residual corticomedullary areas. In contrast, in animals infected with SIV, there was general loss of thymic size, with condensation and folding of the capsule and apparent thickening of the interlobular septa. There was symmetrical reduction of thymic cortical and medullary areas, with irregular reduction in cellular density. Scattered plasma cells were found in the cortices of aged animals and an increased density in SIV-infected animals, but not in the atrophic thymus of the orphaned animal. The thymic involution associated with SIV infection is also associated with changes in the T-cell complement in the peripheral blood as well as the activity of effector T cells, with subsequent affects on antibody production. *These changes are replicated with considerable similarity due to leukemia virus and immunodeficiency virus infections in cats, mice and cattle.*

Degenerative diseases of the thymus

Thymic involution *is part of the normal process of ageing and may be slowed by dietary restriction or accelerated by toxic insult.* It appears that a high caloric intake promotes early development of the endocrine and immune systems, and that the resulting high level of stimulation to end-organ systems results in an excess of tumor formation in secretory and reproductive organs, and early exhaustion of the immune system. This process may be augmented if a high proportion of the caloric intake is made up of animal fat. When a restricted diet of approximately two-thirds of free-choice intake is given to normal laboratory rats and mice, their lifespan is extended, and the level of spontaneous tumors is reduced. In addition, when animals with an inherited tendency for autoimmune disease are subjected to dietary restriction, a tripling of expected lifespan occurs. Thus, *unrestricted diet appears to increase the incidence of allergic and autoimmune phenomenon in the young and to contribute to early senescence.* It is suggested that these observations are explained by a slowing of the age-associated decline in DNA repair. The improved immune function in old animals maintained on restricted diets may have a similar basis. The recognition that a number of environmental and dietary contaminants may accelerate immune deterioration has resulted in the development of testing protocols specifically designed to assess adverse effects of this nature.

In a general sense, *thymic involution can be used as an index of disease severity and duration in young animals*, in which the organ would normally be much larger.

A further form of thymic involution occurs as a result of exposure to a variety of **environmental contaminants** with the most serious effects being those due to exposure to various forms of *dioxin* and various congeners of the *polychlorinated and polybrominated biphenyls (PCB, PBB)*. Much of the work that has been done in this area was based on a crude product known as Aroclor, which had been widely produced for use in the cooling and insulation of electrical transformers. These compounds are stable in the environment and tend to accumulate in the food chain and contaminate the fatty tissues of humans and free-living species. The various congeners within a mixture contained in Aroclor varied tremendously in their relative toxicity, most of which is directed at the immune system and evident in *marked thymic atrophy and degeneration*. In many ways, variation in toxicity of these various compounds had given conflicting information which permitted some studies to conclude that exposure to chlorinated biphenyls was relatively nontoxic, while others may be extremely toxic and several orders of magnitude more active in inducing target organ injury than other congeners with relatively similar atomic constituents but different molecular structure. In relative terms, the 126 isomer of PCB is approximately 3 orders of magnitude more toxic to target organs in the rat than the 128 isomer, with the 118, 156, 77, 153, 28, and 105 congeners intermediate in toxicity in descending order of effect.

Hyperplastic and neoplastic diseases of the thymus

Thymic hyperplasia

Hyperplasia of the thymus occurs as an increase in volume of a histologically normal gland in the young, as the development of germinal centers in a gland of small, normal or increased size, or as a focal area of cortical hyperplasia in an older animal.

Diffuse hyperplasia may occur in any species, but is most likely to be recognized in calves, rabbits and birds that have been *repeatedly immunized*. Grossly, the glands may fill the cranial mediastinum and extend up the neck in calves. The capsules remain thin and delicate and the lobulation is distinct.

Follicular hyperplasia is the result of fully typical B-cell germinal centers forming, usually at the corticomedullary junction, in glands that may have a variety of other changes including reactive hyperplasia and atrophy. *Follicular hyperplasia is found not infrequently in thymoma*, suggesting some period of immune dysfunction preceding development of tumor. In humans, follicular hyperplasia is strongly associated with *autoimmune disease*, particularly myasthenia gravis, and 85% of patients with thymic lesions have this change. Follicular development occurs in dogs with immune hemolytic anemia and systemic lupus erythematosus but the frequency is not documented. Focal hyperplasia is an unusual and incidental finding in older animals, and is most often seen in rats and mice on lifetime studies where a strict protocol requires that the thymus is routinely examined histologically.

Focal cortical hyperplasia is an appropriate term for lesions characterized by proliferation of cortical lymphocytes in one or more lobules of the gland, usually with compression of surrounding, often atrophic, lobules *suggesting an attempt at regeneration* as is seen, for example, in the exocrine pancreas. The lesions are usually lightly encapsulated, often with some laminar infiltration of the perithymic tissues, and significantly with single epithelial cells scattered through a relatively diffuse area of lymphoid proliferation. Focal hyperplasia of the thymic cortex is visible on architectural or low-power examination by the presence of increased numbers of large tingible body macrophages imparting a "starry-sky" appearance similar to that seen in a reactive germinal center.

Focal medullary hyperplasia is seen most frequently in the thymus gland of rats from various studies and is characterized by a loosely defined focus of cells apparently arising at the corticomedullary junction that is recognizable on low-power examination by increased density due to a greater proportion of small cells than the surrounding thymic medulla. Epithelial cells are present throughout in single cell distribution, but Hassall's corpuscles appear not to be present within these nodules. *Their significance is unclear*, but they do not appear to proceed to thymic lymphoma. These masses do not produce clinical signs and are important primarily in their resemblance to early lymphoma.

Thymic neoplasia

Thymoma *is a tumor derived from the epithelial components of the thymus that is invested to a greater or lesser degree with benign lymphoid proliferation.* It is rare for thymomas to be purely epithelial, and the association of lymphocytes with epithelium, even in metastatic sites, suggests that the latter retains some lymphoid inductive capacity, notwithstanding the malignant state. *Thymomas tend to be slow growing, heavily encapsulated tumors that rarely metastasize.* They may be localized to one lobe, or more commonly a remnant of benign thymus may be found compressed to the periphery of the thymic capsule. Thymomas are classified on the basis of cellular composition and the type and degree of atypia of the epithelium, and thus are *predominantly lymphocytic, mixed, or predominantly epithelial.* The major diagnostic difficulty involves the recognition of epithelium in the lymphocytic type, which distinguishes it from the much more common mediastinal lymphoma. The epithelium may be very variable, but it is usually spindle-shaped in storiform or rosette pattern, vesicular in diffuse sheets, or squamous. The latter type is most likely to appear cytologically malignant and to metastasize.

In general, *lymphoid tumors of the cranial mediastinum* in the cat and bovine yearling are aggressive lymphomas, while in the goat, sheep, and occasionally in the dog, they are encapsulated masses that may cause clinical signs due to their size but rarely metastasize. In humans and likely in animals, there is rarely neoplasia of the myoid cells to form a *rhabdomyosarcomatous mass* which is malignant and metastatic.

Thymic lymphoma

Thymic lymphomas occur in *cats, young cattle and dogs*. In the **cat**, mediastinal lymphomas constituted 22% of 547 cases of lymphoma. Characteristically, the tumors reach a large size with dorsocaudal displacement of the lungs before they are presented for clinical examination. Thymic lymphomas are poorly encapsulated and tend to be traversed by irregular, fine, collagenous septa. It is possible that some of them arise in the cranial mediastinal lymph nodes, but at the time of diagnosis the thymus is obliterated and cannot be dissociated from the tumor. Histologically, two-thirds of feline thymic lymphomas are *high-grade tumors of Burkitt-like (small noncleaved cells) and immunoblastic type with a high mitotic rate.* They often have a "starry sky" appearance due to the presence of many tingible body macrophages associated with a high rate of apoptosis of the tumor cells. There is a wide age distribution of feline thymic lymphoma, with 90% occurring relatively evenly between the ages of 1 and 10 years. Less than 8% are of the *lymphoblastic type*, and true *small cell lymphomas of well-differentiated type* are even less common. Phenotypic studies of a series of feline thymic lymphomas are lacking but it appears that they are *usually T-cell type and CD-positive.* Involvement of the lung, even by direct extension, is unusual, although there may be infiltration into the atria and through the pericardium into the base of the heart and around the origins of the great vessels. Infiltration beneath the sternal pleura is consistently present. Metastases may be widespread, but they are rare and small compared to the mediastinal tumor, suggesting that these lesions spread by local expansion until late in the disease.

Thymic lymphoma in **cattle** characteristically occurs in yearlings of the beef breeds, is not associated with infection with *Bovine leukemia virus* (BLV), and does not share tumor-associated antigens with the BLV induced tumors. Typically, there is swelling, sometimes massive, at the base of the neck, and brisket edema. Bloating and dysphagia associated with esophageal compression are common. The animals are seldom leukemic, although in advanced cases there are usually neoplastic lymphocytes in the peripheral blood without changes in absolute numbers of cells, and tumor cells may be identified in sternal marrow aspirates. The tumors may extend from the rami of the mandibles to the base of the heart with a constriction at the entrance to the thoracic cavity, and may weigh 20 kg or more. They are lightly encapsulated and infiltrate the surrounding tissues, often with smooth, rounded, shiny implants appearing on the pulmonary and parietal pleura. There is compression of the lungs by tumor and excess pleural fluid. The lungs themselves may be focally invaded but are rarely extensively involved. Invasion of the pericardial sac produces pericardial effusion that contains neoplastic lymphocytes in large numbers. On cut surface, the tumors are gray with irregular yellow areas of infarction that have hyperemic borders, and they tend to have coarse collagenous septation. Histologically, thymic lymphomas in cattle have *diffuse architecture with a relatively minor stromal component*, and most of the septation is limited to rather heavy hyalinized bands that may be several centimeters apart. Cytologically, they are *high grade, largely of Burkitt-like (small noncleaved type), and with a disproportionately high number of lymphoblastic types.* All appear to be *T-cell type and CD3-positive.*

The thymic lymphomas of other species, including **dogs** and laboratory animals, do not differ markedly from those in the cat, but there is usually not extrathoracic tumor development.

Lymphoid thymoma

Lymphoid thymomas are seen most frequently in the dog, sheep and goat and rarely in the horse. In **dogs and horses**, the tumors are usually clinically apparent, with the animals presented for examination because of signs of respiratory and/or cardiovascular impairment. In **goats and sheep**, the lesions are usually found incidentally at autopsy. Lymphoid thymomas are irregularly shaped masses from 5 to 15 cm in diameter, with irregular rounded projections, and firm fibrous encapsulation. Grossly, the tumors appear as an exaggeration of normal thymic structure with heavy and irregular fibrous septation. Microscopic cysts are frequently observed, filled with pink proteinaceous material that resembles thyroid colloid. These cysts are branchial duct remnants and have a lining that varies from squamous to columnar and ciliated, and may change abruptly from one form to the other. The corticomedullary distinction is lost, and areas may more closely resemble cortex or medulla depending on the proportion of more pale-staining epithelial cells as compared to lymphocytes; however, the latter always predominate. Hassall's corpuscles are present and irregularly distributed throughout a background of benign but densely packed masses of lymphocytes of medium size. The predominant lymphocytes have nuclei only slightly larger than those of normal cortical thymocytes, and are uniformly interspersed with large lymphocytes with coarse retiform chromatin and prominent central nucleoli. *Lymphoid thymoma is distinguished from lymphoma on fine needle aspiration by the recognition of more regular intermixing of small and large lymphocytes and epithelial cells with pale nuclei and abundant cytoplasm throughout the material obtained.* If epithelial cells are not apparent in the aspirate, the irregular mixing of large and small lymphocytes helps to confirm the interpretation of thymoma. Alternatively, with current capability for immunocytochemistry, the epithelial cells are readily identified if of either round or strap-like configuration by staining for cytokeratin. In *lymphoma*, there is homogeneity of cell type, even if occasional epithelial cells are present. In contrast, in *thymic hyperplasia* the normal separation of cortex and medulla usually results in large and small lymphocytes being clustered separately, which suggests their origin from a tissue with normal corticomedullary distinction. There is *characteristic cuffing of small veins by reticular epithelial cells*, creating a clear space resembling a lymphatic, or the epithelium may invest the vessel with laminated stellate cells with plump vesicular nuclei in an onion-ring fashion. In dogs and cats, lymphoid thymomas may contain prominent *germinal centers*, and plasma cells may be present in their vicinity and along the fibrous septa. In these species, follicular activity in thymomas has a high association with autoimmune disease, particularly myasthenia gravis and less often polymyositis. In contrast, germinal centers are not found in thymomas of goats.

Lymphoepithelial thymoma

Tumors of this type are seen most frequently in the *goat and sheep* as space-occupying lesions. They have firm encapsulation with regular but coarse septation, but with minimal stroma in the pseudolobular areas. The proportion of lymphocytes and spindle cells varies from one area of the tumor to another, with focal predominance of either element. Cystic spaces are frequently present, and there may be large areas of hemorrhagic necrosis. *Hassall's corpuscles are present singly and in cornified clusters*, but tend to be less regularly present than in the lymphoid thymomas. Cytologically the lymphocytes are typical of the larger cells of the outer cortex of normal thymus, with compact chromatin and inapparent nucleoli. The epithelial cells are characteristically stellate or fusiform (Fig. 2.109A, B), with oval nuclei with sharply peripheralized chromatin and small central nucleoli. Alternatively, the epithelium occurs in relatively dense *"epithelioid" sheets* that appears syncytial without apparent cellular junctions, and with irregular appearance of small vacuoles containing small lymphocytes with a relatively large surrounding clear halo. Myoid cells may be absent or occur singly in association with lymphocytes rather than with epithelial areas, and may contain striated fibers. Perivascular epithelial cells are more variable than in the lymphoid thymomas, and may be present as focal clusters adjacent to vessels, arranged in rosettes rather than as perivascular cuffs. Germinal centers are not usually found.

Rarely **primary germ cell tumors**, outwardly resembling seminomas, occur in the thymus gland of male humans and animals in the absence of primary tumor in the testicle. Some of these have possibly been described as clear cell lymphomas if phenotypic identification was not carried out.

The revised WHO classification of hematopoietic and lymphoid tumors includes an entity called *mediastinal large B-cell lymphoma*, which is considered one of the variant types of large B-cell tumors. These lesions occur in the dog, and likely also in the cat, but apparently are distinct from the very large lymphomas that characteristically fill the cranial thorax in that species. The mediastinal B-cell lymphomas have a cytology like centroblastic lymphomas, with multiple relatively prominent nucleoli that tend to be located near the nuclear membrane. These lymphomas are also associated with some quite larger nuclei that are often irregularly lobated or indented, all of which mark convincingly with CD79α staining (see Topographic variants of diffuse large B-cell lymphoma, p. 182).

LYMPH NODES

Structure and function of normal lymph nodes

In the dog, the thymus and spleen are formed at 27–28 days of gestation, and the primordial structures of the largest nodes are present

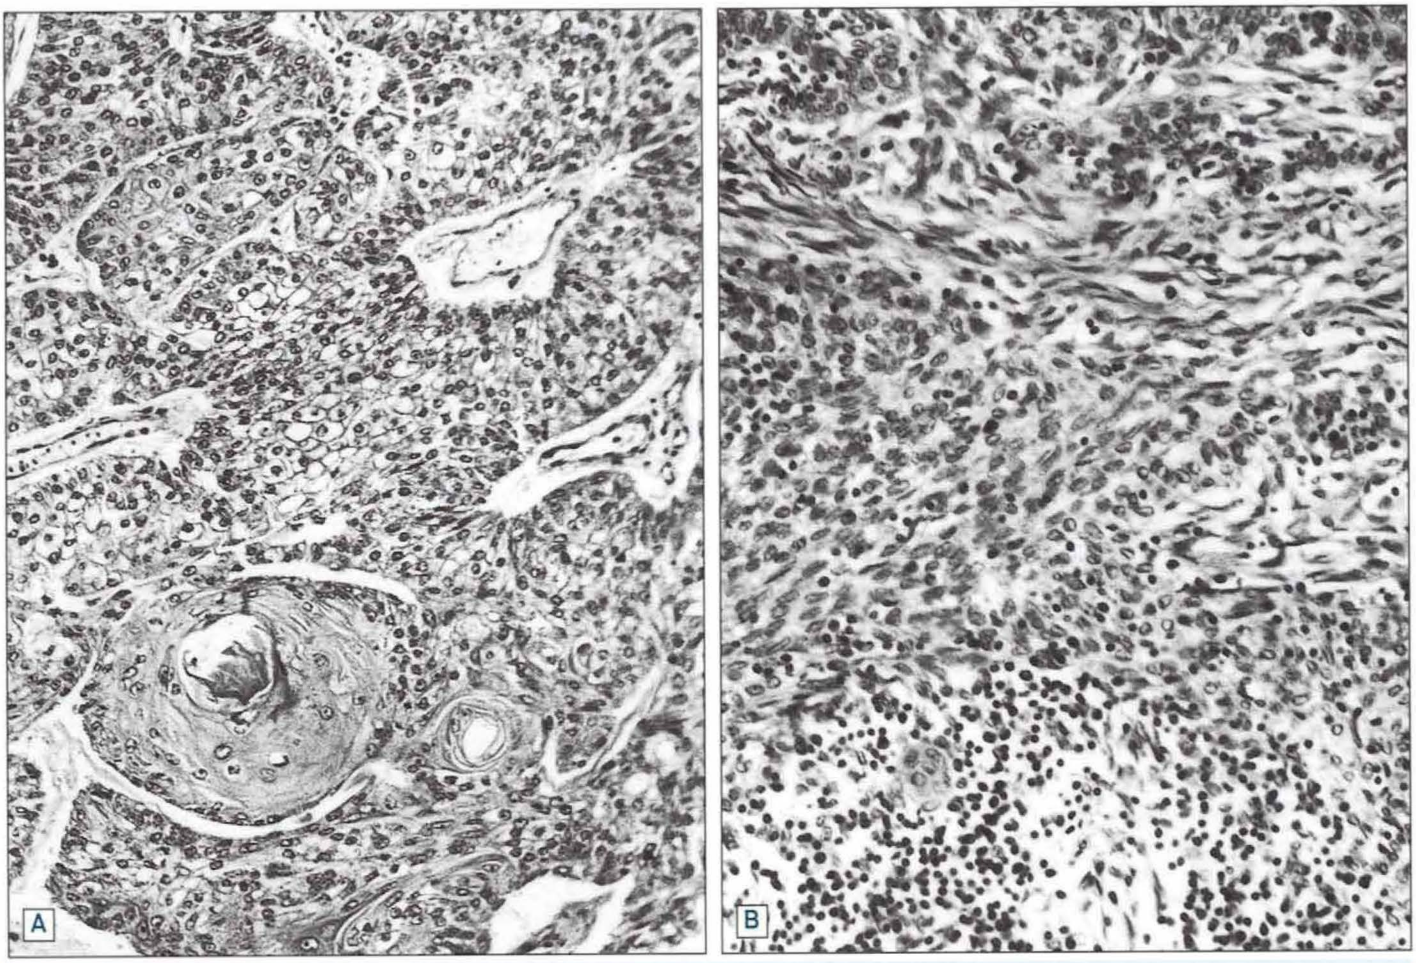

Figure 2.109 A. Thymoma of epithelial type in a dog. **B. Lymphoepithelioma of thymus** to show stromal character of epithelial component in an ox.

at 35–38 days. Lymphocytic colonization of the nodes and spleen is prominent at 52–53 days, and of the thymus at 62–65 days. The lymph node anlage appears to arise from periarteriolar mesenchyme. Lymphatic vessels develop prior to the nodes. At the confluence of lymphatics and arterioles, the lymphatics form cuffs enclosing the arterioles and outpouchings that form the capsule of the primordial lymph node, the hilar area being directed towards the arteriole of origin. As the tissue develops, proliferation of reticular cells within the lymphatic enclosure becomes eccentric to the hilar arteriole, entering the capsule in parallel with the draining efferent lymphatics. The periarteriolar reticular cells form a network that provides an appropriate environment for colonization by thymic and bone marrow-derived lymphocytes.

Lymph nodes, like the spleen, are variably involved in *myelopoiesis* in the fetal stage of development, and convert to *lymphopoiesis* shortly after birth. The actual level of lymph node development at birth varies widely with different species. Calves and foals have well-developed lymph nodes at birth, and may have germinal center formation if there has been intrauterine infection. In contrast, nestlings at birth have readily recognizable lymph nodes in the neck, mediastinal and mesenteric areas; the nodes have a loose reticular structure, very low lymphocyte density, and only limited organization into cortex and medulla.

The **microcirculation** of the mammalian lymph node is closely related to its function, and governs the architectural development of the node. *Afferent lymphatics* enter the capsule and bathe the cortex via the peripheral sinus. *Small lymphatic ducts* perforate the inner capsule of the peripheral sinus and form spherical microanastomotic networks that correspond in size to the germinal centers. On the medullary aspects of these spherical networks, the lymphatics anastomose into larger ducts that drain into the medullary sinuses and then into the major hilar *efferent lymphatics*. In contrast, *blood vessels* both enter (arteriole) and leave (vein) through the hilar region with small vessel arborization in the cortical area. In the outer cortex, small arteries form *meta-arterioles or precapillary arterioles* that perfuse the germinal centers and mantle cell corona. The transition to capillaries occurs at this site, and these vessels then enlarge to form the *postcapillary or high-endothelial venules* (HEV) of the paracortex, across which there is heavy traffic of lymphocytes from the blood to the lymph node parenchyma. These vessels then unite to form progressively larger veins which follow the medullary stroma to form the *efferent hilar vein*. In *pigs*, the cortex and medullary areas of lymph nodes are inverted, but the afferent lymph passes in lymphatics to the center of the node where the germinal centers are normally located. Like other mammals, recirculating lymphocytes enter lymph nodes through postcapillary high-endothelial venules and distribute to T and B areas, and emigrate directly into the peripheral venous system rather than the efferent lymphatics as in other mammals.

The various vascular structures of lymph nodes form characteristic associations with nodal tissue. The *lymphatics* are identifiable as major ducts entering the peripheral sinus but the intranodal lymphatics are not obvious, except for the large medullary sinuses and the efferent hilar vessels. The *arteries* can be identified entering the medullary or hilar area of the node, and they follow the fibrous trabeculae to the medullary sinuses. In this area, the arterioles form a regular and obvious network with the medullary cords, such that the arterioles are centrally placed in the sinuses and connected by a network of reticular stroma to the thin limiting membranes of the medullary cords. The smaller *arterioles* of the paracortex are irregularly visible, as are the terminal arteriolar vessels of the germinal centers and the mantle cell cuffs. In the adjacent paracortex, the *postcapillary venules* are readily identified. *These vascular structures of the blood and lymphatic systems through their interactions form three endothelium-lined compartments, intravascular, intralymphatic and interstitial,* which provide the functional architecture by which the lymph node filters lymph, processes antigen, and returns lymphocytes from blood to tissue.

Functionally, this microcirculatory arrangement directs antigens entering the cortical area in lymphatics to the germinal centers and the outer cortex. The **germinal center** *has a specific polarity directed at the source of antigen,* which in those germinal centers near the outer cortex can directly be seen to be oriented to lymph flow from the peripheral sinus. The germinal center is surrounded by an elliptical cuff of small B lymphocytes that is thicker at the superficial pole region near the peripheral sinus and thinner on the deep pole region adjacent to the deeper areas of paracortex. Within the germinal center itself, the cells in the superficial area have smaller nuclei with more abundant cytoplasm, which produces a lighter staining area on low-power examination. In contrast, the cells in the deep pole of the germinal center have larger nuclei with minimal cytoplasm, resulting in this area having a darker appearance. Within the central area of the germinal center, there are large macrophages that contain ingested apoptotic debris, representing lymphocytes that have undergone somatic hypermutation and have not been selected for further development. Depending on the plane in which the germinal center is sectioned, these large macrophages may form a complete field with a "starry-sky" effect across the circumference of the germinal center. *This polarity of germinal centers is a constant feature of lymphoid tissue in lymph nodes, tonsil, and Peyer's patch,* and is always most readily observed in relation to antigen in those follicles near the peripheral sinus. *Recognition of polarity is an important aspect of differentiating benign follicular hyperplasia from follicular lymphoma.*

Germinal centers that lie deep within the medulla in cases of follicular hyperplasia (Fig. 2.110A) do not have an obvious orientation to the capsule, but it can be assumed that the deep and superficial poles are oriented to the source of antigen and the fine network of lymphatics that drain the peripheral sinus. Paracortical tissue may appear as a solid band encompassing the germinal centers, as is typical of the young. With maturity, paracortical areas irregularly recede and regenerate in loosely defined, but densely aggregated, "*deep cortical units*" (Fig. 2.110B). These units are also defined by cellular composition and vascular supply as are the germinal centers, but, in contrast to the latter, *the deep cortical units are thymus-dependent areas populated by T cells.* There are *gaps* in the inner layer of the outer sinus by which the entering lymph can pass directly to the medullary sinuses. Presumably this route is taken by heavy but nonthreatening flow as occurs when frank blood enters the lymph node during biopsy (red cells appear in the medullary sinuses within minutes of the initiating surgical trauma).

The processing of antigen occurs at random in lymph node cortex but is always associated with a background of **dendritic reticular cells** *that function as antigen-presenting cells of the germinal center.* A portion, if not all, of the follicular dendritic cells arise from Langerhans cells that develop contact sensitization with antigen in epidermal areas drained by the particular lymph node. Langerhans cells in epithelial areas bind antigen relatively inefficiently, but within the germinal centers they undergo maturation in the process of forming tight junctions with other dendritic cells, thus forming a background network for the lymphoid follicles. Blood monocytes cultured in the presence of macrophage colony-stimulating factor (M-CSF) or granulocyte macrophage CSF and IL-4 differentiate without proliferation into CD14-positive macrophages or CD1A-positive dendritic cells. It is believed that this process is repeated in lymph nodes for the *maturation of Langerhans cells to dendritic cells of the germinal centers, and monocytes for differentiation into dendritic cells of the paracortical areas.* The process of B-cell maturation then involves the interaction of B lymphocytes that have undergone immunoglobulin chain rearrangement in preparation for antigen-driven selection by hypermutation. This process takes place with the assistance of T-helper cells and on the basis of antigen presentation in the context of MHC cellular recognition. B lymphocytes bound in this manner are selected for further division, finally to become plasma cells or memory B cells, while those that fail to be bound in the T-lymphocyte interaction undergo programmed cell death and are removed by follicular macrophages.

The dendritic cells of the germinal centers are long-lived and may retain antigen on their surface membranes for weeks or months in the process of antigen focusing, by which the specificity of a germinal center for a specific antigen is maintained. The dendritic cells of the paracortical nodules are also long-lived and, in superficial nodes of humans and cattle, they often contain Birbeck granules characteristic of the Langerhans cells of the skin, consistent with an origin and previous experience in that area. There is functional logic in this arrangement since the follicular macrophages and dendritic cells (B area) are efficient in the digestion and processing of large particulate antigens, whereas those in the paracortex (T area) are more efficient in trapping low molecular weight substances, such as agents producing contact sensitization in the skin, where the resident reticular cells likely had their initial training. *In general, the lymphocytes in the germinal centers are largely B cells while those in the paracortex are largely T cells.* The subsets of T cells are also segregated, but not as cleanly, with the *suppressor and NK cells confined almost entirely to the paracortex,* whereas *the helper cells are largely in the paracortex but also in the germinal centers and their small cell corona of mantle cells.*

The process by which lymphocytes exiting the marrow and thymus are directed to specific tissues is regulated by *homing receptors* on the lymphocytes, called *intercellular adhesion molecules (ICAM),* which bind to tissue specific *addressins* on high-endothelial or postcapillary venules in the peripheral lymphoid tissues. The characteristic development and binding of hematopoietic progenitor cells is mediated by adhesive functions of cell surfaces, called integrins and selectins, which are members of the immunoglobulin superfamily and identified by the CD44 reagent. There are more than 20 types of *integrins,* which are heterodimeric transmembrane proteins, and three major subtypes of *selectins* each with an affinity for various ligands of endothelial cells in different areas of the body. By these means, naive B and T cells leaving the bone marrow are guided to specific areas

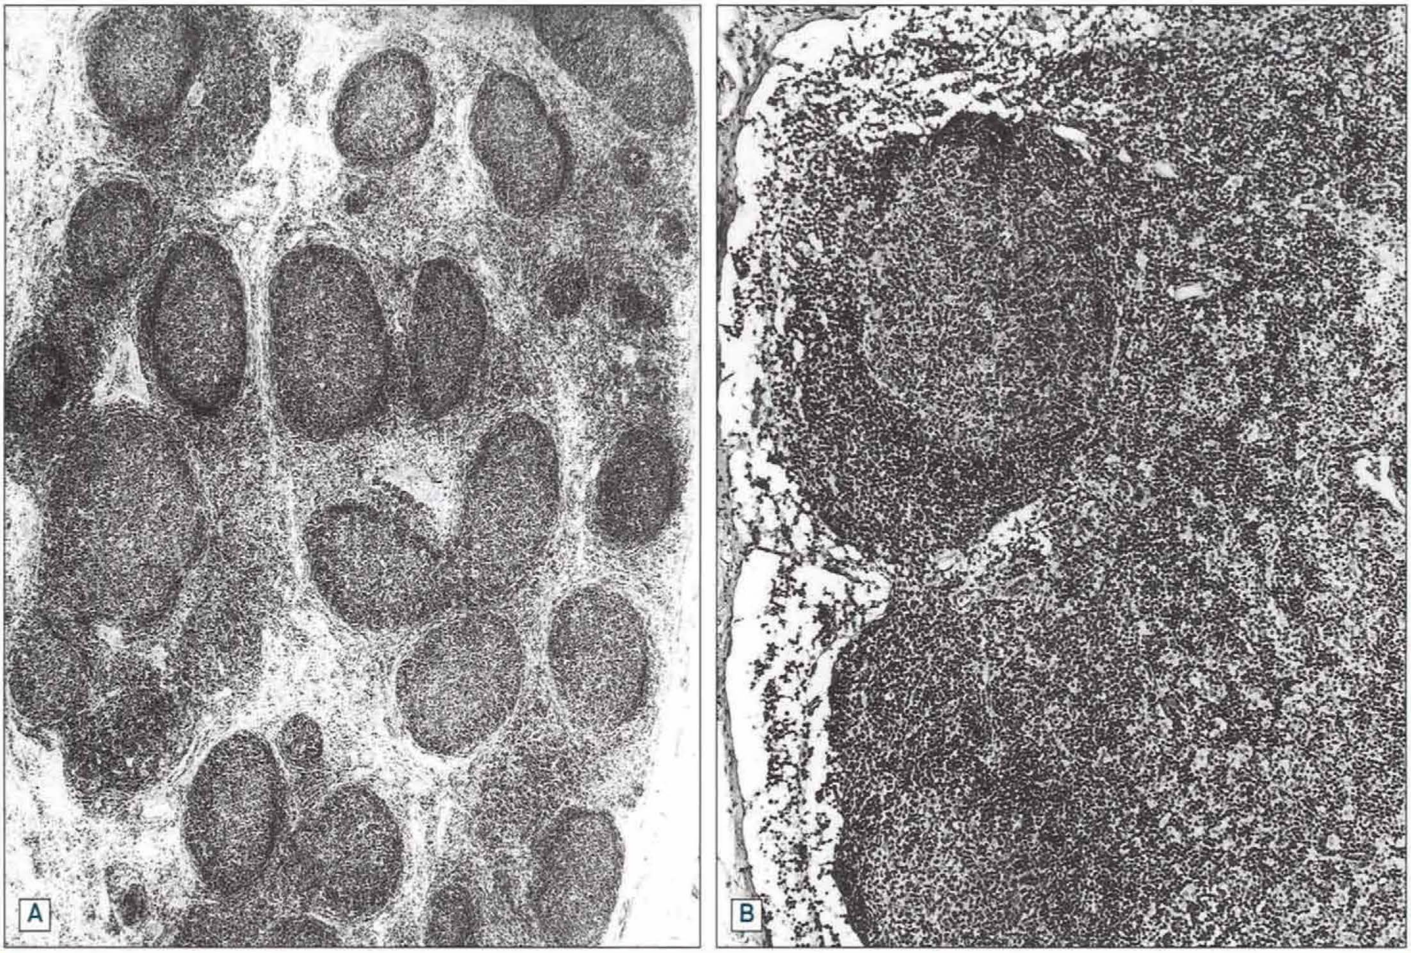

Figure 2.110 A. Follicular hyperplasia in a lymph node of a cat. **B. Paracortical hyperplasia** with typical "starry-sky" effect in stimulated lymph node of a dog.

of maturation in the thymus, intestine, skin and lymph nodes and memory cells are directed to the endothelium of specific tissues. It is worth mentioning in conclusion that *all of the hematopoietic-derived cells resident in lymph nodes are capable of forming malignant tumors including the interdigitating reticular cells.* This is in contrast to earlier concepts that the cells of lymphomas of B- and T-cell types remain relatively confined to the initial site of malignant transformation until late in tumor progression. It is now understood that *neoplastic lymphocytes from either bone marrow or peripheral lymphoid tissues may circulate at low levels early in the development of disease.* Their ability to disseminate is dependent upon the development of cell surface proteins, which mimic those of their benign counterparts, and permit them to bind to endothelium and extravasate to new tissue sites.

The general reactions of nodes to various stimuli are described in the introduction to the lymphomas, and that section is pertinent to the following consideration of non-neoplastic disease involving this tissue.

Degenerative diseases of lymph nodes

The lesions associated with inherited diseases of the immune system are included in Developmental diseases of the thymus. In *severe combined immunodeficiency*, lymph nodes lack both germinal centers and paracortical lymphoid colonization. In *severe T-cell deficiency*, germinal centers are present, as is antibody, but paracortical areas are hypoplastic and the spleen lacks periarteriolar lymphoid sheaths. In *severe B-cell deficiency*, as occurs in agammaglobulinemic foals, germinal centers are not formed in node or spleen, and plasma cells are not found. The paracortical areas have normal cellularity, and cell-mediated immunity is intact.

A strain of black pied Danish cattle, and probably some other European breeds, carries an *autosomal recessive trait for thymic deficiency* (lethal trait A46). The calves appear normal at birth, but by 1–2 months of age they die of disseminated infection that originates in the skin. These calves are able to produce antibody, but *lack cell-mediated immune responses*. The defect appears to be an *inability to absorb zinc* and, if zinc is provided, they recover full immunologic capability and cutaneous signs of zinc deficiency disappear. *Lethal acrodermatitis*, a similar syndrome, occurs in Bull Terriers as an autosomal recessive trait; clinical signs are not relieved by treatment with zinc.

Thymic atrophy develops in an inbred strain of *Weimaraner dogs* that are able to produce antibody but in which cell-mediated responses are depressed.

Developmental diseases of lymph nodes

Cachectic and senile atrophy lead to moderate reduction in the overall size of body nodes. Aging changes are largely limited to mild thickening of the capsule and medullary trabeculae, with reduced density of germinal centers.

- **Senile atrophy** is seldom of note in large domestic animals, and is only seen with frequency in *dogs, cats and primates*. Grossly, senile lymph nodes are small with edematous fascia, and characteristically have dark-brown pigmentation of medullary areas that may extend in decreasing concentration to the subcapsular sinus.
- **Cachectic atrophy** is frequently encountered in *old sheep and goats* with dental attrition. Nodal atrophy associated with cachexia is much more often encountered, and is characterized by retention of the overall architecture with marked reduction in cell density. Germinal centers are small with a hypocellular mantle cell corona, and paracortical areas are sparsely populated. In old animals with cachexia, there are numerous pigment-bearing macrophages in medullary sinuses, and thin proteinaceous fluid may be present in medullary cords and sinuses.

Hemorrhage originating within a node or in tissues drained by the node may be visible in the cortical or medullary sinuses. Red cells delivered to the node through the afferent lymphatics tend to pass through the cortex to the medullary sinuses where they are ingested by macrophages. The breakdown of erythrocytes within lymph nodes results in accumulation of *hemosiderin*, which is always most prominent in medullary areas. In cattle and sheep that die with acute respiratory distress, the cervical nodes are frequently red-black owing to the blood contained in them, much of which comes from the tracheal mucosa where extravasations begin in the lymphoid nodules.

Anthracosis is a regular finding in the pulmonary nodes of *dogs* that live in industrial areas, and is of lesser frequency and degree in cats. The carbon is retained solely in the phagocytes, principally those of the medullary cords, and therefore only the medulla is black. The pigment is inert and of no consequence. An unidentified black pigment, in appearance like melanin, is present in the hepatic nodes of *sheep and cattle* when they have, or have had, hepatic distomiasis. The same pigment occurs in bile ducts infested by *Fasciola hepatica*, and, in the case of *F. magna*, wherever the fluke has wandered.

In **emphysema** of lymph nodes, gas is confined to the sinuses. It affects the mesenteric nodes of swine in association with intestinal emphysema. Emphysema of the bronchial nodes commonly accompanies interstitial pulmonary emphysema of cattle. The lymph nodes are puffy and light. The sinuses are distended and their endothelium is lined by large macrophages and even giant cells, the mobilized cells occurring in small clusters of spotty distribution on the walls of the sinuses.

Lymphoid atrophy, with or without architectural alteration, occurs in a variety of circumstances. Lymphoid atrophy associated with marked dilation of medullary sinuses, termed *vascular sinus transformation*, results from blockage of the efferent lymphatics, and is exacerbated by the development of fibrosis if the venous drainage is also obstructed. These conditions may follow surgical intervention for lymphatic cannulation or occasionally develop in animals that have been recumbent for prolonged periods and suffered concurrent venous infarction of muscle.

Complete or focal infarction of node occurs with lymphoma, and may be the first sign of disease. Infarction is most likely to occur with large-cell lymphomas and, while vascular obstruction appears to be the cause, thrombosis is seldom observed. Infarction with lymphoma is most often seen in the calf form of sporadic bovine lymphoma.

Inflammatory diseases of lymph nodes

Lymphadenitis *results when an infectious agent is present in the lymph node*, as distinguished from *benign lymphoid hyperplasia*, in which the node is immunologically reactive but free of local invasion. Lymphadenitis may result from drainage to the node of the products of a distant inflammatory process that then progresses to involve the node directly. It may be possible to identify the infectious agent responsible for the lymphadenitis or to determine the type of invading agent from examination of the changes in the node (Fig. 2.111A, B).

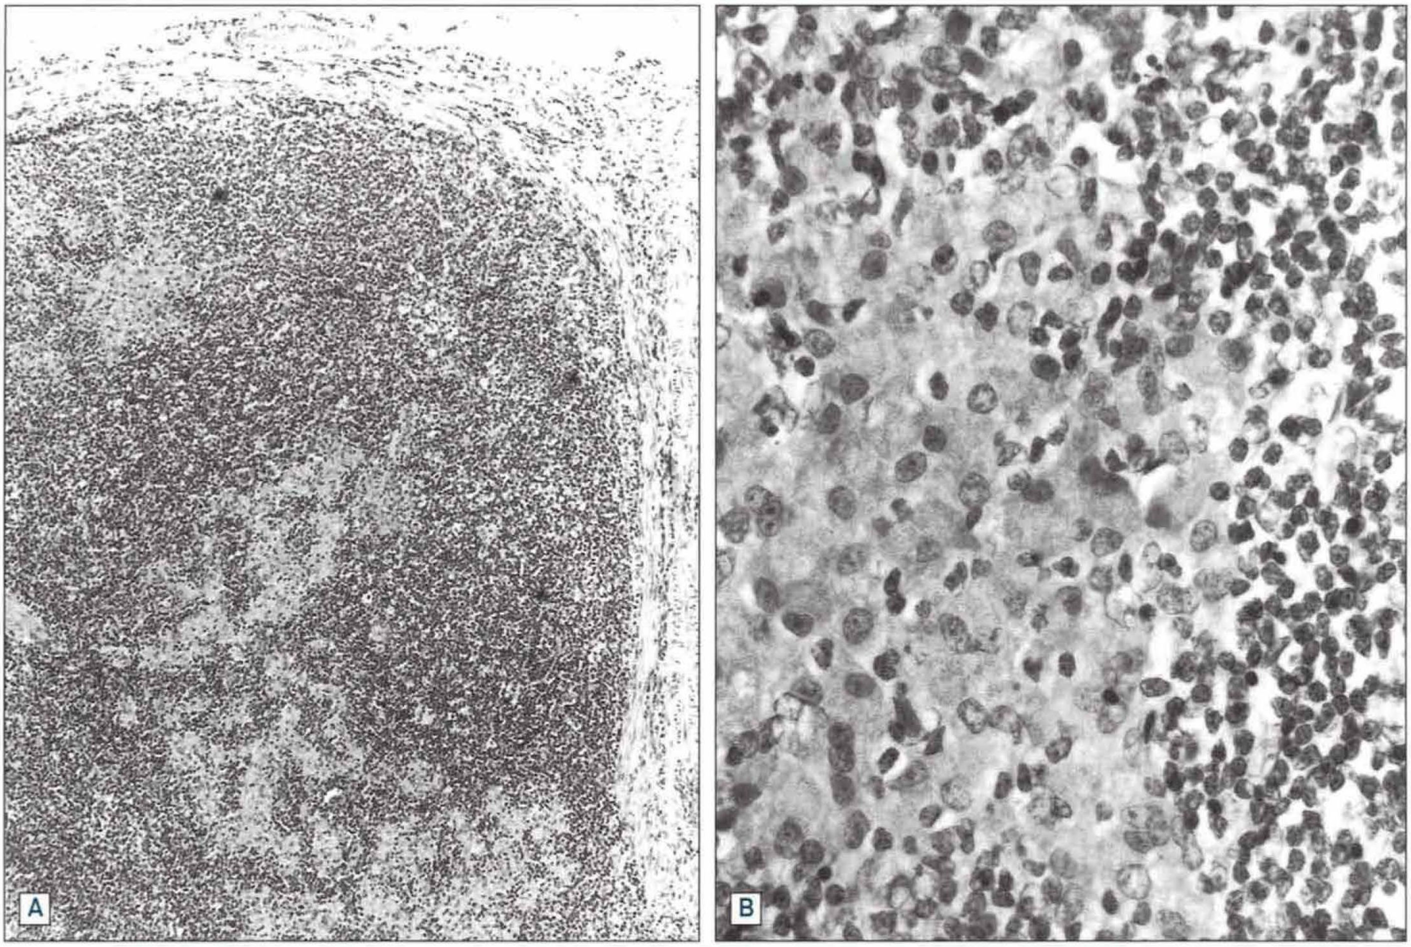

Figure 2.111 Johne's disease in a lymph node of a goat. **A.** Capsule thickened and colonized by inflammatory cells, peripheral sinus narrowed, paracortical hyperplasia. **B.** Epithelioid macrophages of sinuses of (**A**).

Lymphadenitis may be acute or chronic, suppurative, caseous, or granulomatous. These more or less specific types of lymphadenitis are discussed under specific diseases.

Cytologically, **acute lymphadenitis** is characterized by a mixture of small and large lymphocyte types accompanied by neutrophils and eosinophils that may constitute 25% or more of the cells present. Distribution of cell types present, including large macrophages, and the quality and character of the neutrophil nuclei are indicative of the cause of the process, which may be apparent if the phagocytic cells present have ingested bacteria. Characteristically, in lymph nodes involved with blastomycosis, there is a mixed cellular or granulomatous response with the infectious agents often obscured by tightly adherent neutrophils and macrophages. The chromatin pattern of lymphocytes in acute lymphadenitis differs from lymphoma in that large chromocenters persist in small lymphocytes, and larger lymphocytes, which are presumed to be the proliferative population, maintain larger chromocenters in benign conditions but tend to have a more uniform chromatin pattern characteristic of cells in cycle in lymphomas. Needle aspirates from lymph nodes may occasionally yield large numbers of necrotic cells, and it should be kept in mind that focal lymphadenopathy may be due to metastatic tumor.

Grossly in acute lymphadenitis, the lymph nodes are enlarged, soft, locally mobile and hyperemic to a variable degree. The capsule is taut and thinned due to the influx of cells, and on the cut surface the parenchyma bulges and exudes blood and lymph, but mainly the latter. Thus, if imprint preparations are made, it is necessary to repeatedly remove the exuding lymph from the cut surface in order to obtain enough adhesion for cellular exfoliation. There may be focal discoloration due to previous pigmentation or to infarction.

Histologically, acute lymphadenitis is characterized by marked hyperemia with unusual prominence of small vessels in cortical areas. Neutrophils are often present, both through drainage from the subcapsular sinus and by migration from the postcapillary venules. Some useful distinction can be made between granulocytes arriving from these two sources. In general, neutrophils in the peripheral and medullary sinuses indicate inflammation in the tissue area drained and are not necessarily indicative of local sepsis. On the other hand, foci of neutrophils in cortical areas are of hematogenous origin and almost always are reactions to bacterial colonization, as is likely to occur in the mesenteric node in bacterial enteritis. When the inflammation is due to one of the pyogenic organisms, abscessation is likely. Necrosis in lymph nodes is an attribute of some acute infections, such as salmonellosis and toxoplasmosis (Fig. 2.112).

In **chronic lymphadenitis**, hyperemia and edema are irregularly present, and the infected nodes are large and firm, and may be fixed to local tissues if there has been cellulitis. The capsule is thickened as

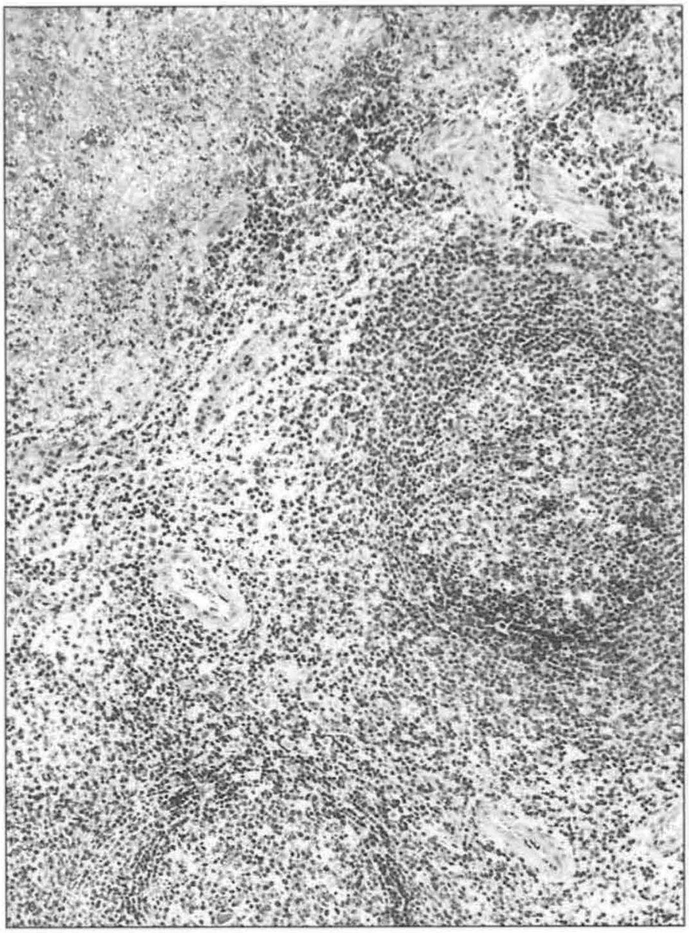

Figure 2.112 Acute lymphadenitis with subcapsular necrosis, in toxoplasmosis in the lymph node of a cat.

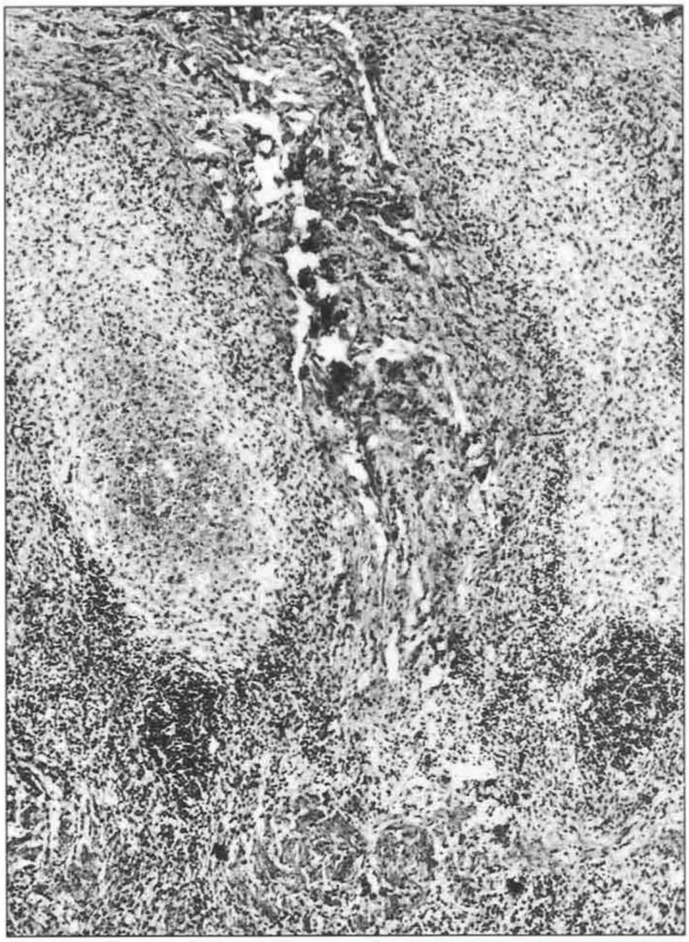

Figure 2.113 Lymphoid follicular necrosis in intestine, in parvoviral enteritis in a dog.

are the internal trabeculae, and with prolonged inflammation the node becomes dry and hard. Changes of this type are characteristically present in the supramammary lymph nodes of cows with brucellosis of long standing, and to a lesser extent in animals with chronic or recurrent bacterial mastitis. In the latter cases, the marked proliferation of the collagenous septa of the medulla may completely displace the medullary cords.

Lymphadenitis may be expressed by changes that are largely degenerative and affect the architecture of the tissue. Thus in some acute viral infections, there is rapid lysis of lymphocytes, as in *canine parvoviral infection* (Fig. 2.113) and in *rinderpest*. In *salmon poisoning* of dogs, the nodes may be much enlarged with follicular hyperplasia and accumulation of macrophages (Fig. 2.114A). In some chronic infections, particularly with the viruses causing immunodeficiency, the nodes are atrophic with wrinkled capsule and depletion of lymphocytes, and with sinus histiocytosis if the production of monocytes by the bone marrow remains competent (Fig. 2.114B).

Parasitic infestations of lymph nodes

The lymph nodes are not a final habitat for any nematode, but some species traverse them in migration and some lodge there accidentally. The larvae of *lungworms* travel by lymphatics from the intestine to the lungs but cause little injury in the course of these migrations. The first-stage larvae of those lungworms that reside in the alveolar spaces, *Muellerius* spp. and *Protostrongylus* spp. particularly, often find their way to the bronchial nodes and there produce granulomatous lymphadenitis. The nodes become enlarged, hard and irregular, and have many firm granulomas and encapsulated caseocalcareous nodules. The larvae of *Strongylus* spp. in horses occasionally produce hemorrhagic lymphadenitis of the abdominal lymph nodes that, when secondarily infected, may suppurate. *Larval trematodes*, probably *Fasciola hepatica*, are often found in the mesenteric nodes of ruminants, as are larvae of *Oesophagostomum columbianum* in sheep. Nodules develop in the cortex or medulla, as well as in capsular tissues. They are 2–5 mm in size and contain yellow-green pus, which in older lesions becomes caseous and calcified. The pus is largely the debris of eosinophils and it is surrounded by giant and epithelioid cells and a well-defined capsule. A very similar lesion is produced by the larvae of *Linguatula serrata*. The larvae of this parasite (see Vol. 2, Respiratory system) are, in some countries, very common in the mesenteric nodes of sheep and cattle. Viable larvae can be found in normal nodes, but usually the nodes show focal or diffuse hyperplasia and edema, with the larvae lying in cavities that contain a milky fluid resembling chyle. Apparently, the larvae die in the nodes and become encysted in abscesses, which may calcify. In active cutaneous infestations by *Demodex* spp. in dogs, the parasite is often found in the peripheral lymph nodes.

Hyperplasia of lymph nodes

Lymphadenopathy *is defined as a regional or generalized lymph node enlargement of unknown or unspecified cause.* **Lymphadenosis**, while not commonly used, more correctly defines generalized lymphoid hypertrophy, which the former term is used to indicate. *Local enlargement* usually reflects a pathologic process limited to the drainage area, particularly inflammatory or neoplastic disease. *Generalized enlargement* of lymph nodes is a more serious finding, since the possibility of primary tumor is much more likely. Infectious causes of generalized lymph node enlargement include tuberculosis, brucellosis, and protozoal infections. Generalized lymphadenopathy produced by an extraordinary degree of paracortical blastogenesis is typical of the early phases of malignant catarrhal fever and theileriosis in cattle. There may be mild generalized lymph node enlargement in adrenal atrophy, and lymphoid hyperplasia to some degree is transient in most young animals. Endocarditis or abscessation may cause generalized lymphadenopathy, as will lymphoma. In general, in acute septic inflammation the lymph nodes are normally mobile within the subcutaneous tissues, but may become fixed with chronic sepsis. Similarly, lymphadenopathy due to lymphoma usually does not cause fixation of the glands in the early stages, but there is usually perinodal colonization with loss of mobility in advanced stages.

The *cytologic picture* in benign lymphadenopathy is variable, with small and large lymphocytes, with cleaved and noncleaved nuclei, and macrophages, plasma cells and neutrophils. Unless the stimulation is less than 10 days old, this mixture of cells should be organized architecturally with evidence of follicular development. In contrast, in primary tumor there tends to be a monomorphic or bimorphic cell population and, in animals in which follicular lymphomas are uncommon, *finding a monomorphic cell population with diffuse architecture suggests lymphoma.* In primary tumor, macrophages may be present, and numerous if there is a high mitotic rate in the tumor and a high rate of cell death. In contrast, plasma cells and neutrophils tend to be less numerous than in lymphadenitis, although the presence of plasma cells in itself is no guarantee of a benign reaction. *The most important criteria for distinguishing lymphoma from hyperplasia are the integrity of normal architecture and the uniformity of cell and chromatin type.* Architecturally, the peripheral sinus is preserved, even in reactive states where there is perinodal colonization by benign lymphocytes. In contrast, the outer sinus is regularly encompassed and destroyed by even low-grade lymphoma of advanced stage.

In terms of the chromatin pattern, *benign and reactive lymphocytes have less internal nuclear detail than their malignant counterparts* and will have a variable amount of chromatin contained within large chromocenters irregularly distributed throughout the nucleus. In inflammatory disease, the chromatin tends to have a fine gradation from light to dark areas, which includes lightly stained but not clear areas. The nucleoli characteristically have a uniform rimming of aggregated chromatin, which makes them appear unusually prominent. In lymphoma, large chromocenters are fewer, and the chromatin pattern tends to be monotonously similar, most often with a retiform or branched pattern with heavy chromatin bands and irregular clear areas, as occurs in the small noncleaved and large cell tumors. Large-cell lymphomas of the centroblastic, and more particularly, the immunoblastic type, tend to have vesiculated nuclei that appear larger because of the internal parachromatin clearing, and prominent and often irregular peripheralization of chromatin causing apparent irregular thickening of the nuclear membrane. In neoplastic lymphocytes, the chromatin aggregations on nucleoli are irregular and discontinuous. Less commonly, tumor cells have cribriform or uniform chromatin patterns without chromatin aggregation, as occurs in lymphoblastic lymphoma. There is more variation in nucleolar size, shape and number in malignant nuclei than in benign nuclei.

One of the most difficult distinctions is between diffuse hyperplasia and lymphoma, and in these cases the decision must be based upon both the architectural changes and the character of the cells interpreted in terms of the history and clinical signs. In the early, marked, immune response, there will be diffuse parafollicular hyperplasia with effacement of pre-existing follicles. The paracortex has a moth-eaten appearance due to the mixture of cells present, which includes many large macrophages and pale dendritic reticular cells. Lymphomas of the T-cell-rich B-cell (diffuse mixed) type have in some proportion small-cleaved and large cells in every field, with the latter benign population predominating. *There are no lymphomas with three or more lymphocyte types regularly present*, and this fact tends to assist in correctly interpreting the early diffuse lymphoid proliferations. If a firm decision cannot be made, it is fully justifiable to request a repeat biopsy in 10 days, at which time a diffuse benign reaction will have developed a follicular pattern.

In **follicular hyperplasia**, even with extension of follicles to the medullary areas, there will be preservation of a narrow but intact mantle cell corona and at least a narrow band of paracortex between the follicles. In contrast, in **follicular lymphomas** the follicles tend to appear "bare" as a result of mantle cell and paracortical atrophy. Follicular lymphomas are composed of cells that are cytologically similar but of different density. In contrast, in follicular hyperplasia, there is marked variation in cell type across the diameter of the follicle as described earlier in regard to the *antigen-oriented polarity of the normal germinal center.*

Some of the more difficult distinctions between hyperplasia and primary malignancy of lymph nodes must be made in hyperimmune diseases. *Eosinophilic myositis* causes a remarkable alteration in lymph nodes with generalized sclerosis and thickening of the capsule, which is irregularly colonized by small lymphocytes and eosinophils in linear arrays, and marked thickening of the cortical and medullary trabeculae. There is diffuse follicular hyperplasia with paracortical atrophy and medullary cord hyperplasia with prominent plasma cell accumulation (Fig. 2.115A, B). Germinal centers vary markedly in size and shape and have accentuation of the large and small cell layers, and sinuses contain a dense matrix of epithelioid macrophages and eosinophils. Eosinophils are also prominent throughout the collagenous trabeculae. *Brucellosis* and *trypanosomiasis* present no problem in distinction from cancer, and result in a regular picture of follicular hyperplasia followed by paracortical atrophy, with generalized sclerosis and medullary cord hyperplasia.

An unusual type of follicular hyperplasia occurs in *old sheep and goats* that are in poor condition and may have been destroyed due to debility. There is regular capsular thickening and increased prominence of medullary trabeculae. The follicles may be very large, angular and facetted in an irregular fashion. Paracortical atrophy is marked, and there is medullary cord hyperplasia and empty medullary sinuses. The most marked changes affect the follicular vessels, which are large, tortuous arterioles with hyalinized media and often mineralized endothelium. The follicular centers include large epithelioid macrophages and often a very marked tingible body reaction. This reaction resembles *angiofollicular lymph node hyperplasia of the hyaline vascular type* as it is described in humans.

A *nodular reaction of the paracortical areas* occurs in lymph nodes draining malignant tumors as well as other conditions, and appears to represent an exaggerated thymus-dependent response. The nodules may be multiple and coexist with follicular atrophy, raising concern that they represent a multifocal diffuse lymphoma. *The nodules represent deep cortical units.* They are centered on networks of dendritic reticular cells and are densely cellular, but with the cytologic variation in cell type characteristic of paracortex. These paracortical nodules, unlike germinal centers, are irregularly defined from the surrounding paracortex by a lighter staining border of larger pale-staining dendritic cells and macrophages and fewer small densely stained lymphocytes.

A *distinctive peripheral node hyperplasia of young cats* is illustrative of the difficulty in separating strong reactive hyperplasia and neoplasia. It is usual in these cases, which range in age of onset from about 6 months to 2 years, for all peripheral nodes to be enlarged. The nodes are firm with smooth capsules and yellow-tan to white on cut surface. The architecture is severely distorted with loss of discernible trabeculae and of subcapsular, trabecular and medullary sinuses. Cortical lymphoid follicles may be many and large and in some areas they are encroached upon and partially obliterated by the expanded paracortex. The paracortex is comprised of a mixture of lymphocytes, blast cells, histiocytes and plasma cells with abundant mitoses and starry-sky appearance. The paracortical expansion may involve the capsule and adjacent adventitial tissue. High-endothelial venules are prominent in the paracortex. *The cause of this lymphadenopathy in cats is not known.* Recovery is expected after a course of variable duration. A similar lymphadenopathy can be caused by feline leukemia virus infection, as an unusual response to that virus. Argyrophilic intracellular bacteria are described in some of the spontaneous cases of lymphadenopathy but their nature and role remain to be determined; of interest is the morphologic similarity of these organisms to those described in humans affected by cat-scratch disease.

One of the more common indications for lymph node aspiration in dogs and cats are those associated with *chronic dermatitis or otitis.* Lymph nodes draining areas of pigmented skin that have been chronically inflamed frequently contain melanin-bearing macrophages in the outer cortex and these are frequently present in aspirates of draining nodes. Cytologically, *the melanin granules in melanocytes and macrophages from benign sources are of uniform size, shape and pigmentary density, and in the dog resemble tiny rice grains.* In contrast, melanin granules that are associated with pigmented melanomas are markedly

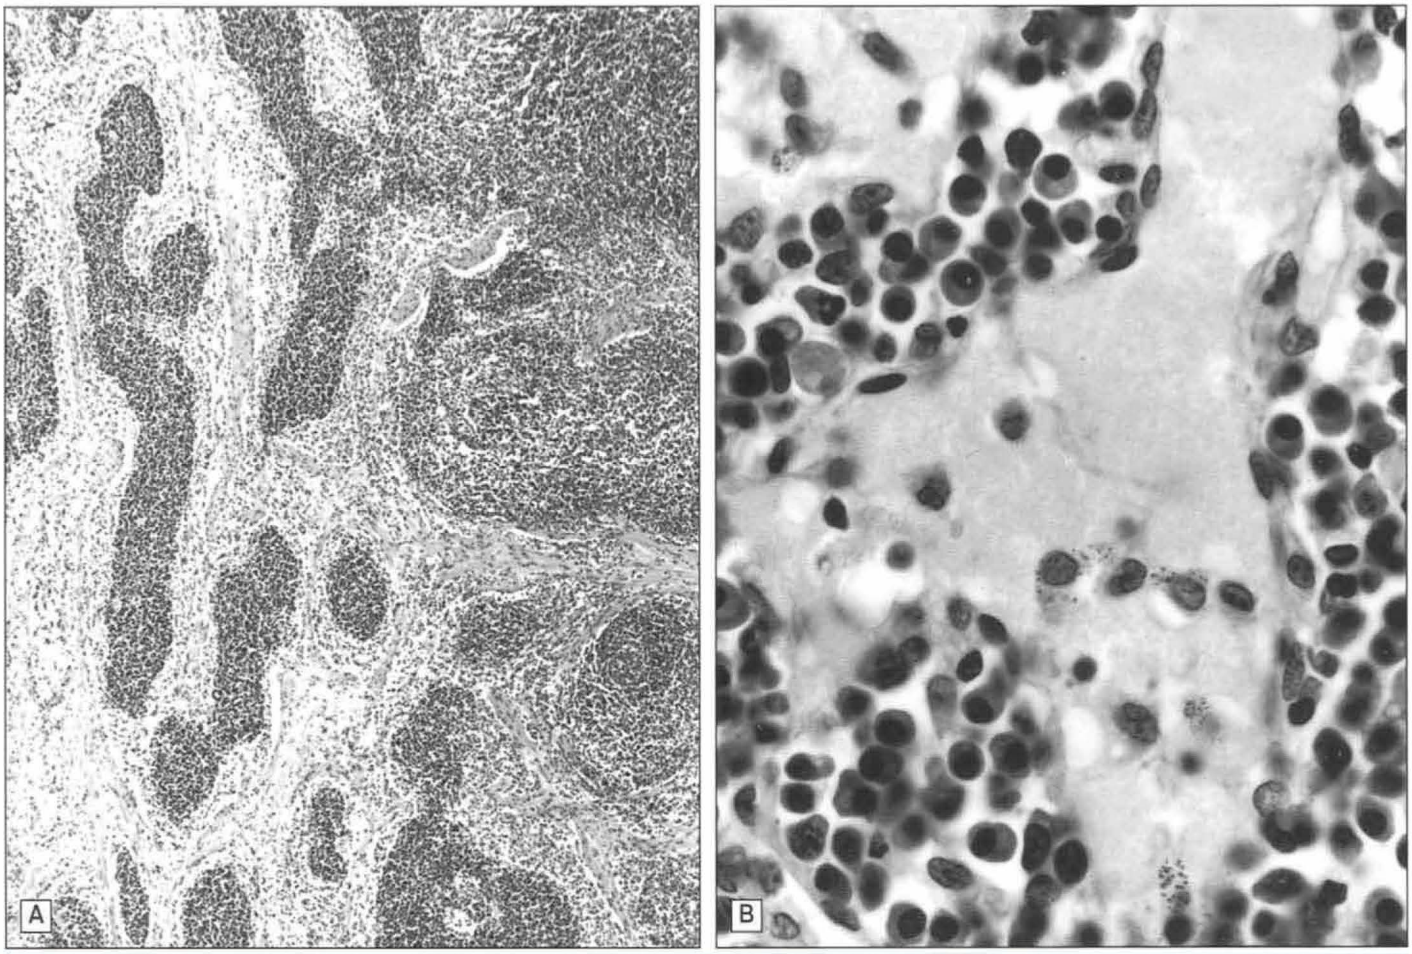

Figure 2.115 Medullary cord hyperplasia, lymph nodes. **A.** Characteristic of chronic immune response. Cords are sharply defined by high density of small lymphocytes and mature plasma cells. **B.** The sinus macrophages contain small granules of hemosiderin in a dog with leishmaniasis.

variable in size, shape and staining density and are more likely to be associated with a sclerotic reaction in the node.

Neoplastic metastatic diseases of lymph nodes

The general reaction of lymph nodes to nonlymphoid cancer is atrophy of greater or lesser degree due to the systemic effects of cancer, apparently mediated by tumor necrosis factor. If the tumor causes inflammatory drainage to local nodes, these will have changes of *reactive hyperplasia and lymphadenitis*, as occurs in mesenteric nodes draining an area of ulceration due to carcinoma. It is significant that the specific reaction of local nodes to local tumor is usually little more substantive than that of nodes distant from the primary site of malignancy.

In general, *the response of local nodes to adjacent cancer is sinus histiocytosis*, and it has been felt that the strength of this reaction is as important to the prognosis in a given case as the characteristics of the tumor itself. *It is therefore part of the nature of the malignant process that the nodes are not more reactive and that the malignant clone was permitted to survive and spread.* Direct evidence of this process may be seen in dogs with mammary carcinoma where the inguinal and axillary nodes are usually buried in fat and hard to find unless enlarged due to growth of metastases. Normally, these nodes are thin, oval and discoid, and only 3–4 mm in thickness, and are identified by medullary pigmentation. Histologically, the capsule is lax and undulating and the peripheral sinus wide and poorly cellular. There is little follicular activity, paracortical atrophy with a few small deep cortical units that do not alter the depth of the node, and relatively empty medullary cords and sinuses. If metastases are present, they will consist of single cells and small clusters in the peripheral and medullary sinuses. The tumor cells appear to pass through the cortex to the medulla through the cortical gaps, and largely avoid processing through the cortical system of antigen surveillance. The sinus macrophages do not appear to be specifically attracted to the tumor cells, even when they invade the cortical parenchyma. Indirect evidence for the mechanism of this restrained lymphoid response has been found in that nodes draining an area containing melanoma (one of the more highly antigenic tumors) have an increased level of suppressor cell activity which presumably damps down the local defensive responses.

In human pathology, there is considerable interest in the concept of *sentinel node detection* in order to determine the lymph nodes most likely to be indicative of spread from an adjacent carcinoma. These studies are related to areas such as the axilla and mesentery where nodes may be small and multiple and embedded in fat and inobvious on surgical excision. Lymphatic mapping strategies have been devised using radio-labeled colloids to define drainage areas from a particular anatomic site. An immunohistochemical stain for cytokeratin on nodes draining an area of carcinoma easily and dramatically demonstrates single cell metastases as well as the often very subdued cellular reaction to them.

There are minor variations in this reaction with specific tumor systems. Highly secretory *adenocarcinomas* may have more reaction to their secretion than to the tumor cells themselves. *Metastatic mast cells* cause the same reaction in nodes as in primary sites, but tend not to incite a strong cellular and stromal reaction even when highly granulated. As noted earlier, the medullary cords of lymph nodes form a tissue–vascular boundary similar to marrow, and extramedullary hematopoiesis will colonize these sites.

Similarly, in *myeloid leukemias* the tumor cells colonize the medullary cords and, as in marrow, the benign cells are displaced, in this case to the adjacent medullary sinuses. In the acute myeloid leukemias, the primitive tumor cells have round nuclei and resemble the surrounding residual lymphocytes, making recognition of the metastatic disease difficult with oversight stains. Diagnosis is aided by the identification of megakaryocytes in either the cords or sinuses since, if conditions in the marrow are conducive to extramedullary colonization, it is likely that both malignant and benign stem cells are displaced and that the benign system will have trilineage progeny.

The most difficult metastatic tumor to recognize in a lymph node is a tumor of lymphoid origin. In situ lymphoma is rarely observed, but appears occasionally in nodes collected from abattoirs, suggesting that the animal affected was culled for poor performance even though the tumor was undetected. These cases provide a unique opportunity to observe the effects of lymphocyte homing in practical application. Lymphoid tumors represent clones of cells "frozen" in some state of maturation, either primitive for the high-grade tumors, or relatively mature for the low-grade lymphomas. The *lymphocyte-homing receptors* vary in their expression directly with the degree of lymphocyte maturity. There is, however, marked heterogeneity of homing receptor expression within a given histologic category of lymphoma. Thus those large-cell lymphomas that have well-developed homing receptors tend to be widespread at diagnosis because the tumor cells are able to bind to "*addressins*" on the *high-endothelial venules* of lymphoid tissue throughout the body and subsequently invade locally. In contrast, animals with large-cell lymphomas possessing poorly developed homing receptors tend to be presented with localized disease, since although the tumor cells may be in circulation they are unable to bind to endothelium in a site conducive to colonization. As would be expected, these interactions are complex and, while some primitive lymphomas, such as those in the mediastinum, may become very large locally without widespread dissemination, others such as the follicular lymphomas (Fig. 2.116) which tend to be clinically indolent have no, or low, levels of homing receptor but disseminate widely. The recognition of these receptors provides a logical mechanism for the observation that some lymphomas, such as the mucosal-oriented tumors (MALT, BALT), remain localized for long periods and may be best handled by surgical removal. In cattle, the effects of these homing tendencies are likely demonstrated by the plasmacytomas that convert whole nodes to medullary cords, and by the large-cell lymphomas where the tumor cells are recognizable by nuclear cleavage and are confined to the medullary sinuses, while the benign large cells occupy the cords.

SPLEEN AND HEMOLYMPH NODES

The **spleen** *can be defined as a hematopoietic organ which filters blood through a sinusoidal system.* In contrast, **lymph nodes** *are part of the same organ system with capability for filtering lymph through sinusoids.* The vascular system of the spleen consists of arteries, veins and efferent, but no afferent, lymphatics. As a consequence, all antigen reaches the spleen through the blood, which determines that primary sensitization and antibody production take place in the spleen only if the first contact with antigen occurs by hematogenous sensitization. On subsequent challenge, the germinal centers of the spleen play an important role in the humoral anamnestic response, both by local production of antibody and by the provision of committed B memory cells to the peripheral lymphoid organ. The clearance of bacteria from the blood by the spleen predominates only if systemic opsonization is deficient. In other circumstances, the clearing appears to occur mainly in hepatic Kupffer cells. Thus, *splenectomy increases susceptibility to a number of blood-borne infections*, including septicemia and protozoal infections such as malaria, anaplasmosis, and hematotrophic mycoplasma infection (hemobartonellosis).

The **blood circulation of the spleen** is central to its function and consists of arborizing arterioles that terminate in the *penicilliary radicles*. As the arteriolar system of the spleen branches, the smaller muscular vessels become ensheathed with a cuff of T-cell lymphocytes forming the *periarteriolar lymphoid sheaths*. Irregularly along the length of these sheathed vessels, the lymphoid tissue widens eccentric to the arteriole and forms the B-cell derived germinal centers (Malpighian bodies). The germinal centers are supplied by a thin-walled branch of splenic sheathed arteriole providing both sustenance and antigen to the germinal centers. The germinal centers are surrounded by a *narrow cuff of small lymphocytes* analogous to the mantle cell layers of lymph nodes. Outside of the mantle cell cuff is an area of marginal zone cells that may vary from inobvious to a well-defined corona of larger cells with more abundant cytoplasm. The germinal centers are sheathed with definite boundaries by a narrow band of flattened connective tissue-like cells in rats and New World monkeys but not in other mammals. The sheathed arterioles at their termination form an arborization of penicilliary vessels that are ensheathed by a few plump reticular cells that form a potentially *contractile ellipsoid*. Under normal circumstances, the spleen functions largely as an "open" system with the blood from the penicilliary vessels entering more or less directly into large adjacent venous sinuses that drain into the splenic veins. Thus, normally almost all of the blood delivered to the spleen passes directly to the venous system, while as little as 3% perfuses the splenic cord areas where sorting and processing by the macrophages is carried out to remove effete or injured red cells. The flow rate through the spleen is relatively large and even with this low sorting fraction, *all of the blood passes through the splenic cord system once per day*. With increased arterial flow, or decreased direct drainage to veins, the spleen functions as a "closed" vascular system in which the penicilliary arterioles discharge largely into the Bilroth cords, and thus a much greater fraction of the arterial flow passes through the sinusoidal filter.

The structure of the **sinus walls** is central to the filtering function. They are composed of elongated endothelial cells that are irregularly supported by encircling reticular fibers, like the staves and hoops of a barrel. Adjacent endothelial cells are not joined by junctions, and they therefore form a lattice-work through which blood cells readily permeate to pass from the functional Bilroth cord, or filtering area, back into the venous or systemic circulation. The Bilroth cord/sinus areas or "*red pulp*" of the spleen consist of a system not unlike the medullary cords and sinuses of lymph nodes. The blood from the small penicilliary vessels appears able to enter directly into a sinus area or into a cord area that consists of a loose reticular stroma in which macrophages, lymphocytes and plasma cells are enmeshed. This system allows for slow flow for cells that enter a cord, with maximum opportunity for recognition of altered cells and their removal by splenic macrophages. Alternatively, those cells that in most circumstances are the majority enter a sinus area and rapidly regain the large veins and return to the systemic circulation essentially unfiltered. Under normal circumstances, there appears to be a constant relationship between splenic volume and body weight, as is the case for liver and kidney.

The marginal zone region receiving the blood exiting the germinal center is the area most densely populated with cells that have recently arrived from the general circulation. As a consequence, animals with marked neutrophilia will have many neutrophils in the area immediately surrounding the corona of the splenic follicle. Increased neutrophils in this area are more likely to be seen in the cat, dog, and horse that are characterized by response to infectious diseases such as salmonellosis with a strong neutrophilia, whereas in calves and mature cattle, bands and metamyelocytes may be found in this area. Since many of these animals die with neutropenia, neutrophil accumulation in this site is less frequently observed.

One of the most valuable aspects of phenotypic identification of B- and T-cell areas of the spleen is the opportunity to understand that the spleen is a highly ordered immune structure that varies in morphology as predictably as lymph nodes in response to various stimuli. In addition, the dissection of the phenotypic structure of the spleen clearly demonstrates the differences between hyperplastic and neoplastic lymphoid proliferations arising from one of the three layers of the splenic germinal center.

Hemal nodes (hemolymph nodes) occur in ruminants and a similar structure occurs in rats. They are enclosed by a fibromuscular capsule and have a general architecture similar to that of lymph nodes. *Hemal nodes have a blood vascular circulation and afferent and efferent lymphatics*, although the former are apparently much diminished in comparison to lymph nodes. The arteries entering through the hilar area arborize peripherally and are followed closely by veins that apparently communicate through a trabecular structure similar to that of the spleen. Hemal nodes have germinal centers, but the paracortical areas are much reduced in comparison to those of lymph nodes. Unlike lymph nodes, where the subcapsular sinus is poorly cellular, hemolymph nodes contain red cells in density similar to that of peripheral blood. Red cells are not present in the afferent lymphatics and very few are present in the efferent lymphatics; however, the larger sinuses of the hemonodes may be filled with blood and more closely resemble sinus areas of the spleen. Macrophages occupy the trabecular areas and phagocytosis occurs as in the spleen. Myelopoiesis does not occur in hemal nodes either under normal circumstances or under conditions of hematopoietic stress.

Developmental diseases of the spleen

The spleen may be *congenitally absent* as occurs regularly in a strain of inbred mice, and rarely in humans and outbred animals when it usually occurs in conjunction with multiple anomalies. In nude mice and rats with thymic deficiency, there is loss of the periarteriolar lymphoid sheath areas of the spleen. The least rare anomaly is the presence of *accessory spleens*, one or more, usually present in the gastrosplenic omentum. *Acquired "accessory" spleens* are implants of splenic parenchyma following traumatic rupture of the main organ (see splenosis).

Duplication of the spleen is occasionally observed in normal swine and as one of multiple visceral defects in nonviable calves and lambs. *Ectopic pancreatic tissue*, either exocrine or endocrine, is occasionally observed in spleens that are otherwise developmentally normal.

Degenerative diseases of the spleen

Senile atrophy affects the spleen, as it does other lymphoid tissues, and is seen particularly in old dogs and old horses. Atrophy accompanies starvation and is seen in wasting disease. Microscopically, the capsule is contracted and thickened, and there is lymphoid atrophy, the severity of which is an indication of the duration and severity of the atrophic process. The sinus areas appear fibrous due to condensation of the sinusoids, and lack of blood and resident hematopoietic cells.

In *hyperimmune states*, there are characteristic changes in the germinal centers of animals that are severely stressed. Lympholysis occurs, and germinal centers appear epithelioid and hypocellular. If the cell loss is acute, there will be prominent tingible body macrophages, as in foals aborted due to *Equid herpesvirus 1* infection. If the reaction has persisted for more than a day, the cell debris is gone and only the dendritic cells remain. A variety of vascular changes occur, consisting of hyaline changes in small arterioles that may proceed to mineralization.

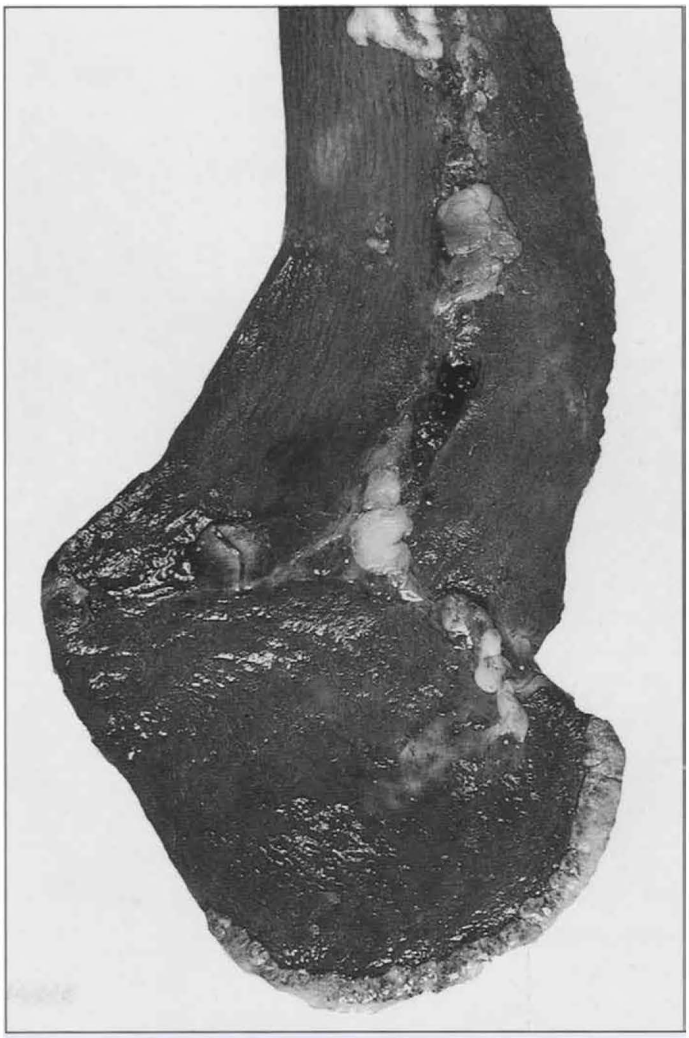

Figure 2.117 Siderotic encrustations of tip and capsule of spleen, dog.

Old dogs often have *yellow encrustations along the splenic margins*, or even covering most of the capsule (Fig. 2.117). Microscopically, there is condensation and thickening of the capsule, trabeculae and perivascular tissue. *The yellow or brown encrustations are known as* **siderotic nodules** *or Gamna-Gandy bodies, and represent deposits of iron and calcium in connective tissue, usually the trabeculae.* The salts become encrusted on connective tissue and elastic fibers, which are swollen, refractile, and stain with hematoxylin. The encrusted fibers occasionally are misinterpreted as fungal hyphae. In association with ceroid, these nodules likely represent the residual effects from areas of *hemorrhage*. Their deposition in the capsular margins and internally suggests that a dystrophic or storage phenomenon may be more likely.

Amyloidosis of the spleen (Fig. 2.118) occurs as part of generalized amyloidosis, but the deposits in the spleen may not be detectable grossly or histologically without appropriate stains. Amyloidosis of an obvious degree is not common, and when present it involves the germinal centers and may spare the sinus areas completely. This distribution of amyloid gives the organ the "sago-spleen" appearance in which the enlarged and waxy follicles protrude from the cut surface. The spleen is not enlarged. The deposition of amyloid occurs first in the small arteries of the lymphoid nodules, and minor depositions are common.

Histiocytes of spleen and lymph nodes are enlarged in most *storage diseases* (Fig. 2.119) (see Vol. 1, Nervous system).

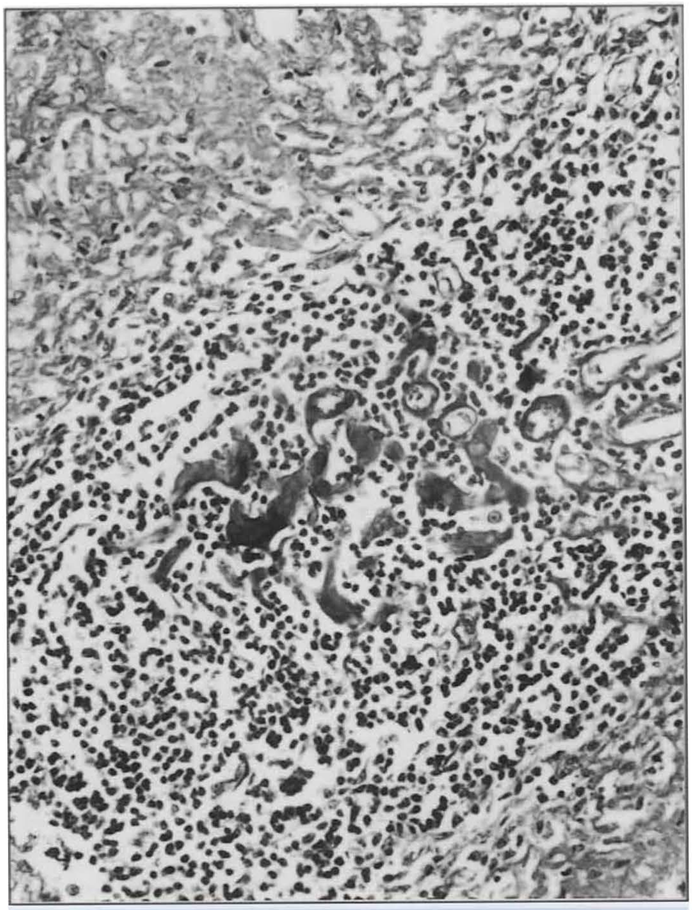

Figure 2.118 Amyloidosis in the spleen of a cat.

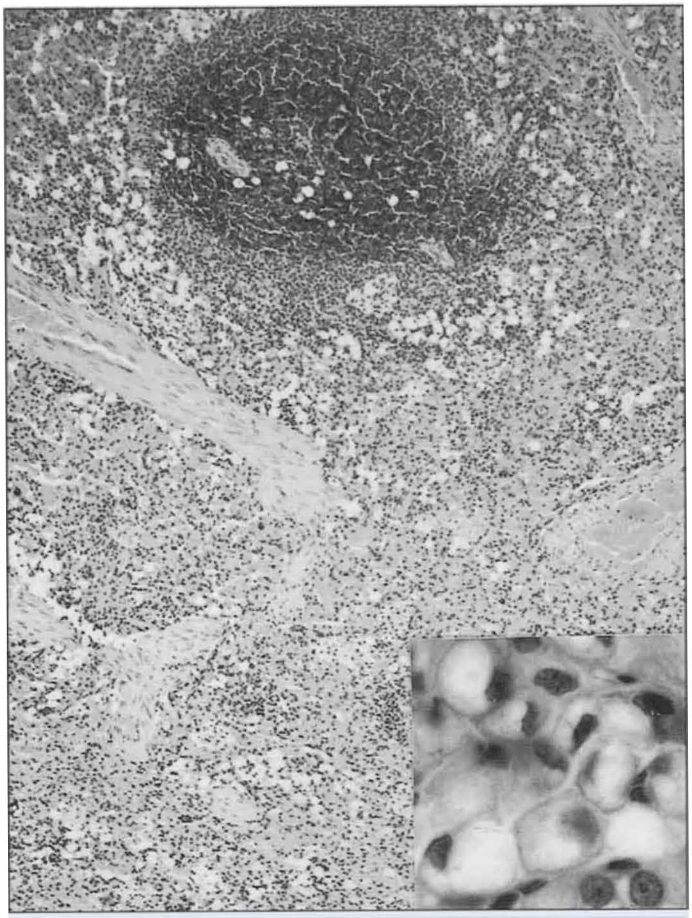

Figure 2.119 Sphingomyelin storage in the spleen of a dog. Clusters of large macrophages with clear cytoplasm in both follicles and pulp. Inset: storage cells.

Hemosiderin *is a storage form of iron and the only splenic pigment of importance.* The amount and form of storage iron varies greatly in normal animals with age and species. The pigment is usually present only in macrophages, but in long-standing iron accumulation it may be encrusted on fibers of connective tissue. The amount of hemosiderin is significant only when it is in excess to the point of causing tissue injury and fibrosis, and justifies the name hemosiderosis. Iron is absorbed in excess in any anemia where it is sufficiently available. Increased iron is one of the splenic changes in the hemolytic anemias. The patterns of iron storage in the spleen and marrow can yield information about the type of anemia. In nonresponsive anemias, the iron is very largely aggregated into large coarse granules within the phagocytes that themselves are unapparent. In responsive hemolytic anemias where there is rapid iron turnover, there is a spectrum of iron deposition from barely stainable, diffusely or focally distributed ferritin, to coarse hemosiderin. In the anemias of chronic disease, there is increased coarse splenic iron due to continued scavenging of the transferrin system by the acute phase reacting proteins.

Rupture of the spleen

A normal spleen can be ruptured by the level of *trauma* that cats and dogs suffer regularly in automobile collisions. The result is more or less severe loss of blood into the abdomen.

There is usually a concurrent rise in transaminases, indicating *hepatic laceration* as an additional source of abdominal hemorrhage. The spleen may be fully divided into two or more parts, or merely ruptured and healed, the lines of healing producing notches and fissures. *Pathologic rupture* may occur in any species with only minor trauma if the spleen is enlarged and the capsule thinned. The latter pathogenesis may occur with splenomegaly of any cause including congestive, hemolytic, infectious, or neoplastic types (Fig. 2.120). Lymphoma is a common cause of splenic enlargement leading to fatal internal hemorrhage. Following rupture of the splenic capsule and spilling of the sinus cells into the abdominal cavity, there may be widespread seeding of splenic explants onto the serosal surfaces. This is called **splenosis**.

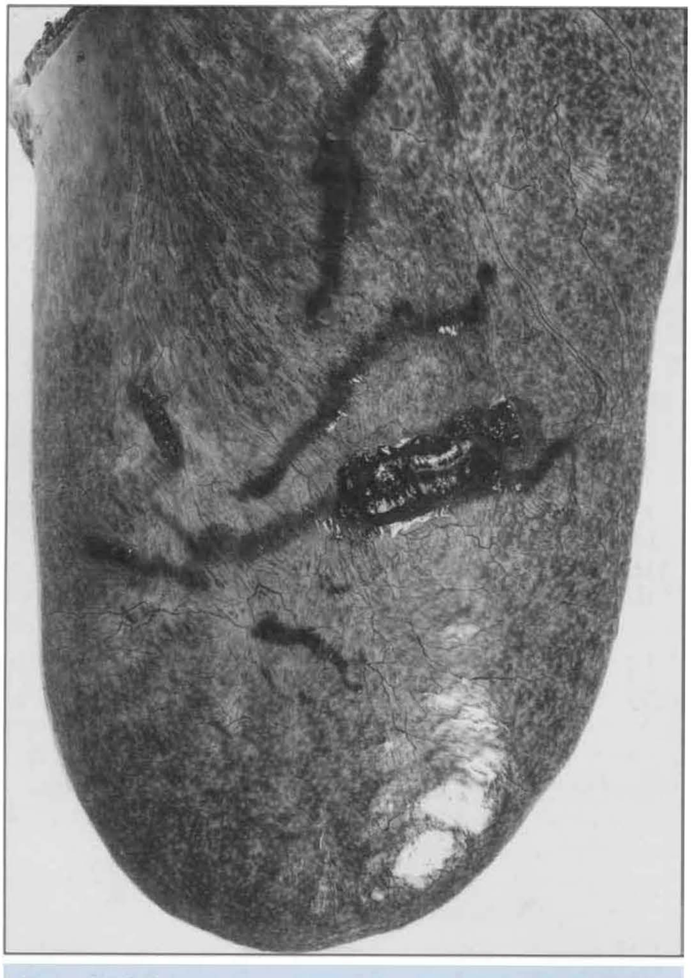

Figure 2.120 Spontaneous rupture of swollen spleen, lymphoma, ox.

These accessory spleens are functional and there may be hundreds on the omentum with a few on the peritoneum. They appear grossly like hemal nodes and histologically like normal spleen. Following splenectomy, any splenic implants present will increase in size and may give some protection against septicemic disease.

Torsion of the spleen

Torsion affecting only the spleen occurs in *pigs, dogs* and humans and rarely in horses, and *torsion of the spleen and stomach occurs in dogs.* When the whole spleen is twisted on its mesentery, there is severe congestion and *hemorrhagic infarction* due to occlusion of the vein and ultimately blockage of the artery. When the distal portion is twisted, only the vein tends to be occluded, causing hemorrhagic infarction and congestion. Splenic torsion in the **dog** occurs in large breeds and is characterized by enlargement of the upper abdomen with painful guarding on palpation, and the passage of dark-brown urine. Hematologically, there is a characteristic brown discoloration of plasma due to leaching of blood pigments through the capsule as it becomes necrotic. Associated signs consist of the postsplenectomy state with many distorted red cells, hypersegmented neutrophils and the presence of Howell-Jolly bodies and *red cell pits,* which are unusual in the peripheral blood of the dog with a normally functional spleen. The spleen, on surgical removal, may weigh as much as 5 kg and contain a large proportion of the original red cell mass. As is the case in humans who survive splenectomy, there is risk of infection by organisms normally controlled by the spleen. In the dog, hemotrophic mycoplasma infection and severe hemolytic anemia are the most likely adverse sequelae.

Splenic torsion in pigs usually occurs in **sows,** and often several are affected in the same herd over a period of a few days. Circumstantial evidence suggests that a change from once- to twice-daily feeding will prevent further losses, but other factors must be involved. Affected animals usually die acutely, and in white-skinned pigs cutaneous pallor suggests esophagogastric ulceration. Grossly the spleen is blue-black, massively and uniformly enlarged, and twisted 180° about its long axis.

Cysts

Splenic cysts are unusual. Occasionally, *Cysticercus tenuicollis* and hydatids are found there. *Pseudocysts* may result from cystic degeneration of hematomas. *Neoplastic cysts* are hemangiomas or hemangiosarcomas. The latter are relatively common in the dog and have a rather characteristic history of repeated bouts of malaise and weakness, with apparent recovery over 2–3 days. Severe anemia accounts for the weakness. Pallor may be noticed and results from rupture of the tumor with abdominal hemorrhage. The recovery over a few days is too rapid for new red cell production, and indicates autotransfusion of the extravasated blood. The hematologic picture is also typical with distorted red cells, even in the absence of abdominal hemorrhage, due to the effects of abnormal vascular walls and arteriovenous shunts. After hemorrhage, the red cell distortion is much worse and the formerly extravasated red cells appear tattered and effete, and the plasma is brown due to extensive hemolysis. There are usually Howell-Jolly bodies in the blood along with hypersegmented neutrophils. If abdominocentesis is performed, the presence of an occasional rubricyte is an indication of hemorrhage from the spleen rather than from another abdominal site.

Circulatory diseases of the spleen

Active hyperemia is common in acute systemic infections and also occurs in some acute bacterial intoxications, such as clostridial enterotoxemia of calves, erysipelas of swine, and *Streptococcus pneumoniae* infection in neonatal calves and goats. *Passive congestion* of the spleen may arise as a result of disturbances in the systemic and portal circulation, and is a feature of some of the acute hemolytic anemias. The most common cause of passive congestion is the use of barbiturate drugs. Central (cardiac or pulmonary) venous congestion does not usually cause congestion of the spleen in animals, partly because they usually do not live long enough, and partly because the splenic capsule is not elastic as in sheep, or is highly muscular as in the dog and horse and not easily distended. Portal obstruction, with chronic hepatic fibrosis and portal obstruction, causes significant splenic congestion in humans, but this sequence of events is rare in animals.

An acutely congested spleen is enlarged, moderately turgid, and cyanotic with the capsule blue-black. The normal architecture is not discernible on the cut surface, and the pulp is red-black and progressively exudes blood. Microscopically, the splenic sinuses are dilated with packed red cells, and the germinal centers are widely separated and trabeculae are thinned. The extent of acute congestion may make histologic examination difficult in the horse because the tissue, being largely clotted blood, fragments on sectioning. Splenic samples from horses destroyed with barbiturate should be taken from a thin marginal area where the parenchyma is supported on two sides by capsule. With chronic congestion, the organ becomes firm and the capsule and trabeculae thickened. There is lymphoid atrophy and sinus proliferation, with a marked increase in fixed cells in the red pulp and heavy sinus colonization with macrophages and hemosiderin.

Thrombosis of the splenic vein has been observed in association with traumatic reticulitis and portal thrombosis in cattle, and with splenic abscesses in horses. Thrombosis of both arteries and veins is seen in hypercoagulable states such as immune hemolytic anemias, purpura, and hemorrhagic pancreatitis. Spleens that are enlarged for any reason are prone to thrombosis and infarction, which is likely to occur in myeloma, lymphoma and in leukemia, due both to the thrombocytopenia and procoagulant content of hypogranular promyelocytic leukemia or more often the hyperviscosity of myeloma granulomas. In acute hog cholera, there is widespread endothelial swelling and proliferation with fibrinoid thrombosis of splenic arterioles in 50% of cases, resulting in raised dark infarcts 0.2–2.0 cm in diameter in the splenic capsule. The spleen may suffer septic infarction in the hyperviscosity syndrome associated with myeloma and gammopathy. The spleen is enlarged due to infiltration by tumor cells and flow is further compromised by the hyperviscosity of blood. The septic component is likely due to loss of normal antibody and displacement of phagocytes by the myeloma cells.

Embolism with infarction is not uncommon. The emboli are usually derived from valvular vegetations. The outcome has the usual dependence on whether the emboli are septic or bland.

Inflammatory diseases of the spleen

Systemic inflammations cause a regular and fairly predictable pattern of response in the spleen. In septicemia and following injection of endotoxin or gram-negative bacterins, there is rapid accumulation of neutrophils in the splenic marginal zone and surrounding area of sinus. There is bacterial destruction and processing of antigen in this area followed by a predictable pattern of migration, the foreign material moving in specialized macrophages (*metallophils*) successively into the marginal zone and then to the small lymphocyte corona, reaching the germinal center in 10–12 hours. In contrast, immune complexes appear to move by flow and not by cellular transport. *Overwhelming infections* result in lympholysis of the follicular center cells, with the production of nuclear debris and the exposure of the underlying dendritic reticular cells, whose cytoplasm becomes more intensely stained in disease to attain the tinctorial properties and density of epithelioid macrophages. The nuclear fragments are rapidly removed so that the follicular center appears empty, with the nuclei of the dendritic cells relatively widely spaced and surrounded by their densely pink cytoplasm. These epithelioid germinal centers are seen in a variety of acute toxemic diseases in young animals. In older animals, the changes occurring in splenic germinal centers are often more severe and long-lasting, and consist of a depopulation of the follicular center cells and transudation of plasma proteins into the germinal centers to form a fairly persistent coagulum recognized as *intrafollicular hyalinosis*. These fibrinous exudates may be removed, with restitution of the follicular center cells or, if there is extensive vascular damage, they may become mineralized and result in involution of the germinal center.

Septicemia and bacteremia result in microbial deposition in the Billroth cord areas, where the abundance of phagocytic cells usually leads to their rapid destruction. Occasionally small foci of bacterial colonization develop in the cord and sinus areas of spleens, primarily in young animals with severe gram-negative bacterial infection of the enteric tract. In septicemic splenitis, there is splenic enlargement, with acute congestion and degeneration of the lymphoid follicles and hypercellularity of sinus areas. In very acute diseases, such as anthrax in cattle, the reaction is almost solely vascular. In the less severe septicemias such as erysipelas in swine, there is moderate reactive hyperplasia which may be more developed than that seen in acute fulminant gram-negative septicemias such as salmonellosis. Marked hyperplastic changes of the sinus areas are a feature of some diseases such as malaria, trypanosomiasis, equine infectious anemia and malignant catarrhal fever, although involution characterizes some infections.

Splenic abscesses may be miliary or large and focal, but both types are uncommon. Abscessation may be due to various organisms including *Arcanobacterium pyogenes*, but some commonly localize preferentially in the spleen (see Specific infections of the lymphoid tissues, this chapter). Purulent splenitis may develop by local extension in cattle from penetrating wounds of the reticulum and, in horses, by extension from the colon due to strongyle migration.

Hyperplastic diseases of the spleen

Nodular hyperplasia

Nodular hyperplasia is frequently observed in the spleens of *old dogs*, occasionally in old bulls, and rarely in other species. Most nodules are up to 2 cm in diameter and project hemispherically above the capsule, but may be 5 cm or more in diameter. On cut surface, the nodules vary from gray to pink to a variegated red and white, with yellow necrotic areas in the larger ones. The variegated pattern is due to persistent islands of sinus in a diffuse field of lymphocytic proliferation. Architecturally, the nodules are unencapsulated but compress adjacent trabeculae, and irregularly meld with surrounding sinus areas that have a much higher density of red cells. Lacking germinal centers, the nodules consist of monomorphic medium or large lymphocytes with moderate cytoplasmic volume and small nucleoli. The nuclei are round with thin nuclear boundaries, and are more open and less hyperchromatic than are lymphoma cells. There may be many mitoses, and *the lesions are judged to be benign more on a knowledge of behavior than cytology*. Architecturally benign focal lymphoid proliferation in the spleen tends to be arranged in large irregular islands that are loosely facetted in a relatively cohesive mass. In contrast, lymphomas of a mantle cell or marginal zone type can be seen to be related to the arteriolar structure of the spleen in multiple smaller foci, some of which contain remnants of germinal centers. Proliferation *immediately surrounding fading germinal centers* of small cell type are likely of mantle cell lymphoma. If the proliferation can be seen in some foci to surround *the outside of the mantle cell cuff* and is composed of intermediate-sized cells, then the lesion is likely marginal zone lymphoma. Focal lymphoid proliferations in the spleen, either hyperplastic or neoplastic, may be clinically apparent due to effects of the expanding mass on adjacent vascular sinuses resulting in vascular pooling and thrombocytopenia.

In contrast, **splenic plasmacytoma** is a rare condition of dogs with gross features indistinguishable from nodular hyperplasia. Cytologically the cells are uniform and of moderate size but with abundant, usually eccentric cytoplasm that stains deeply. Nucleoli are small but prominent and central and there is mild heterochromatin aggregation. Mitoses are less numerous than in the surrounding normal tissue and there may be some degree of gammopathy. Plasmacytoma may be indolent for long periods, but may progress to an immunoblastic type of lymphoma within a year of biopsy.

Hematopoietic alterations

Extramedullary hematopoiesis results when there is hormonal induction for increased cell production and pluripotential hematopoietic stem cells available. These cells normally circulate in very low numbers and, in preparation for extramedullary hematopoiesis, they return to embryonic sites of colonization, sparing the germinal centers and periarteriolar lymphoid sheaths. Extramedullary hematopoiesis is *characteristically trilineage* but one cell line may predominate, such as the myeloid system in canine pyometra or the erythroid system in hemolytic anemia (Fig. 2.121). Megakaryocytes are the most obvious hematopoietic precursor and characteristically lie adjacent to the smooth muscle trabeculae when stimulation is mild, but may become diffusely distributed in the sinus areas when stimuli are pronounced and prolonged. Splenic erythropoiesis is coincident with increased splenic red cell destruction in immune hemolytic anemias.

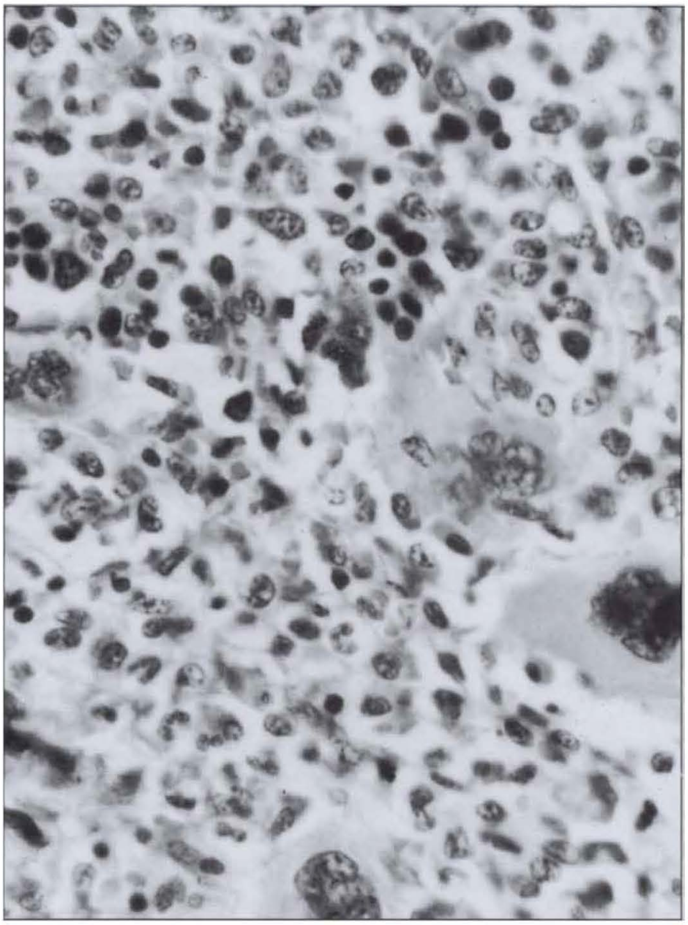

Figure 2.121 Extramedullary thrombopoiesis and erythropoiesis in pyometra in the spleen of a dog.

In contrast, **myeloid metaplasia** is a condition where there is marrow myeloid hyperplasia without an apparent target for the increased cell production (see Myelodysplastic syndromes (MDS), and Chronic idiopathic myelofibrosis/myeloid metaplasia with myelofibrosis). The disease tends to run a course of prolonged hyperplasia followed by myelofibrosis and displacement of the still functional stem cell system to embryonic sites of production. Grossly, the spleen is uniformly enlarged with turgid capsule and rounded borders. The parenchyma is dry, and the light pink of hematopoietic marrow rather than dark and cyanotic as with congestion. In myeloid metaplasia of the spleen, there is *myeloid predominance but all cell lines are present to some degree*. As part of the character of the disease, some dysplastic changes will be present in the extramedullary hepatopoietic cells in splenic sinusoids. **Dyspoiesis** may affect only one cell lineage, or more commonly all three, and is characterized by multinucleated rubricytes, incipient Howell-Jolly bodies, giant and donut forms of metamyelocytes, and hypofusion and segmentation of megakaryocyte nuclei. Myeloid metaplasia is accompanied by immune hyperplasia, hemosiderosis and splenic fibrosis. This is preceded by follicular hyperplasia of the spleen and nodes, and later hematopoietic colonization with gradual reduction in the lymphoid volume in the spleen, and eventual atrophy as the stem cell system becomes increasingly committed to myeloproliferation. Small infarcts develop and are likely the result of loss of plasticity, and fibrous impairment of vascular structures.

Rarely the spleen contains a **myelolipoma,** which stands out grossly as a focal pale area on the cut surface and histologically because the empty fat cells contrast sharply with the sinus parenchyma. Myelolipoma is composed of outwardly normal marrow with about 50% hematopoietic and the rest large typical fat cells.

Lymphoid hyperplasia of the spleen may be segmental and affect only the germinal centers, which may be enlarged and hypocellular as may be seen in immune hemolytic anemias followed by prolonged steroid treatment. Alternatively, there may be hyperplasia of the periarteriolar lymphoid sheath with prominent broad cords of lymphocytes surrounding the branches of the medium-sized arterioles. In contrast to both of these changes, there may be hyperplasias of the marginal zone cells which prominently surround all germinal centers and may fuse with adjacent germinal centers or actually surround adjacent periarteriolar lymphoid sheaths. The follicular structure of the spleen is usually not apparent on gross examination unless there is hyperplasia or neoplasia involving some or all of these lymphoid compartments. The germinal centers in hyperimmune states increase in both size and density, and the accentuation of the marginal zone, mantle cell corona, and follicular center cells is increased, often resulting in a "target" appearance. Since sinus and follicular hyperplasia of the spleen tend to occur together, their concurrence results in an overall increase in splenic weight.

Splenomegaly

The hematological effects of an enlarged spleen include pancytopenia or selective cytopenia, but almost always anemia and thrombocytopenia (see Hemolytic anemia due to splenic hyperfunction). **Splenomegaly** is an enlarged spleen, whereas **hypersplenism** describes a spleen that is overactive in cell destruction. Usually the two coincide but *whereas the enlarged spleen is always hyperactive, the hyperactive spleen may not always be enlarged.* Since the spleen is almost always involved to some degree in both red cell production and destruction, the decision on whether to remove the spleen in hemolytic anemia may require scintillation counting of labelled red cells to determine if splenectomy would be helpful. In concurrent hemolytic anemia and thrombocytopenia, as it occurs in dogs, immediate splenectomy is indicated to prevent fatal intracranial hemorrhage. The apparent decoupling of splenic size and function in cell destruction is mediated in large measure by the presence of opsonizing antibody which greatly reduces the chances of a given cell re-entering the vascular system after being shunted into the splenic cord system.

The degree to which splenic size departs from normal is difficult to assess, but weight is always a useful parameter, particularly in animals that die without exposure to barbiturate anesthetics. Splenomegaly is common, and the interpretation of splenic size at autopsy can be gained by reference to the whole carcass and to the cut surface of the organ. *The following is an arbitrary list of diseases to be considered when splenomegaly is present.* The absence of splenomegaly does not eliminate any of them, but makes them unlikely. Multiple focal lesions do not as a rule cause splenomegaly, although hemangiomas of the canine spleen and metastatic melanomas of the equine spleen are exceptions.

- Cattle and sheep
  - Anthrax
  - Salmonellosis
  - Lymphoma-leukemia
  - Babesiosis, trypanosomiasis, anaplasmosis
  - Congestive splenomegaly
  - Acute septic processes with bacteremia and toxemia

- Horses
  - Equine infectious anemia
  - Lymphoma-leukemia
  - Metastatic melanoma
  - Isoimmune hemolytic anemia
  - Salmonellosis
  - Anthrax

- Pigs
  - Torsion
  - Congestive splenomegaly
  - Salmonellosis
  - Erysipelas
  - Lymphoma-leukemia
  - Isoimmune hemolytic anemia
  - Protozoan diseases of blood
  - African swine fever

- Dogs and cats
  - Barbiturates
  - Lymphoma-leukemia
  - Acquired hemolytic anemias
  - Histoplasmosis
  - Amyloidosis
  - Leishmaniasis
  - Hemangiomas and hemangiosarcomas
  - Torsion (dogs)
  - Mast cell tumor (cats)

Splenic enlargement may occur in *storage diseases* of which there are many (see Vol. 1, Nervous system). Sphingomyelinosis of dogs is an appropriate example (Fig. 2.119).

Neoplastic diseases of the spleen

The vascular tumors of the spleen (Fig. 2.122) are described in Vol. 3, Cardiovascular system, and leukemic diseases involving the spleen are described with the myeloproliferative and lymphoproliferative diseases (this chapter). *The spleen is expected to be involved in systemic malignancies of the lymphoid system, but this is not always the case or apparent.* In a review of lymphomas (and assuming that when lymphoma was suspected the spleen would always be examined), there was splenic involvement in only 41 of 72 cases (57%) in dogs, 35 of 81 cases (43%) in cats, and 27 of 90 cases (30%) in cattle. *Although the spleen may not be invaded in lymphoma, it is much more likely to be involved in frankly leukemic lymphoid and myeloid leukemia.* In all situations, but particularly in lymphoma, the size of the organ or the microscopic structure cannot be taken in itself as evidence for the presence or absence of tumor. Careful cytologic examination must be carried out to determine whether a suspect cell population is like that of unequivocal tumor elsewhere.

The evidence for well-defined tissue homing by lymphocytes, added to recognition of B-T subsets, facilitates the interpretation of lymphoid changes. Thus the loss of specific trophic factors, or the displacement of stem cells from a cellular compartment, explain the atrophy of lymphoid, particularly thymic-dependent, areas that are generally seen in cancer. More than 90% of peripheral lymphocytes are T cells and under normal circumstances they make up most of the cellularity of the sinus areas; consequently in lymphopenia the sinus areas of the spleen appear hypocellular and vice versa. In polyclonal B-cell hyperplasia, as occurs in cattle with trypanosomiasis and the persistent lymphocytosis stage of bovine leukemia virus infection, there is enlargement of the marginal zone areas around the splenic germinal centers.

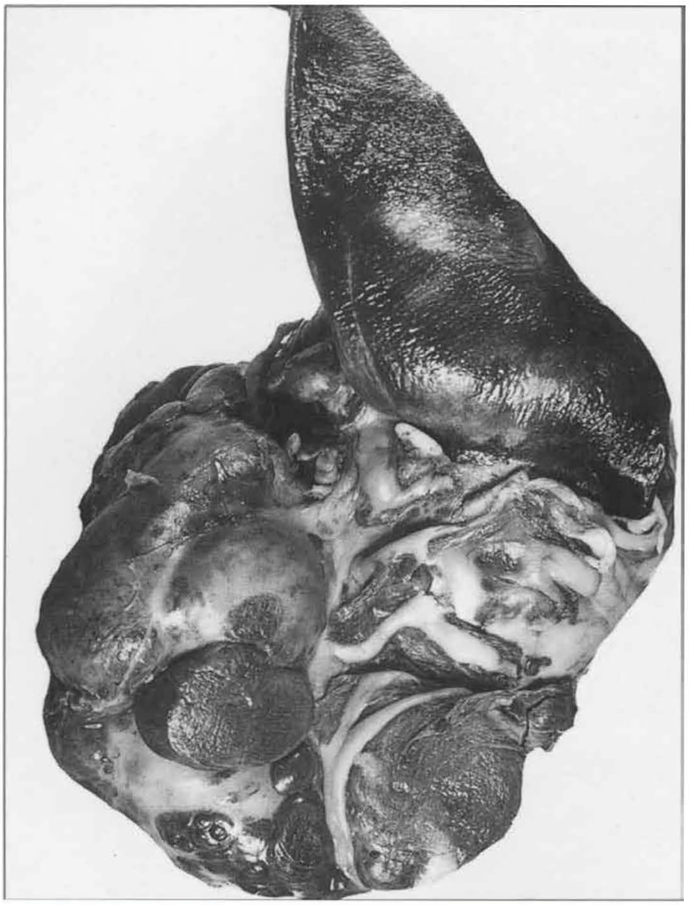

Figure 2.122 Hemangiosarcoma in the spleen of a dog.

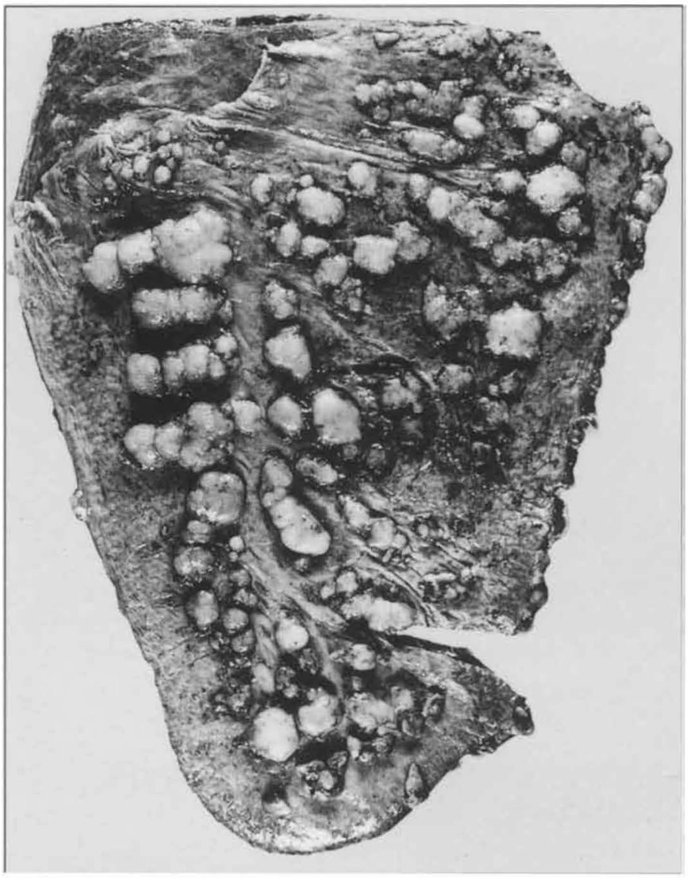

Figure 2.123 Implants of **squamous cell carcinoma** on splenic capsule, ox.

In cats and dogs with lymphoma, there is usually unequivocal involvement of lymph nodes, portal colonization of the liver, and atrophy of the periarteriolar lymphoid sheaths and germinal centers in the spleen. Splenic involvement is typically a late phenomenon in thymic lymphoma of all species. The identification of the hepatosplenic T-cell lymphomas of the cat and dog demonstrate that there is leukemia with heavy involvement of spleen but paradoxically not of bone marrow. Thus these are leukemic diseases that do not follow the usual pattern in which the marrow is the tissue most heavily involved.

When the spleen is symmetrically enlarged to a mild or greater degree, the histologic infiltration is usually diffuse, as occurs in leukemia, and occupies all of the sinus areas. There is initially, at least, mild atrophy of the germinal centers and periarteriolar lymphoid sheaths. A diagnosis of lymphoma in the spleen may be difficult when there is a prominent follicular pattern, and *the most reliable criterion of malignancy is subendothelial colonization of large muscular sinuses by lymphocytes*. Usually, when this change is found, lymphocytes of similar morphologic type will be identified in other areas, particularly the liver. In splenic follicular lymphoma of large-cell type (a rare disease), the tumor is multifocal and centered on germinal follicles, as can be demonstrated by collapse of the mantle cell corona and identification of residual benign small cells in the center of the enlarging tumor foci. In the horse and dog, lymphoma may be focal in the spleen, and in these cases there is more likely to be atrophy of lymphoid tissue in the benign area as the tumor increases in size. When the spleen is involved in adult cattle with diffuse (non-follicular) lymphoma, there is usually malignant colonization of the germinal centers, probably reflecting the bone marrow origin of the cells involved. A similar pattern of involvement occurs in cats and dogs, and there is usually a dense homogeneous cluster of lymphocytes 2–3 times the diameter of a normal follicle, with complete atrophy of the mantle cell corona and marginal zone cells. In contrast to follicular lymphoma, these are focal aggregates of diffuse tumor, and again their homing pattern can be demonstrated by identification of residual small benign cells in some of their centers as well as their constant relationship to the splenic arterioles.

Metastatic neoplastic disease of the spleen is uncommon. It is not likely that migration of tumor cells to the spleen is unusual, but rather that the functional efficiency of the cord and sinus macrophages usually prevents colonization. Metastatic carcinoma involving the spleen and liver usually arises from the pancreas or reproductive system. With neoplasia arising in the liver, metastases to the spleen are isolated and most are probably of arterial origin. Carcinomatous implants originating from other abdominal viscera can mimic peritoneal tuberculosis (Fig. 2.123).

SPECIFIC INFECTIONS OF THE LYMPHOID TISSUES

The strategic location of the lymph nodes, and blood flow through the spleen, determine their role in resistance to infections and make their involvement, either locally or generally, directly or indirectly, inevitable in any infectious disease. For the most part, the lesions produced in the nodes and spleen are not specific for the cause. On the other hand, there are some infectious diseases in which these tissues are chiefly or consistently involved, and they are the subject of this section.

Caseous lymphadenitis

Caseous lymphadenitis (CLA) is a suppurative infection of the lymph nodes primarily of sheep and goats caused by ***Corynebacterium pseudotuberculosis*** *(ovis).* The disease occurs in sheep wherever they are raised, but horses, camels, deer, mules, and rarely cattle and humans may be affected. Cattle can develop a pathologic syndrome that resembles that in sheep, but they do so quite rarely, and the infection generally remains localized to 1–2 regional nodes draining an infected surface wound or a segment of intestine. *Coryne-bacterium pseudotuberculosis* is also the cause of *ulcerative lymphangitis* in cattle and horses, and of *pectoral abscesses* in horses.

There are two serotypes with *type I* in ovine, caprine and occasionally bovine isolates and *type II* in buffalo and most infections in cattle. An *exotoxin* that consists of a phospholipase D is an important aspect of virulence with effects including intravascular hemolysis, necrosis, pulmonary edema and shock.

C. pseudotuberculosis survives briefly in the environment and is able to spread indirectly, which is an important means of spread in sheep and goats that are routinely corralled on the same bed ground to avoid predation. Infection also occurs in shearing wounds in sheep and butting abrasions in males.

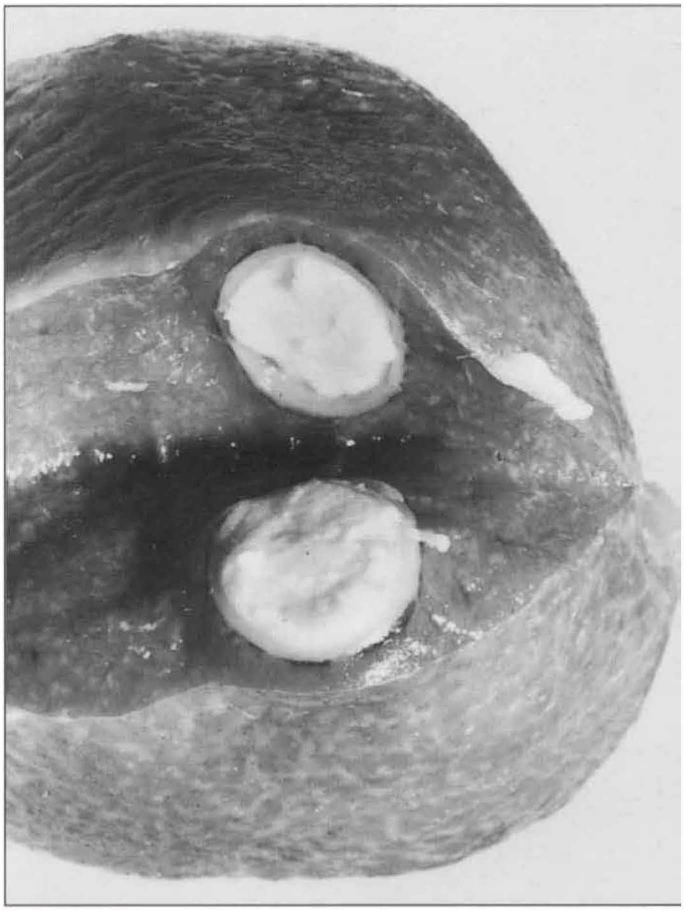

Figure 2.124 Abscess of melioidosis, spleen, goat. (Courtesy of WR Kelly.)

In **horses**, the disease occurs as ulcerative lymphagitis on the fetlocks, which is consistent with the concept that skin abrasions are important in spread of the organism. The seasonal incidence of abscesses in the pectoral and other regions of horses suggests that the organism may also be borne by arthropods.

The disease in **goats** can be more severe than in sheep, the most frequent lesions being in the *lymph nodes of the head and neck.* The lesions in goats closely resemble those of pseudoglanders or melioidosis (*Burkholderia (Pseudomonas) pseudomallei*), and it is important to distinguish these diseases (Fig. 2.124). Female goats and intact males have more extensive lesions than castrated males. In sheep and goats, there is slow spread of the disease with the prevalence of abscesses increasing as a function of age. *Caseous lymphadenitis is widespread in goats and the disease differs from sheep in the distribution of the abscesses.* In goats the mandibular lymph nodes, followed by the parotid nodes, are most often involved suggesting that the organism is acquired through the buccal mucosa, as well as through skin wounds. Superficial abscesses of the jaw and neck region are common and infection is probably acquired from feed stalls or collars carrying the bacterium. In only a small proportion of goats does infection spread to involve the mesenteric or mediastinal nodes grossly.

Caseous lymphadenitis in **sheep** almost always follows a *wound infection*, usually a shearing wound. The organism can penetrate the intact skin of freshly shorn sheep however, and may be transmitted by dipping fluids. Docking and castration wounds and the umbilicus are of minor importance. Occasionally, the infection may be acquired by ingestion, as indicated by confinement of the lesions to the nodes draining the buccal cavity. Less commonly the organism is inhaled, producing lung abscesses. Parasitic wounds of the lower alimentary tract are not a portal of infection.

While the phospholipase toxin is an important aspect of pathogenicity, the natural infection in sheep, even when generalized, gives scant clinical evidence of intoxication, though the exotoxin facilitates the spread of infection from the primary site. Vaccination with the exotoxin provides a degree of protective immunity. The leukotoxic surface lipid allows persistence within inactivated macrophages in which the organism is effectively a *facultative intracellular parasite*. The acquisition of host resistance may also be in part due to the selection of a population of macrophages resistant to and capable of destroying the toxic surface lipids of the bacteria.

The *sequence of events in progressive CLA* is infection of a superficial wound, spread of infection to the local lymph nodes which suppurate, and then lymphogenous and hematogenous extension to produce abscesses in internal organs. The progression is slow and may reach the bloodstream only in older animals, whereas in young animals the disease tends to be confined to the superficial lymph nodes, most commonly the precapsular and precrural.

Spontaneous recovery from the primary infection of cutaneous wounds, even when they suppurate, is more common than is progression of the infection to the lymph node, as judged by results in the experimental disease in which only about 20% of sheep develop abscesses in the nodes. Even when abscesses develop in the nodes, the primary cutaneous lesion heals, but secondary cutaneous lesions may develop as fistulae when the nodal abscess ruptures to the exterior. This occurs more often in goats than in sheep. *As a general rule, once the infection gains the nodes it is persistent*, although a few infections may be cleared when the node ruptures and discharges on to the skin.

The initial lesion in lymphoid tissues is diffuse lymphadenitis that is probably the result of the soluble exotoxin. When the organism reaches the nodes, multiple microscopic abscesses form in the cortex. Eosinophils are prominent in the reaction and cause the pus to be green. These foci rapidly coalesce and the central areas caseate to form a structureless mass which contains fragments of nuclear material and discrete clumps of bacteria. The abscesses are rapidly encapsulated, and when this occurs the acute reaction in the surrounding tissues subsides, but the abscesses continue to enlarge. With enlargement, there is progressive necrosis and re-formation of the capsule, which gives the lesion a very characteristic structure of concentric lamellations (Fig. 2.125); these are particularly prominent when calcareous granules are deposited in successive layers at the margin of the expanding lesion. In old lesions, the contents lose their green color, become inspissated and resemble putty. The lamellation is specific to the organism, not the organ involved. The nodal lesions often attain a diameter of 4–5 cm and exceptionally they may reach 15 cm. The larger lesions in superficial nodes cause pressure atrophy and depilation of the overlying skin; they frequently rupture to discharge chronically through a narrow fistula.

Caseous lymphadenitis is rarely fatal, and indeed it seldom even causes debilitation. Its economic importance is due to regulations concerning the trading of carcasses that show evidence of the disease. When fatalities do occur, they are caused principally by large pleuropulmonary abscesses. Rarely, *Corynebacterium pseudotuberculosis* causes small outbreaks of polyarthritis in lambs, but they recover spontaneously.

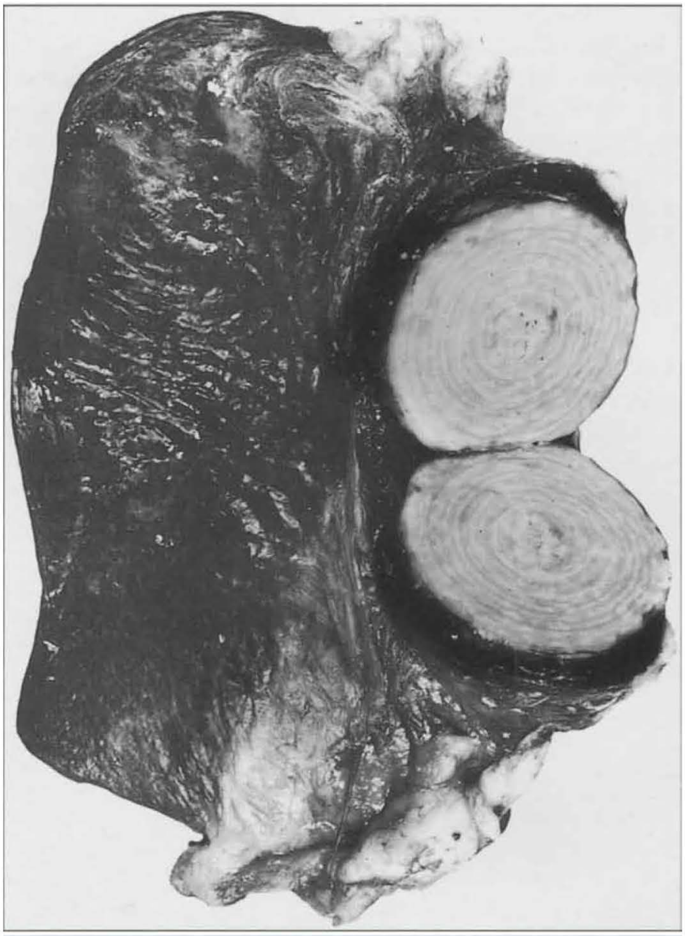

Figure 2.125 Laminated abscess of caseous lymphadenitis, spleen, sheep.

The mature lesion of CLA is an encapsulated abscess with pus of a distinct green hue and of caseous or caseopurulent consistency. The initial cutaneous lesion may not be evident, having resolved, but it is noted that occasional subcutaneous abscesses, principally of the face and belly, do occur without relation to known aggregations of lymphoid tissue. Mastitis, as occasionally observed in sheep and often observed in goats, probably represents an extension from a wound of the overlying skin; when the mastitis is early and acute it is diffuse and suppurative, and when chronic it is localized to encapsulated abscesses. The disease is easily diagnosed by fine-needle aspiration of the focal lesions, which allows both cytopathology and bacterial culture.

Spread from the lymph nodes produces lesions in the lungs, and these are rather common with advancing age. They also occur in young lambs, in which the progression is more rapid than in adults. The pulmonary lesions may consist of extensive bronchopneumonia, when abscesses rupture into bronchi in which there are soft caseopurulent foci, or there may be discrete nodules of various sizes and numbers. In cases of bronchopneumonia, and overlying those nodules which are immediately subserosal, there is pleuritis, often with adhesions. When the adhesions are few and localized adjacent to the nodules, the remaining pleural cavity may be normal. When the adhesions are more diffuse, there is a large amount of serous fluid in the cavities and a thin layer of fibrin on the pleura. The nodular lesions in the lung are similar to those in lymph nodes, and have a narrow zone of bronchopneumonia outside the capsule. With time, the pulmonary nodules become sharply circumscribed, encapsulated, subpleural abscesses. The pulmonary lesions are associated with characteristic lesions in *bronchial lymph nodes* which may be much enlarged. Dissemination of the infection from the lungs to other viscera is uncommon. Metastases are occasionally observed in the renal cortex as discrete abscesses or as descending pyelonephritis. Other viscera, chiefly the liver and spleen, may contain solitary abscesses of the typical form.

Antibody detection tests that may be useful in detect carriers include an enzyme-linked immunosorbent assay (ELISA) and a bovine gamma interferon ELISA. The agent itself can also be detected rapidly by PCR. Vaccines containing various combinations of whole cells and toxoids have had some success; DNA vaccines are under development. The organism is sensitive to a number of antimicrobials, but response to therapy is poor both because of the intracellular location of the organism and the characteristic formation of abscesses into which drug penetration is ineffective.

Anthrax

Anthrax is caused by ***Bacillus anthracis***, a large, gram-positive, spore-forming organism that is *highly pathogenic for most herbivorous animals and humans*, whereas carnivorous birds and reptiles are resistant. Domestic animals are susceptible to *B. anthracis* in the decreasing order of goats, sheep, cattle, horses, pigs and dogs. Farmed mink are highly susceptible. *In ruminants, the disease is usually brief and septicemic; in horses, pigs, and dogs, it is frequently localized to the throat or intestine and may be fatal before invasion of the blood occurs.*

When the disease is septicemic, as it usually is in herbivores, the blood and tissues of the animal swarm with vegetative organisms which, when exposed to air or oxygen, form spores of most remarkable durability. *It is the combination of these two factors, the number of organisms and the resistance of spores, which is of paramount importance in the epidemiology of the disease.*

Bacillus anthracis probably has limited capacity for growth in the external environment, due in part to antagonistic soil bacteria. Growth may occur in alkaline soils with much decaying vegetable matter, and alternate periods of rain and drought and temperatures in excess of 15.5°C may also facilitate growth. The spores are known to remain viable in soil for at least 15 years, and probably much longer, since they have been noted to retain their vitality and virulence for 50 years in the laboratory. Natural survival of vegetative organisms is rather short, equivalent to the short duration of an infection; vegetative organisms do not survive in a carcass, but are rapidly killed by putrefactive bacteria. In the terminal stages of the disease, large numbers of bacilli are excreted in all natural excretions, as well as pathological exudates, and these organisms sporulate and perpetuate infections. As a general rule, *the spores are very resistant to methods of disinfection*, with the exception of chemical disinfectants which are oxidizing agents. Spores on skin have even survived tanning processes to become a hazard for humans.

Reliable details on how spontaneous infections are initiated in animals are not available, but the disease in wild herbivores often follows construction requiring excavation, such as fencing and excavation of dug-outs for watering livestock. It is accepted that dogs and pigs acquire the infection as a result of eating an animal that had anthrax, and deaths in humans have occurred after eating inadequately cooked meat from a goat dead of anthrax. Anthrax in pigs has been traced to the ingestion of bone meal which was not sufficiently sterilized. Vegetative bacilli are unlikely to cause the disease since they are rapidly destroyed in the acid medium of the stomach. Cattle and sheep are presumed to obtain the infection by ingestion of contaminated food and water, entry through mucous membranes possibly being aided by local trauma. Cutaneous infection is rare in cattle but has been reported in India, and pulmonary anthrax resulting from the inhalation of spore-laden dust can occur. Infection through the skin is occasionally seen in sheep, and may be assisted by grass seed infestation. Ingestion is an important mode of infection in horses and dogs, as indicated by the common occurrence of lesions in the throat. It is also thought that infection can be transmitted to horses by blood-sucking insects. Intestinal anthrax in pigs probably reflects infection by ingestion.

The **pathogenesis** *of anthrax is an initial lymphangitis and lymphadenitis* (Fig. 2.126), *which develops into septicemia.* This sequence is especially well illustrated in the pulmonary form of the experimental disease; spores that are inhaled are ingested by cells lining alveoli and transported in them to the tracheobronchial nodes, in which vegetation and true initiation of the infection occur. Spread to the blood is via lymphatics as well as by lymphovenous connections within lymph nodes, and numerous bacilli spread in the lymph from node to node as the filtering mechanism of each is successively swamped. Bacilli that enter the blood are taken up in other parts of the mononuclear phagocyte system, especially the spleen, to establish secondary centers of infection and proliferation.

There is notably little response on the part of a susceptible animal to the local establishment of anthrax infection. *Physiological disturbances, clinical signs and death depend on the development of a massive septicemia.* In immune animals, e.g., guinea pigs, infection is followed by a period of 2–4 hours in which the bacilli proliferate; the area then becomes infiltrated by leukocytes, and the bacilli fragment with little or no phagocytosis of intact organisms. The lysis of bacilli, of which the first sign is loss of capsule and staining properties followed by fragmentation, is apparently due to anthracidal substances in plasma or, more likely, liberated from leukocytes. Anthrax has always been regarded as dependent on invasiveness rather than toxigenicity, but it appears that antitoxic immunity does, in some manner, inhibit invasiveness.

Vegetative cells produce a small array of **toxins**. The organisms themselves and the capsular material are virtually nontoxic, although the capsular material may act as a spreading factor and inhibit the activity of leukocytes. The activity of toxins in septicemic anthrax is well illustrated by the demonstration that, once the degree of bacteremia passes a certain threshold, which is about 0.3% of the usual

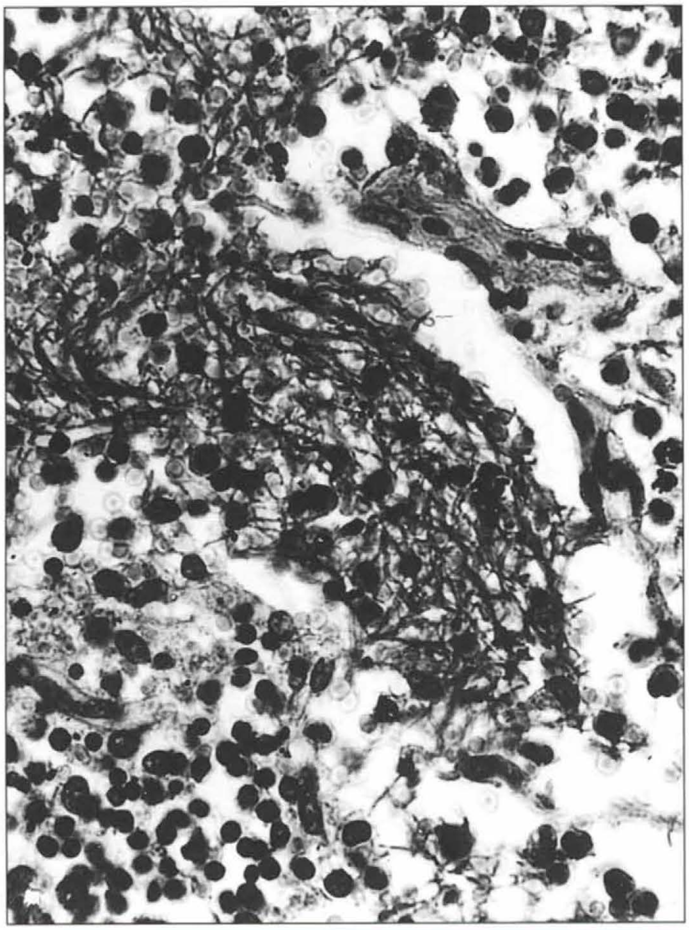

Figure 2.126 Anthrax bacilli in peripheral sinus, lymph node, ox.

maximum, death will occur even though all bacilli may have been destroyed by antibiotic therapy. *The toxin consists of three complementary components designated factors I, II, and III, or edema factor, protective antigen, and lethal factor*, respectively. *Edema factor* is an adenylate cyclase that increases cyclic AMP after activation by calmodulin. *Protective antigen* is likely a receptor-binding protein that appears to be essential for the biological effects of edema and lethal factors. *Lethal factor* is a CNS depressant, but its major effects may be elsewhere. The toxins have been assessed only in experimental laboratory animals, between species and strains of which there are considerable differences in sensitivity. The three toxins are serologically distinct and, since there is autostimulation, it is not surprising that they do not produce lesions when injected separately. *The combined effects of the three toxins are injury and inactivation of phagocytes, increased capillary permeability, anticomplementary activity, and impairment of coagulation.*

Immunity to anthrax appears to depend on the neutralization of toxin. Antibodies against the bacterial cells and capsules are useless, as is evident from the experience that completely avirulent or dead bacilli are not immunogenic; in fact, the most potent vaccines are of bacilli that proliferate and cause acute local inflammation but that do not invade the blood. The antigen that provokes antitoxic immunity is the protective antigen discussed above; it is presently regarded as being a nontoxic degradation product (toxoid) of the very labile toxin found in the blood of affected animals. The vaccine of Pasteur apparently resulted from the loss of a temperature-sensitive plasmid that encoded for the protective antigen.

When an animal is suspected of having died of anthrax, organisms should be detected in smears of blood or local exudate. All bacilli in internal organs are likely to be destroyed in 48 hours or less by putrefaction. Hence, *it is best to obtain blood for diagnostic purposes from close to the coronet or the tip of the tail*, places that are likely to be involved last by putrefactive processes that destroy the vegetative bacilli. *Bacillus anthracis* occurs in blood in pairs or in short chains of 3–4 cells. They are large truncate organisms that are easily observed. *They are differentiated from putrefactive bacteria by their distinct capsule, which stains pink with old methylene blue, and by having square ends when these are apposed.* The free ends of *B. anthracis* are often rounded as in *Clostridium* spp. The organism can be cultured readily from putrefied exudates if advantage is taken of its aerobic requirements and the heat resistance of the anthrax spores, to separate it from nonsporulating organisms and sporulating anaerobes. The organism can also be purified in guinea pigs by applying the inoculum to scarified skin. In nonsepticemic anthrax, such as occurs in swine and dogs, it is best to look for the organism in the local exudates and affected lymph nodes. For the diagnosis of anthrax, when other methods have failed or the tissues are old and dry, the Ascoli agar-gel precipitin test is useful but not completely specific.

Bovine anthrax is usually septicemic, and *sudden death* is usually the first indication of its presence in a herd. Even when cattle are observed closely, they may be dead within 1 hour of showing signs of illness, although some will show general signs of illness for about 24 hours before death. The signs of illness vary with the route of entry and when, as usually happens, entry is by inhalation or ingestion with no area of localization, the animals are depressed and listless. On examination there is high fever, increased heart and respiratory rates, and congested and terminally cyanotic mucosae that show evidence of bleeding. Animals that survive for a day may have dysentery, abortion, edematous swellings of the perineum, throat and abdominal wall, and blood-stained milk. Although infection may be virtually synonymous with disease and death in goats and sheep, it is not necessarily so in cattle, in which species *some infected animals probably recover*. This is suggested by the recovery of some animals that are experimentally inoculated and by the occurrence of transient febrile reactions attributable to no other causes, in herds in which fatal anthrax is occurring. For most animals, however, treatment to be effective must be administered early before there is marked septicemia and toxin production.

The carcass of an animal dead of this disease putrefies quickly, becomes very rapidly distended with putrefactive gases, and blood exudes from the natural orifices. These changes are, of course, not diagnostic, but when they are observed in an animal that has died suddenly in an area in which anthrax is endemic or has at any time occurred, the examination of smears of blood should always precede autopsy. Anthrax in the fulminating disease is very largely an intravascular infection with most of the organisms in the blood and the rest in the spleen. Septicemia in anthrax is a terminal event, and smears of blood may not be helpful when prepared more than a few hours before death.

The morbid picture of the disease in cattle is characterized by *splenomegaly*, multiple hemorrhages, and edematous effusions in connective tissues. *A very large soft spleen is the most significant lesion, and very rarely is it absent*. Splenomegaly occurs in other diseases of cattle, but rarely is it as large in association with sudden death. In anthrax the spleen is soft, sometimes it ruptures spontaneously, and when it is incised the pulp exudes very thick black-red blood which brightens in color on exposure to air. Smears and sections of the spleen reveal very large numbers of bacilli if the carcass is fresh but, when decomposition is advanced, they are destroyed by putrefactive changes. In some cases, splenomegaly is the only lesion. The histology of the spleen is not revealing. The sinus areas are distended with sludged red cells and the lymphoid follicles are widely separated and hypocellular, but numerous leukocytes and bacilli in chains are present. *It is typical of septicemic anthrax that the organisms are always intravascular.*

The blood is thick and dark, frequently described as tarry, and either it is not clotted or the clots are very soft and friable, compatible with the effects of the combined toxins in inhibiting the clotting system. There are likely nonspecific effects present, such as the disseminated coagulopathy and fibrinogenolysis that accompany hyperthermia. Small hemorrhages are common in the mucous and serous membranes and in the subcutaneous connective tissues. Loose connective tissues in any location may be infiltrated with gelatinous fluid, and accumulations of such fluid in serous cavities are stained with blood. There is congestion, swelling, and degeneration of parenchymatous organs. The myocardium is dull and flabby.

Cattle are moderately resistant to *B. anthracis* so that local lesions may occur at the site of entry. Local lesions are usually in the small intestine and take the form of *ulcerative hemorrhagic enteritis*, but acute inflammation in the abomasum and large intestine may also occur. The most severe lesions may be over the lymphoid tissues of the intestine, or extend for a considerable distance from these. The mucous membrane is intensely red, and at a greater distance is sprinkled with small hemorrhages. The contents of the intestine are then deeply stained with blood. Superficial necrosis and ulceration occur in some areas of most intense hyperemia. The corresponding mesentery, up to the regional nodes, is infiltrated with gelatinous fluid as a result of acute lymphangitis, and the fluid may be stained with blood. The regional nodes have the appearance of the spleen. They are enlarged, red-black, and on cut surface are moist and shiny. The vessels are intensely congested, and hemorrhage extends into the peripheral sinuses and cortex. Bacilli are numerous and leukocytes are present, but there is no necrosis.

In some cases in which the organisms gain entry through the oropharynx, there is hemorrhagic lymphadenitis of the nodes of the throat and edema of the connective tissues in these regions. The occasional case of *pulmonary anthrax* in cattle is characterized by acute congestion and consolidation of a portion of the lung with larger areas of interstitial edema, edema of the mediastinum, and regional hemorrhagic lymphadenitis. The pulmonary lesion is exudative, but lacks the full gamut of inflammatory change unless another cause of pneumonia is superimposed.

Sheep are more susceptible to *B. anthracis* than are cattle, and local lesions do not occur except in the unusual instances of percutaneous infection, in which the lesion may take the form of spreading edema from the outset or initially appear as hard circumscribed nodules. The disease in sheep takes the same course as that in cattle except that it is even more rapid. Splenomegaly is not as prominent in sheep as in cattle, likely because of the greater level of collagen in the splenic capsule of sheep. The parenchyma is, however, dark and soft. Edematous effusions do not occur in sheep.

Clinical signs of anthrax in **horses** may last for several days and are characterized by *colic* or by *large edematous swellings*. The swellings, which can be very extensive, occur on the ventral part of the abdomen and thorax, the legs, in the perineal region and about the external genitalia. Dysentery may accompany the acute colic. When ingestion is the route of infection in horses, the primary lesion may be in the throat or the intestine, and death may occur from the local reaction and without septicemia. Intestinal lesions are similar to those described above for cattle, and pharyngeal lesions are similar to those described below for swine. When septicemia occurs, the morbid changes are the same as in cattle, including very prominent enlargement and congestion of the spleen.

Pigs are relatively resistant to anthrax. They acquire the infection from eating infected flesh and the infection remains localized to the throat or intestine. Since septicemia is exceptional, splenomegaly is not a prominent part of the gross picture. *The characteristic sign is swelling of the pharyngeal region and neck.* Some pigs have diarrhea and dysentery, but it is unusual to have intestinal localization without pharyngeal localization. Anthrax without illness has been observed in swine; in such cases the disease is limited to isolated mesenteric or pharyngeal nodes.

The local lesion of anthrax is swine is a typical carbuncle at the point of entry, with acute regional lymphadenitis and lymphangitis. Some bacilli no doubt reach the blood, but they do not establish septicemia. Bacteria may localize in liver, spleen or kidney to produce a metastatic carbuncle but, usually, only individual nodes near the site of entry are involved. The lymphadenitis may be diffuse or focal but in both cases it is, in the initial stages, hemorrhagic. An intense leukocytic infiltration occurs, all cells within the affected portions of the node die, and the focus becomes encapsulated. With necrosis, the affected tissue changes from a brick-red to a gray friable mass that can be easily shelled-out when the gland is incised.

In *primary intestinal anthrax in pigs*, the initial lesion is focal or multifocal hemorrhagic enteritis, with a central zone of diphtheresis that eventually ulcerates. The adjacent serosa and mesentery are thickened with edema fluid and yellow, with foci and streaks of hemorrhage; they are the site of focal hemorrhagic necrosis due to acute necrotizing vasculitis and lymphangitis. These mesenteric lesions extend only as far as the regional nodes, which show the type of lymphadenitis characteristic of anthrax in swine.

Dogs are reputedly quite resistant to *B. anthracis*, but a number of outbreaks have been observed in kennels in which the dogs have inadvertently been fed meat from an animal that has died of the disease. Anthrax in dogs may pursue a *peracute course* to sudden death, it may be of the *pharyngeal type* in which extensive edema develops in the face, head and neck, or it may be of the *intestinal type* with signs of acute gastroenteritis. Anthrax may occur in **mink** with high mortality after feeding fresh meat from infected animals.

Streptococcal adenitis in swine

Jowl abscess *is a cervical adenitis caused by* ***Streptococcus porcinus***, and like strangles of horses, the deep infection follows colonization of the oral cavity and likely the tonsils. The disease has become less common with the introduction of better hygiene, age-matched groups, and feeding equipment designed to avoid sharp projections. The organism has 8 serotypes, based on carbohydrate antigens, of which type 4 is most frequently isolated from cervical lymphadenitis of swine. Baby pigs have passive immunity, and transmission occurs through direct contact with infected animals that can shed organisms for months, and also from contaminated environment. Invasion of the nasopharynx is followed by mild fever and leukocytosis that resolve, and by lymph node enlargement in 2 weeks, which less often progresses to open drainage. The mandibular nodes are most often involved, followed by the retropharyngeal and parotid nodes. The disease is not often of clinical importance, and affected animals grow well, but losses result from condemnation at slaughter. Bacterins are less effective than live oral culture in prevention.

The abscesses are usually multiple and measure 1–10 cm in diameter. The pus is typically without odor, green, and creamy in consistency. *Streptococcus porcinus*, a beta-hemolytic *Streptococcus* that belongs to Lancefield's group E, can be isolated regularly from the pus.

Rhodococcus equi is often present in the submaxillary lymph nodes of swine and has been proposed as the cause of lesions typical of tuberculosis in these nodes. Evidence suggests, however, that *R. equi* is not responsible for the tubercle-like lesions, which are thought to be caused by *Mycobacterium* spp. of one or other variety. *Rhodococcus equi* has been isolated from lymphadenitis in cattle.

Streptococcal adenitis in dogs

Streptococcal adenitis of dogs is similar to the disease in swine. It occurs in minor endemics in kennels and is characterized by pharyngitis, fever, conjunctival discharge and enlargement of the submaxillary nodes. The illness is transient in most cases, but in approximately 10% of dogs the course is prolonged for 2 weeks or more, and in these there is a tendency for the nodes to suppurate. The abscesses may be encapsulated and sterilized, or they may fistulate on to the skin and heal. Dysphagia, and occasionally asphyxia, occur in puppies. Typically, the *Streptococcus* belongs to Lancefield's group G and, coincident with the pharyngeal infection, bitches may have inflammation of the genital tract caused by the same organism.

Cervical adenitis caused by the group G organism may occur in **kittens**.

Tularemia

Tularemia (deer fly fever) is caused by ***Francisella tularensis***. The disease was first described in Tulare county of California and is still more common in the western USA than elsewhere. The organism is a tiny, gram-negative, very pleomorphic coccobacillus that is a strict aerobe and shares many cultural and epidemiological features with *Yersinia pestis*, the cause of bubonic plague. *Francisella tularensis* is found worldwide except for Australia and Antarctica, but the biovar tularensis is found only in North America. *Francisella tularensis* infects a wide range of species, including most *domestic animals, humans, and wild rodents*, and it is in these last two that the disease is most often fatal.

The organism is abundant in nature as an infection of many species of rodents, and it is from these, either directly or by the mediation of insect vectors, that humans and domestic animals acquire the infection. The organism is able to penetrate intact skin and mucous membranes, but it is also infective by ingestion, inhalation, and inoculation by biting insects and ticks.

Tularemia in humans is a severe systemic disease, with various manifestations depending on dissemination or localization. *The disease in rabbits and rodents is recognized by the presence of miliary white foci 2 mm or more in diameter in the liver, spleen and lymph nodes.* They are indistinguishable grossly from the lesions caused by *Yersinia pseudotuberculosis*. Histologically, the lesions are characterized by *very focal but complete necrosis*. Neutrophils and pus may be present early and macrophages accumulate, but in slightly older and larger lesions there is total coagulative necrosis with a granularity that resembles caseation (Fig. 2.127). A very few fibroblasts and macrophages produce a sharp, narrow margin for the lesion. The bacteria can be demonstrated quite readily in lesions, in clumps in macrophages and especially as dead but still distinguishable ones in the center of the focus. The lesions in lymph nodes are often larger than those in the liver and may be readily visible grossly as wedge-shaped areas of cortical necrosis demarcated by a narrow zone of intense reactive hyperemia. The affected nodes are palpably enlarged in the living animal and may discharge a thin red pus on to the skin. The lymphadenitis may be generalized or restricted to the nodes draining the site of infection which, if visible, is an ulcerated papule.

Francisella tularensis is probably common as an infection in animals, but *the disease tularemia is not common*. It is probable, too, that

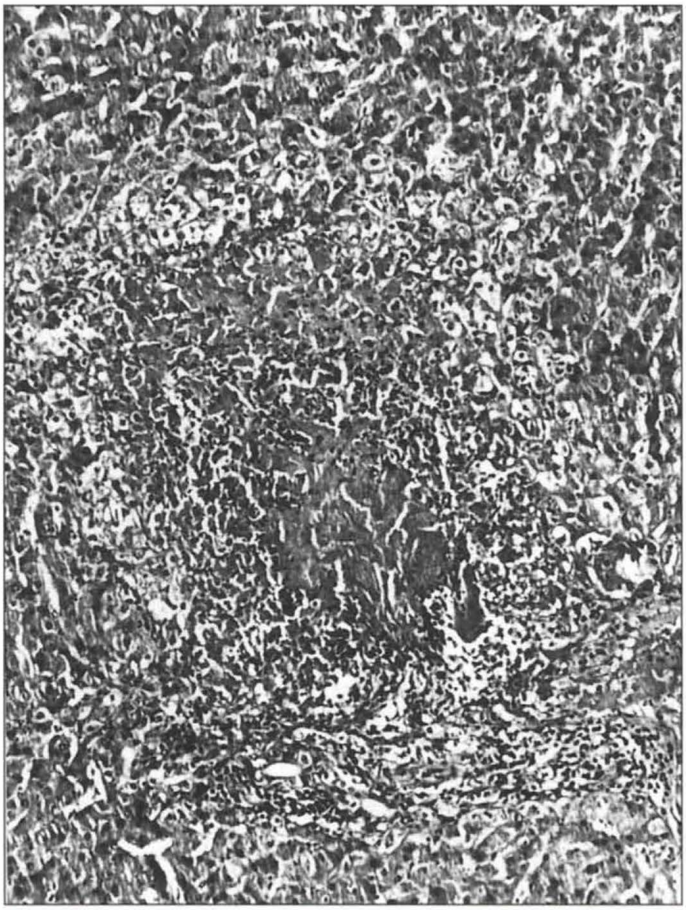

Figure 2.127 Pyogenic granuloma in tularemia in the liver of a sheep.

the infection may remain latent in domestic animals for long periods without causing ill health and with or without focal lesions, as has been observed in dogs. As a facultative intracellular parasite, it may persist for years as a latent infection, for which effective immunity is cell-mediated.

Naturally acquired, latent (subclinical) infections with *F. tularensis* have been observed in *dogs and cats* but, as a general rule, these species are resistant to the disease. Fatalities due to tularemia have been observed in *foals and sheep* in association with heavy infestations by ticks, and it is probable that the disease is endemic in sheep in areas where the reservoir rodents and ticks, especially *Dermacentor andersoni* and *Amblyomma americanum* abound. The disease in foals is characterized by a systemic and febrile illness with, at autopsy, enlargement of liver, spleen and kidneys, and the presence of the typical small necrotic foci of this disease. Tularemia in sheep is also associated with a heavy infestation of ticks; recovery can occur if the ticks are removed before the illness is far advanced. Affected sheep have high fever, stiffness of gait, depression, diarrhea and an increased respiratory rate. Lesions may be confined to the superficial lymph nodes or show the more classical localization. Pneumonia, probably of other cause, and anemia caused by the ticks are frequently present.

Pseudotuberculosis

Yersinia pseudotuberculosis occurs worldwide in wild rodents and birds and is widespread in nature, recoveries having been made from soil, milk and feed. The organism regularly produces disease, often in epidemic proportions, only in *rodents and birds*. Sporadic infections with this organism and occasional outbreaks of disease occur in domestic species, laboratory colonies, mink and chinchilla colonies, and zoos. *Cats*, because of their contact with rodents and birds, are the domestic species most apt to be secondarily involved by outbreaks of the disease in its natural hosts. Losses of serious proportion, however, occur in *sheep* which are exposed to large numbers of organisms during outbreaks of the disease in rodents during cold weather. *The ovine disease is known as "pyemic hepatitis."*

The general pattern of this disease is the same in all species, the variation that occurs with respect to severity and duration being related to species susceptibility, and numbers and virulence of the organisms. *Yersinia pseudotuberculosis* is a *facultative intracellular parasite*, which explains the latent carrier state and the need for strong cell-mediated immunity for protection from infection. *The route of transmission is by ingestion* and, in susceptible animals, organisms enter the body through the intestine. Small necrotic foci develop in the Peyer's patches of the ileum and colon, and extend as lymphangitis to the regional nodes. The organism becomes septicemic and may kill susceptible rodents at this stage; more typically, and in all domestic species, *caseonecrotic foci form in the mesenteric nodes, spleen and liver* (Fig. 2.128A, B), often in association with fibrinohemorrhagic inflammation in the small intestine. The hepatic foci, which are the most obvious, are 1–10 mm in diameter, white and have no or scant tendency to encapsulation or softening. They are interspersed with irregular areas of parenchymal collapse that probably result from vasculitis and thrombosis (Fig. 2.129A). Microscopically, there is necrosis, with bacterial colonies and fragmented leukocytes surrounded by macrophages. Giant cells are absent, even from later contracting granulomas (Fig. 2.129B). The mesenteric nodes and spleen contain similar foci, and are enlarged by lymphoid and histiocytic hyperplasia. The mesenteric nodes in the cat may be 2–4 cm in diameter and can be grossly confused with intestinal toxoplasmosis or lymphomatosis.

Yersiniosis has emerged as a significant cause of disease in *farmed ruminants*, including deer. Affected deer may be found moribund or dead, but animals under observation are systemically ill with profuse diarrhea. The incidence of disease in younger age groups rivals that of salmonellosis. In addition to the *mesenteric lymphadenitis and hepatitis, enteritis* is consistently present and characteristic in its histologic expression. Numerous bacterial colonies are present in the lamina propria, associated with multiple suppurative foci or a diffuse suppurative enteritis.

In view of the extraordinarily wide host range of *Y. pseudotuberculosis* in natural infections, it is surprising that the infection is not recorded more often. This may be due in part to a preference of the organism for growth at room temperature rather than at 37°C.

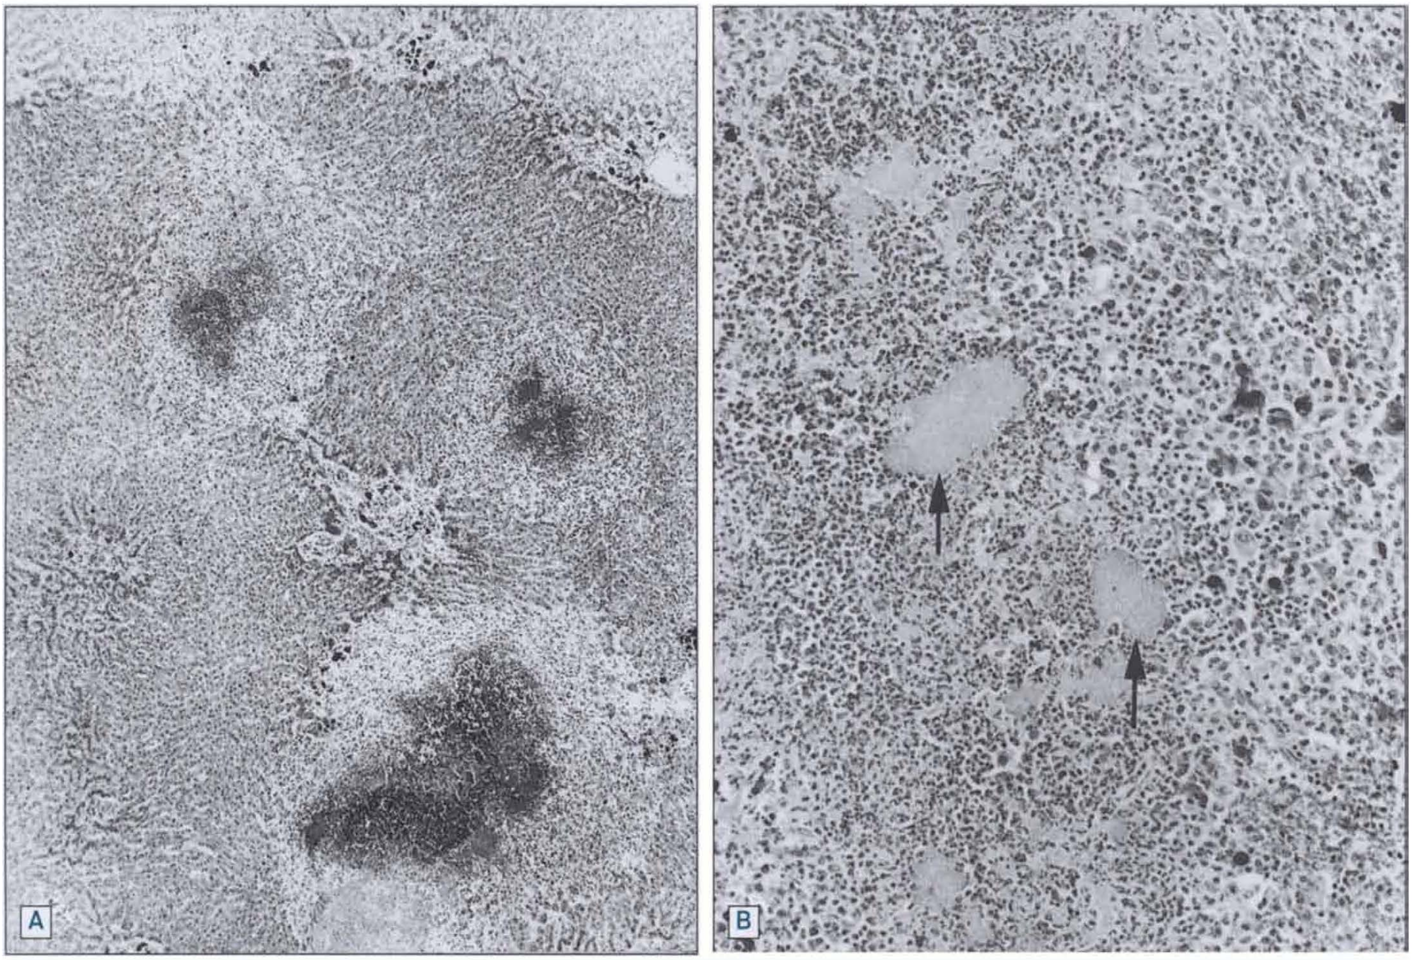

Figure 2.128 ***Yersinia pseudotuberculosis* infection** in a sheep. **A.** Multiple pyogenic granulomas in liver. **B.** Acute suppurative splenitis. Large bacterial colonies (arrows).

While susceptible laboratory species, such as guinea pigs and mice, are readily infected experimentally, there are few pathogenetic studies in domestic species. The frequency of natural infection in cats contrasts with the difficulty in establishing experimental infection in this species, which suggests the need for some predisposing alteration in the alimentary mucosa.

The related organism ***Yersinia enterocolitica*** causes *gastroenteritis and mesenteric adenitis* in a wide variety of species, including wild and domestic animals and is increasingly isolated from cattle. The organism has been isolated from deer, rabbits, dogs, pigs, horses, mink, various avian species, as well as sheep and goats. *Yersinia enterocolitica* shares an antigen with *Brucella abortus* that may result in false-positive agglutination reactions in serologic testing for brucellosis.

Histoplasmosis

Histoplasmosis is caused by ***Histoplasma capsulatum***, a facultative intracellular parasite of macrophages, and is characterized by diffuse involvement of the mononuclear phagocyte system. *Histoplasma capsulatum* is a dimorphic ascomycete fungus. The *parasitic phase* is yeast-like, whereas the *nonparasitic phase* produces an abundant mycelium. The mycelium produces two types of spores: a small, smooth, globose *microconidium* 2–3 μm in diameter, and a large, thick-walled, globose *macroconidium or chlamydospore* that bears prominent surface projections. The chlamydospores are an identifying feature of the fungus and also the initiators of the parasitic phase.

Histoplasmosis has a worldwide distribution and is frequently diagnosed in the Mississippi, Ohio, and St. Lawrence river valley areas of North America. *It is a largely noncontagious disease of humans,*

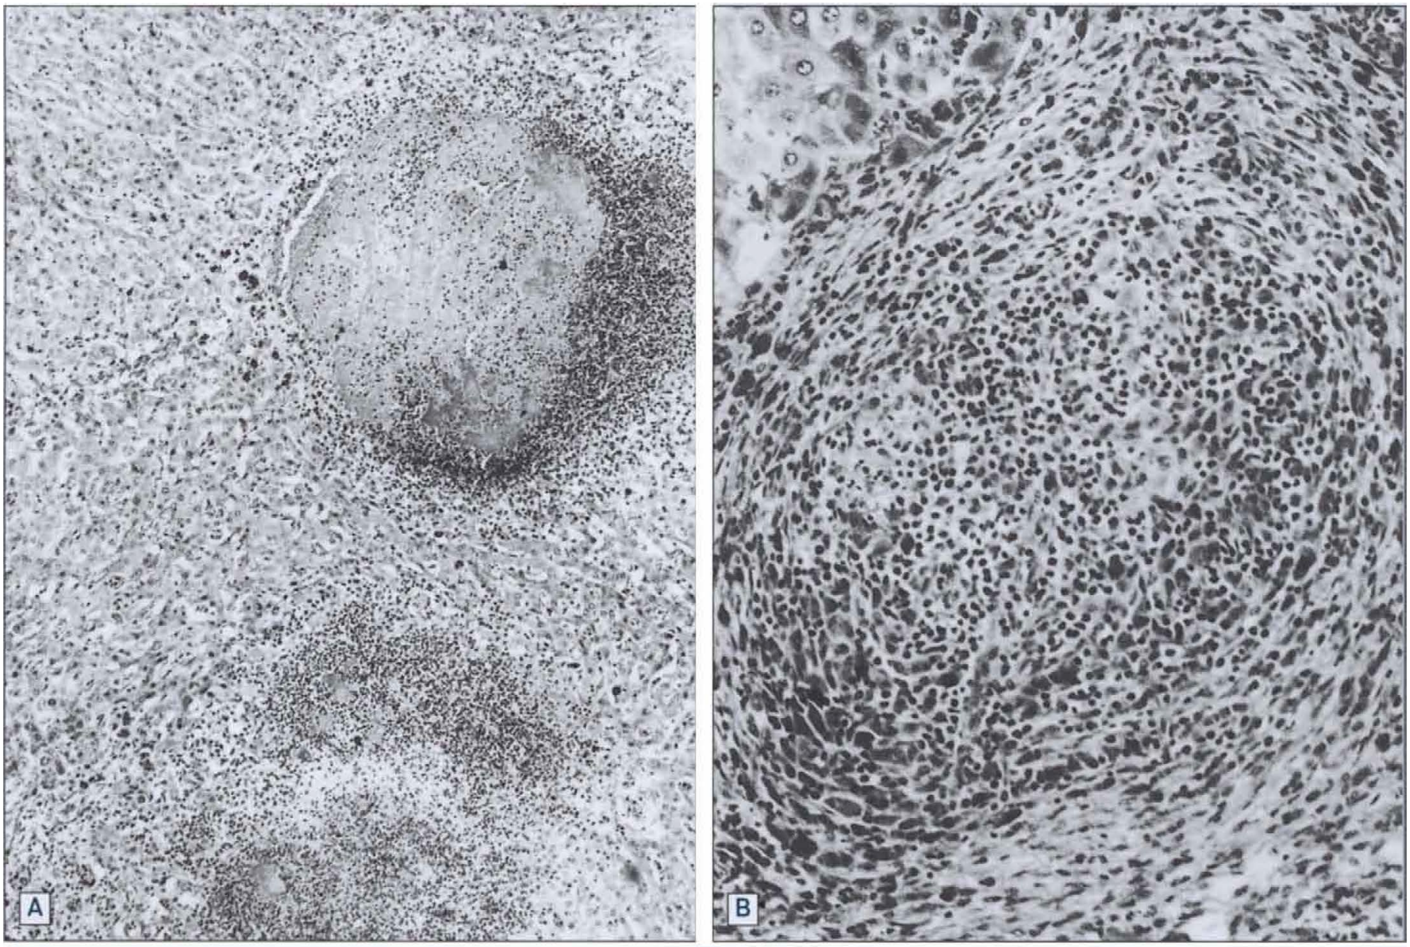

Figure 2.129 ***Yersinia pseudotuberculosis* infection** in the liver of a sheep. **A.** Septic phlebitis, sublobular vein. **B.** Residual granuloma of protracted infection.

dogs, cats, swine, cattle, horses, and wild animals, and it is suspected that the endemic distribution of the disease is related to factors that favor the persistence and growth of this environmental mold in the soil. The ubiquitous nature of the organism, its intracellular habitat, and its low infectivity suggests that cell-mediated immunity may be a major factor in the pathogenesis of disease.

It is generally agreed that *infection is obtained from soil*, either by ingestion or by inhalation of dust, and a distinct association has been repeatedly demonstrated between *Histoplasma capsulatum* and places where *pigeons* congregate, with abandoned *chicken* runs and houses, and with *bat* caves. Chickens themselves are not infected because their high body temperature is not conducive to growth of the organism.

The disease in animals is seen most frequently in *dogs* and less often in *cats*. Transmission from dog to dog has been established, but it is not known if dogs can transmit the disease to humans. When histoplasmosis becomes apparent clinically, the infection is disseminated, and the disease is then progressive and always fatal. Only a minority of infections become disseminated and cause disease, while *the majority occur without signs or lesions*. A high incidence of infection in endemic areas has been confirmed by cultural means, either by direct culture of organs or by first passing infected tissues through mice, which are highly susceptible to *H. capsulatum*. Bats, however, are resistant to infection with *H. capsulatum*, and frequently shed spores in their feces. Caves inhabited by bats are heavily contaminated with fungal spores, and it is suggested that this may be a further means of soil contamination particularly in the south and western United States. Positive cultures can be obtained from about 50% of unrelated cats and dogs.

Transmission is by inhalation of airborne conidia, followed by phagocytosis in the lung and then transport in phages to other areas of the body. This route accounts for the high incidence of infection in the bronchial and cervical lymph nodes. Since intestinal lesions are usually present, it is felt that ingestion might provide a direct route of infection. However, in disseminated disease, the intestine could be secondarily infected like many other tissues.

The course of *latent infections* in animals is not known, but the evidence suggests that such infections can persist for many months and possibly are permanent. Infection has been known to persist, without causing ill health, for 2 years in guinea pigs, 6 months in other laboratory rodents, and 4 months in kittens.

Animals with advanced disease due to *Histoplasma capsulatum* show emaciation, persistent diarrhea, pyrexia and enlargement of liver, spleen and lymph nodes. In a particular animal, the clinical signs are most commonly related to either the respiratory or the gastrointestinal tract.

Animals with histoplasmosis most consistently have mild nonresponsive, normochromic normocytic anemia. Leukocytic changes vary with the reserves of the animal and the stage of the disease. If the animal is in good body condition, the bone marrow is competent and there is neutrophilic leukocytosis with some degree of monocytosis. Later with debilitation, the leukocyte count drops to normal levels or lower with left shift and marked toxic changes, including the appearance of Doehle bodies. There is usually lymphopenia and eosinopenia. *Since the organisms are readily recognized on microscopic examination, fine-needle aspiration of liver, spleen, enlarged lymph nodes, marrow or skin provides adequate material for diagnosis in appropriate cases.* Occasionally the organism may be diagnosed in fine-needle aspirates of lung or bronchoalveolar lavage fluids, or lavage of the turbinates in animals with sinusitis. Cytologically, *the organisms are present in the cytoplasm of macrophages*, unless the cells have been injured, and are somewhat larger than when seen in histologic preparations.

Grossly, the *pulmonary lesions* of histoplasmosis may be in the form of gray, rounded nodules of 1–2 cm in diameter and with a distinct tendency to become confluent, or there may be a diffuse increase in the consistency of the lungs. When the *intestine* is involved, as it frequently is, the lesions are located chiefly in the lower part of the small intestine. The mucosa is the site of nodular thickenings or of corrugations similar to those seen in Johne's disease of cattle. The thickenings are due to infiltration of lymphocytes, plasma cells and macrophages in the lamina propria and submucosa, and they may extend also through the wall to the subserosa giving the gut a thickened pipestem appearance. When the thickening is extreme, ischemic ulcerations occur.

The *lymph nodes* are greatly enlarged, but are discrete and without adhesions. There may be no indication of normal architecture on the cut surface, with the uniformity resembling lymphoma, except that the nodes are firm and dry. Histologically, there are coalescing granulomas with histiocytosis, and cortical replacement by the reaction. The spleen is enlarged (Fig. 2.130), sometimes to several times its normal size, gray and firm. There is marked sinus expansion and filling by fixed cells of stromal origin and by colonization with macrophages, many of which contain the ingested organisms. There is lymphoid atrophy, varying in degree with the stage of debility of the animal. The liver is uniformly enlarged, firm and gray. The discoloration is diffuse and related to capsular thickening without focal lesions. The infiltrating cells collect in miliary foci in the portal triads and sinusoids, causing extensive displacement and atrophy of the parenchyma (Fig. 2.131A). The adrenal glands are often involved, the medulla, the cortex, or both, in histoplasmosis that is allowed to run its full course (Fig. 2.131B). Scant normal tissues may then remain in these organs.

Since *Histoplasma capsulatum* is an intracellular parasite of macrophages and causes diffuse involvement of the mononuclear phagocyte system, focal discrete lesions are not to be expected. *The enlargement of organs is due to extensive proliferation and infiltration with monocytes and epithelioid macrophages in whose cytoplasm many of the typical yeasts in small or large numbers are found* (Fig. 2.131B). The yeast bodies in sections and when stained with H&E appear as *basophilic dots with a clear halo*. The halo is part of the yeast's cell wall and can be demonstrated by stains for bound glycogen, the organism then appearing as a ring. Such stains are very helpful in distinguishing these organisms from cellular debris, but are not necessary when the yeasts are plentiful. Necrosis of tissues is not often present in histoplasmosis, although central caseation without mineralization may occur in large, dense accumulations of macrophages. Giant cells are seldom seen and there is only mild fibrosis.

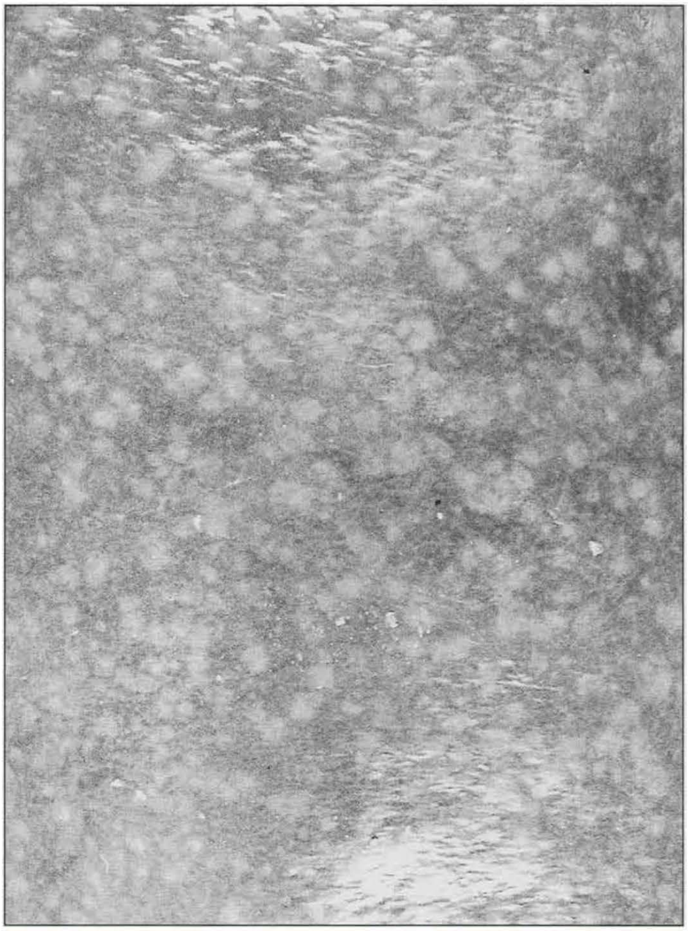

Figure 2.130 Histoplasmosis in a dog. Miliary epithelioid granulomas in the capsular surface of enlarged spleen.

The diagnosis of *occult histoplasmosis* can be made only by isolation of the organism from tissues. Responsibility of this organism for focal nonprogressive lesions can be accepted only when the fungus can be demonstrated histologically in the lesion, and this is rarely possible even in animals that are sensitive to histoplasmin.

The organs mentioned above are those most consistently and obviously involved in histoplasmosis. In the fatal disseminated disease, lesions of similar type may be found in other organs and tissues. *There is seldom any difficulty in demonstrating organisms in sections, although Grocott stain and PCR are more sensitive than H&E, and clinically they are readily cultured.* Culture should not be undertaken without precautions to prevent the inhalation of chlamydospores. Biopsy of enlarged lymph nodes and aspiration biopsy of bone marrow are useful for diagnostic purposes. In some cases, the organisms can be demonstrated in circulating monocytes, but they are never plentiful, so examination is best performed on buffy coat preparations.

Leishmaniasis

The genus ***Leishmania*** is of protozoan parasites which are classified in the family Trypanosomatidae. Species of the genus are parasites of *humans, dogs, and other mammals*. Species of sandflies (*Lutzomia*) are the intermediate hosts and are essential for the maintenance of virulence, whereas other blood-sucking insects, including members of the genera *Phlebotomus* and *Stomoxys* and the tick *Rhipicephalus*, may act as mechanical vectors. Direct transmission and vertical transmission may occur in kenneled dogs.

The protozoa proliferate by binary fission in the midgut of the female sandfly and assume a *leptomonad form*, leaf-shaped with a single flagellum arising at the anterior pole. Infection of mammals occurs when the sandfly sucks blood, and in the mammalian host the protozoa assume the *leishmanial form* as rounded cells of ~2.0 μm in diameter with a vesicular nucleus and small kinetoplast but no flagellum. They multiply by binary fission and as leishmanial forms, the Leishman-Donovan bodies, are intracellular parasites of macrophages.

Leishmaniasis is important as a disease of humans, and wherever it occurs in humans it may also occur in dogs. Leishmaniasis actually includes three diseases:

- **cutaneous leishmaniasis** ("oriental sore") is caused by *L. tropica* and occurs in countries about the Mediterranean Sea;
- **mucocutaneous leishmaniasis** ("espundia") is caused by *L. braziliensis* and occurs in Central America;
- **visceral leishmaniasis** ("kala-azar") is caused by *L. donovani* and is endemic in parts of Europe, Africa, and Asia.

The species of *Leishmania* are not well distinguished; however, sequence data on kinetoplast DNA on several species permits their specific identification. Speciation depends on degrees of cross-immunity, different clinical manifestations, geographic location, and reservoir hosts. In some regions, such as India, the human population may be the reservoir but in other regions dogs, cats and other carnivores including rats probably serve as reservoir hosts.

Infections of animals with *Leishmania* spp. are probably quite common in endemic areas, but disease appears not to be. Latency of the infections, especially in the case of *L. donovani*, is also probable. *Both cutaneous and visceral forms of the disease have been described in dogs*, as well as cases of visceral disease in which the organisms are diffusely present in the dermis. Leishmaniasis is a disease of the monocyte–macrophage system, and the visceral disease mimics histoplasmosis. The protozoa

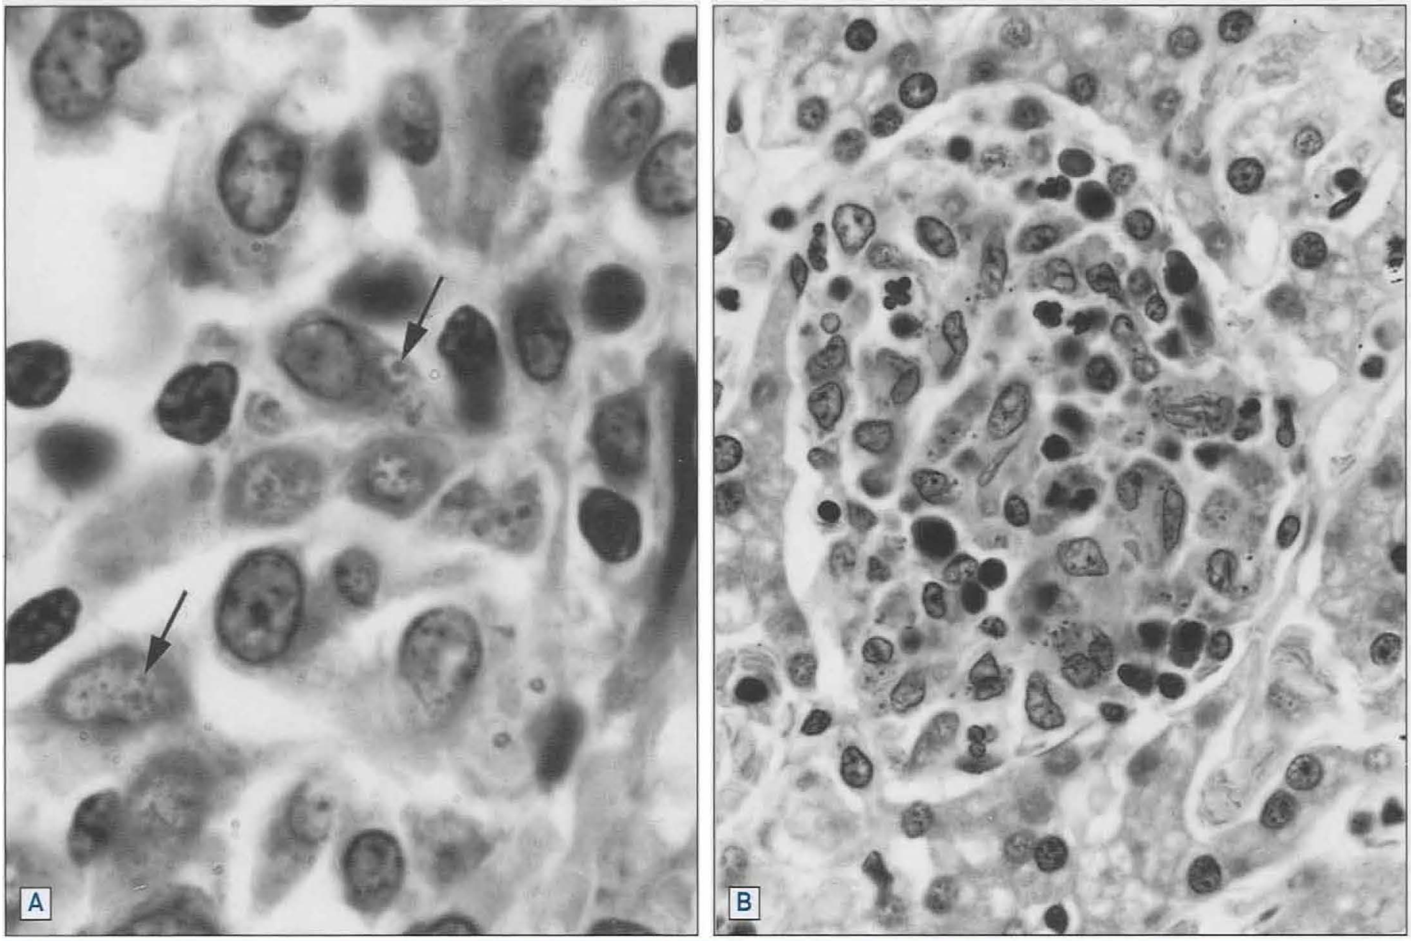

Figure 2.132 Leishmaniasis in a dog. **A.** Sinus area of spleen with macrophages, some containing *Leishmania* (arrows). **B.** Epithelioid granuloma in liver.

are not cytopathogenic in the usual sense, and destruction of host macrophages appears to be purely a mechanical consequence of proliferation of the protozoa in the cytoplasm.

Cutaneous lesions take the form of chronic ulcers that develop from inflammatory papules at the site of the insect bite. The organisms are inoculated by the biting insect and are soon ingested by histiocytes. Rapid proliferation of the protozoa disrupts the phagocytes, and the released organisms are ingested by further phagocytes to repeat the process. Lymphocytes and plasma cells surround the lesion and neutrophils are attracted to the debris. When the inflammation extends to the overlying epithelium, ulceration occurs. Numerous parasites are present within macrophages, and some are free in the tissue (Fig. 2.132A).

The *clinical signs of visceral leishmaniasis* in the dog are of chronic debility and often recurrent oculonasal discharge, with some crusting of the nose, and recurrent diarrhea. There may be mild enlargement of lymph nodes, and the spleen is always enlarged to some extent in the visceral form, but at any particular time may not attract clinical attention.

Grossly there are often focal scurfy skin lesions, but generally, in visceral leishmaniasis, the presentation is of a *mature dog in poor body condition with a rough hair coat.* The oral and cervical viscera are normal and the lungs generally have mild tan mottling but are otherwise normal, as is the heart. The liver contains numerous granulomas (Fig. 2.132B), and is symmetrically enlarged and dark brown. The spleen is 2–3 times or more normal size with symmetrical enlargement and is dark brown to black on capsular surface. There is mild irregular enlargement of lymph nodes with no other significant changes in the abdominal cavity except that the kidneys are darker than normal, and while of normal contour, there may be significant immune-complex glomerulonephritis and chronic renal failure. The bone marrow is uniformly reddened in midfemoral shaft in well-developed cases, but the fat is generally of normal character.

The lesions initially are of hemic-lymphatic hypertrophy with macrophage proliferation and focal granulomas (Fig. 2.132B). Splenic follicles are hyperplastic, often with follicular hyalinosis. In advanced cases, there is atrophy of nodes and spleen, and the sinus areas may be diffusely occupied by large macrophages heavily laden with intracytoplasmic organisms and numerous plasma cells (Fig. 2.133). The lesions in bone marrow may be focal, but consist of clusters of epithelioid macrophages with phagocytosed organisms (Fig. 2.134A, B). In the dog with a well-developed infection, the bone marrow will have remarkable plasma cell hyperplasia that may approach 50% of cells present and there is characteristically hypergammaglobulinemia. The protein is broadly polyclonal and the plasma cells lack atypia. Renal changes are variable and may consist of interstitial scarring with some parasitic involvement; however, the effects of hyperproteinemia and immune complexes appear to injure the kidney indirectly. Animals with leishmaniasis and amyloidosis have been described, and there may be concurrent changes due to both processes. *Diagnosis is based*

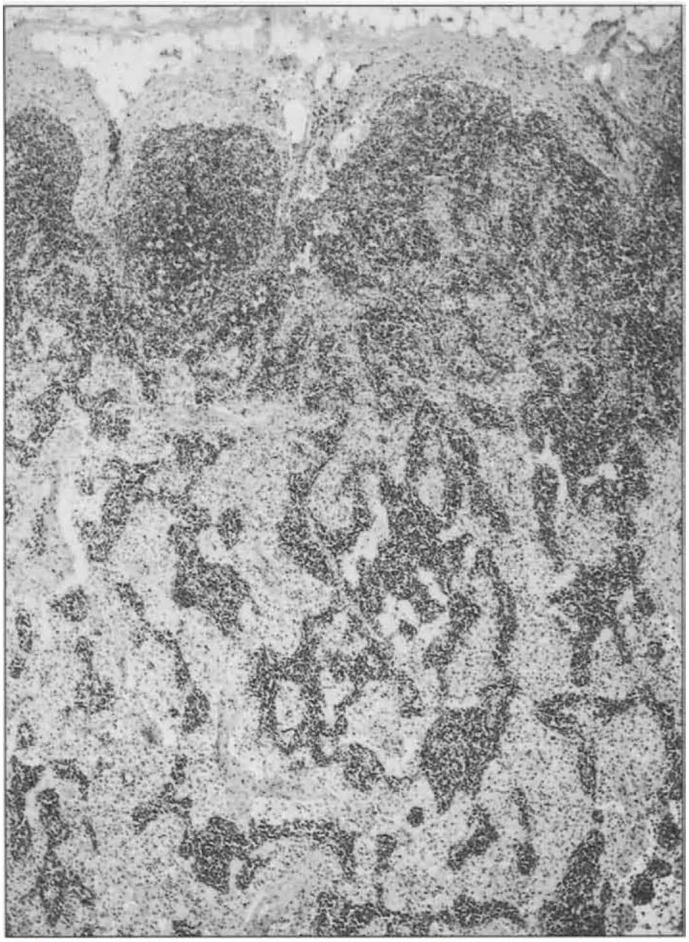

Figure 2.133 Leishmaniasis in a lymph node of a dog. Follicular and paracortical atrophy of chronic disease. Sinus histiocytosis and medullary cord hyperplasia.

on the demonstration of the organism in cytologic (Fig. 2.134A) *or in histologic preparation*, the former being easily achieved by aspiration of marrow, node, spleen, or liver.

Theileriosis

Theileria are protozoan parasites of the order Piroplasmida, family Theileriidae. Speciation within the genus is not precise and the system in use depends on geographic distribution, vector, mode of pathogenesis, morphology, and frequency of schizonts in lymphocytes and of piroplasm stages in red cells, as well as on cross immunity and host specificity. Phylogenetic classification can be expected to evolve as more molecular-based investigations are conducted. The species presently recognized as pathogenic for cattle include:

- ***Theileria parva parva***, the cause of **East Coast fever** of east and central Africa;
- ***Theileria parva lawrencei***, the cause of **Corridor disease** (buffalo disease) of southern Africa;
- ***Theileria parva bovis***, the cause of **January disease** (Rhodesian theileriosis) of east and central Africa;
- ***Theileria annulata***, which causes **Mediterranean or tropical theileriosis** across north Africa and central Asia; and
- ***Theileria buffeli*** group (*T. buffeli, T. orientalis; T. sergenti* (invalid term)), which are widely distributed in East Asia and are relatively benign.

Theileria mutans causes benign theileriosis, a less important tick-borne disease of cattle in Africa, North and South America, Asia, Australia, and Europe. ***Theileria hirci*** and ***Theileria ovis*** are parasites of sheep in North Africa, the Middle East, and southern parts of Eurasia. *Theileria* spp. *reproduce by schizogony in lymphocytes (leukocytic or tissue phase) and are subsequently found in red cells (erythrocytic phase)*. A related genus is *Cytauxzoon*, which reproduces by schizogony primarily in macrophages and by fission in red cells.

The *Theileria* are spread by *biological tick vectors*, principally of the *Rhipicephalus* and *Hyalomma* genera. Larval and nymphal ticks ingest parasites in the erythrocytes of infected hosts. After engorgement, they detach from the host animal and molt through to the next instar. During this period, the parasite migrates to the acinar cells of the salivary gland of the tick. At this stage, the parasite in the salivary gland of the unfed tick is not infective for cattle. Once the infected tick has started to feed, the parasites multiply in the salivary gland, and maximum infective stages for cattle are excreted in the saliva between 3–5 days after commencement of blood feeding.

This description relates particularly to *T. parva* and the acute form of the disease, **East Coast fever**, which is encountered when susceptible animals are introduced to endemic areas and subjected to challenge by large numbers of infected ticks. The number of adult ticks provides an index of infection pressure, but the outcome of exposure is determined also by the susceptibility of the cattle and the virulence of the infecting strain of parasite. Thus, theilerial disease can

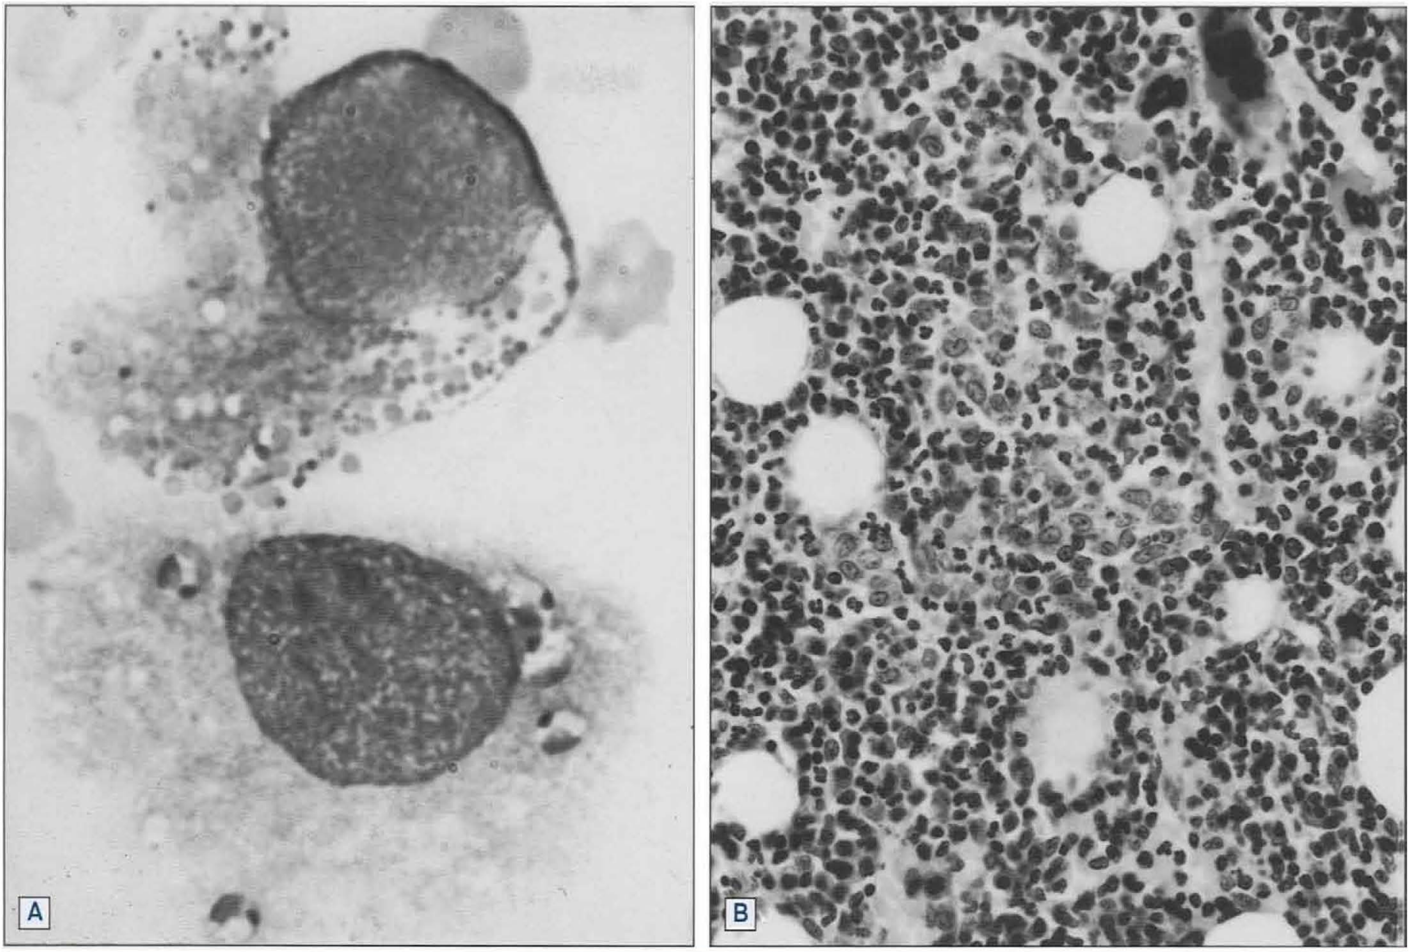

Figure 2.134 Leishmaniasis in a dog. **A.** Marrow aspirate. Epithelioid macrophage with intracytoplasmic *Leishmania*. Ruptured eosinophil at top. **B.** Marrow histology. Hyperplasia with dense cellularity, increased granulocytes and macrophages.

vary from a benign or nonclinical infection to one of acute course with high morbidity and mortality.

There is no evidence that different breeds of cattle vary in their initial susceptibility to *T. parva* or that, antigenic differences between strains notwithstanding, the parasites are capable of antigenic drift in the course of infection, although this might be expected. The components of virulence of *Theileria* organisms are incompletely understood. The sporozoites, of tick origin, invade and infect host lymphocytes, and this capability is one component of virulence and a result of receptor-mediated parasite-directed phagocytosis. Merozoite entry into red cells occurs by a similar process. *Infected lymphocytes are transformed in vitro into lymphoblastic cells, and this appears to parallel the in vivo event as the main indicator of pathogenicity.* Macroschizonts develop in the cytoplasm of the transformed cells and then divide synchronously with the host lymphocytes to infect their daughter cells. The rapid clonal expansion so induced causes the clinically recognizable **polylymphadenopathy.** While East Coast fever, and Corridor disease, are ultimately lymphocytolytic, and virulence is probably associated with macroschizogony, the pathogenesis of disease associated with some other species of the genus may be more intimately related to fission of the piroplasm forms in erythrocytes.

Most breeds of cattle are highly susceptible to *Theileria parva*, and with a high level of challenge mortality approaches 100%. The main vector is the tick *Rhipicephalus appendiculatus*. In enzootic areas, 40% of the calf crop may die of this disease if ticks are uncontrolled. The severity of the disease is directly proportional to the number of organisms inoculated into the animals by the ticks. From 4 to 20 days after infection by the transmission of **sporozoites** from an infected tick, **macroschizonts** are found in lymphoblasts of the lymph nodes draining the site of infection. These schizonts increase in number throughout the lymph nodes by an order of magnitude each 10 days, until virtually all of the lymphocytes are parasitized. Macroschizonts, 2-16 μm in diameter, may be identified in cytoplasm of infected lymphocytes using blood stains, and are known as **Koch's blue bodies** (Fig. 2.135), *which are considered diagnostic for the disease.* From the tenth day of lymph node infection, increasing numbers of macroschizonts enter the **microschizont** stage in which the host cells are destroyed and **merozoites** are released to invade erythrocytes. **Piroplasms**, which are the intraerythrocytic stage of the parasite, are infective for ticks and first appear on the 12th day after infection. They increase rapidly in number until death, at which point a high proportion of the erythrocytes are parasitized. They may be rod-shaped, round, oval, or anaplasma-like red cells, with light blue cytoplasm and red-purple nuclear staining with Geimsa stain.

Enlargement of lymph nodes is a typical sign of East Coast fever disease affecting all nodes, but the enlargement of other than the local nodes is not always apparent, and enlarged nodes shrink to about normal size terminally. The node of particular interest is that

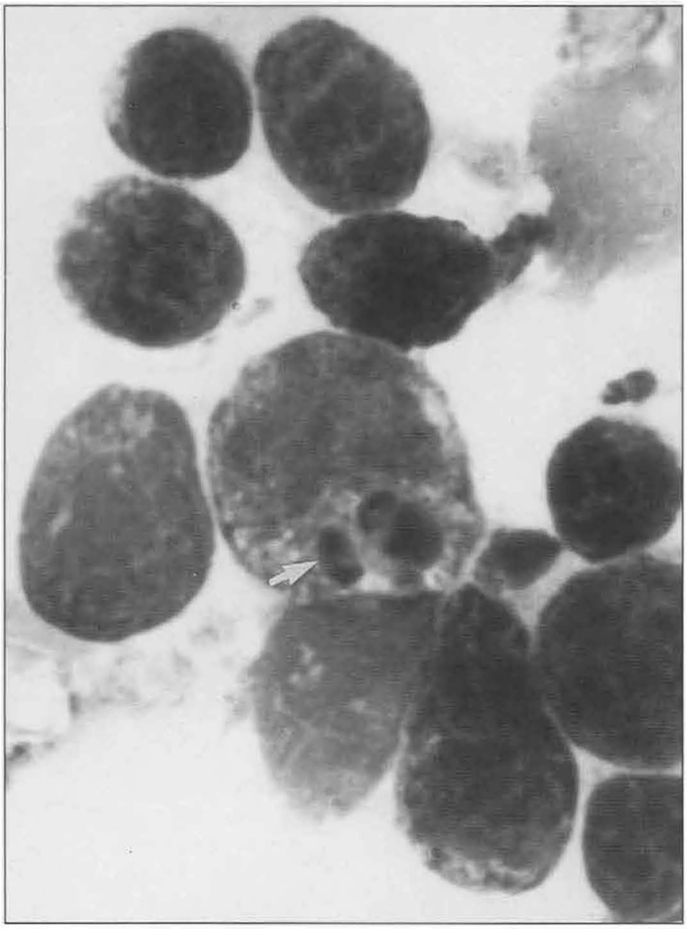

Figure 2.135 Theileriosis in an ox. Lymph node imprint, large lymphocytes with Koch's blue body (arrow).

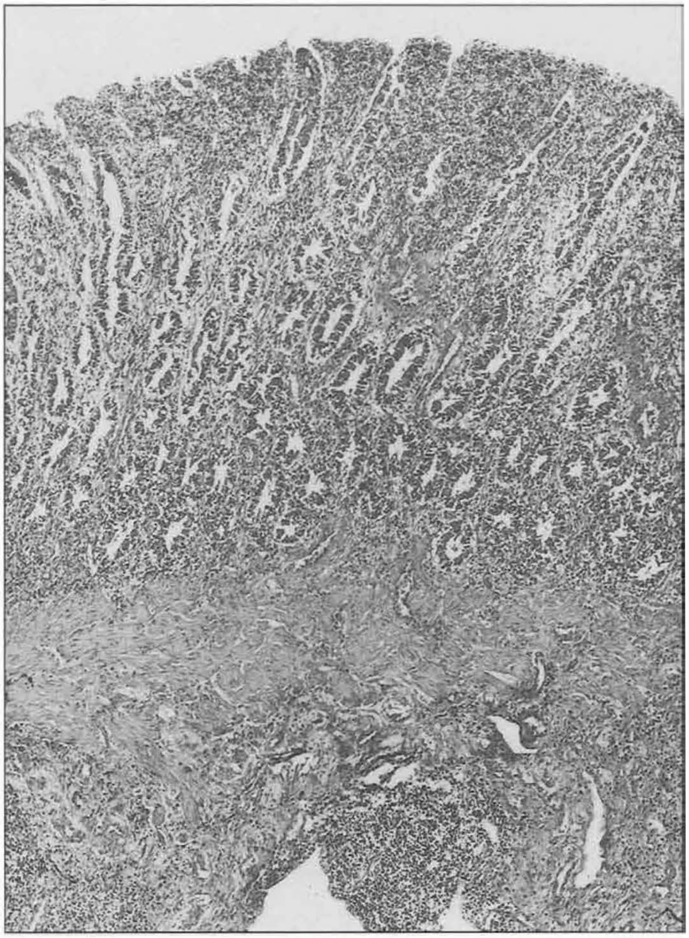

Figure 2.136 Theileriosis in an ox. Mucosal and submucosal lymphoid infiltration with mucosal erosion of the small intestine.

local to the site of infection which, with *Rhipicephalus appendiculatus*, is about the ears.

The end of the incubation period of ~2 weeks is heralded by *high fever*, followed in a couple of days by red cell parasitemia. Drooling, lacrimation, depression, diarrhea, and particularly progressive and prominent enlargement of the superficial lymph nodes give the disease a *close clinical resemblance to malignant catarrhal fever*. Severe pulmonary edema with dyspnea is common and terminal in many animals, while others become prostrate and comatose. The course of the disease is ~1 month and the mortality is ~95%. During the acute phase of the disease, more than 60% of lymphocytes may contain Koch's bodies. *The acute disease appears to be caused by massive lympholysis and progressive anemia.* An outstanding feature of East Coast fever is *leukopenia*, which is progressive from the onset of fever, and, terminally, very few leukocytes may be seen in blood smears. The total white count is seldom above 2×10^9/L and often only a fraction of this, with the cells remaining primarily neutrophils and lymphocytes. There is brief initial stimulation of myelopoiesis, but by the third day of disease there is neutropenia with immaturity and toxemia. The disease is progressive with loss of precursors, and ultimately there is a trilineage depression with accumulation of hemosiderin in macrophages. Terminally, the bone marrow is hypoplastic, and the remaining cells consist of large blastic parasitized lymphocytes and atypical erythroblasts.

Gross lesions *in the acute disease resemble those of malignant catarrhal fever*. Of principal interest is the *enlargement of lymphoid tissues, including Peyer's patches*. On cut surface, the lymph nodes are diffusely discolored with a red-brown cortex containing focal hemorrhages, and a dark red-brown medullary area. Serous effusion and gelatinous or hemorrhagic edema of connective tissues are common. The spleen is enlarged in the acute disease, but in cases with a prolonged course it may be shrunken and strap-like. There is ulcerative abomasitis, likely nonspecific. *The so-called "infarcts" of the liver and kidney are actually proliferative foci of perivascular lymphocytes.* These foci, which project slightly, produce a mottling of small gray-white patches visible on the surface of the liver and kidney. The lungs are congested and edematous with increased texture on palpation, and increased weight. Small hemorrhages associated with foci of hyaline degeneration occur in the muscles, and petechiae are commonly present under the tongue and in the vulva. Erosive or catarrhal enteritis overlies lymphocytic hyperplasia and infiltration of the gut mucosa (Fig. 2.136).

Histologically, in the early stages of infection, there is *diffuse lymphoid hyperplasia* (Fig. 2.137A), apparently at least partially due to constitutive production of IL-2 by infected lymphocytes. In animals that have died with East Coast fever, there is *widespread lympholysis* with hemorrhage and fibrinous exudate throughout the cortical areas of nodes. Lympholysis is prominent in germinal centers and there is a general loss of small lymphocytes, with those that remain

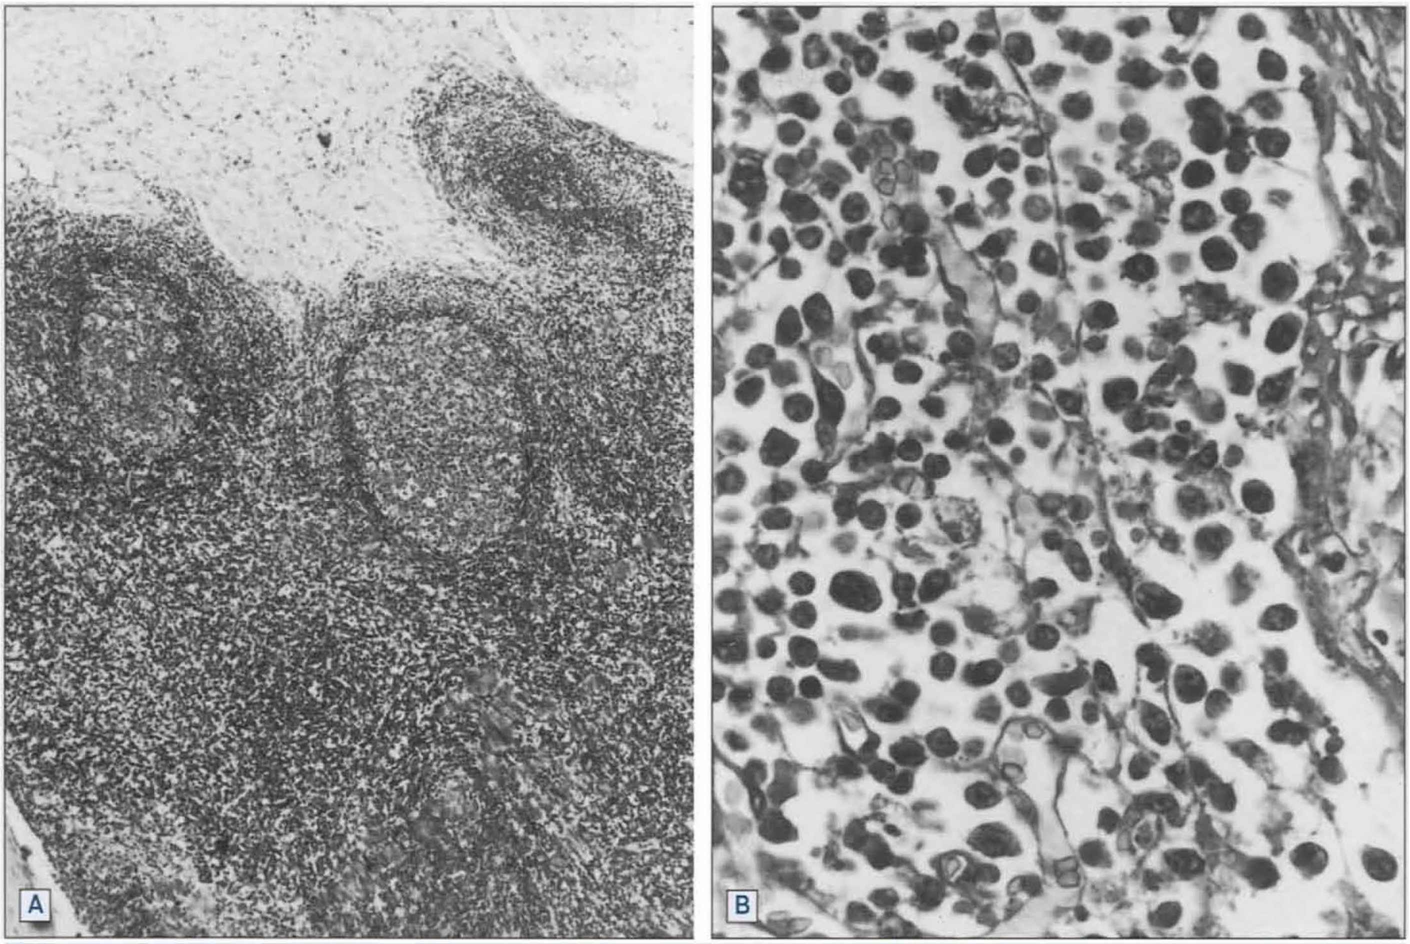

Figure 2.137 Theileriosis in an ox. **A.** Early follicular hyperplasia. Reduced paracortical density with moth-eaten appearance due to tingible body macrophages. **B.** Lymphoblastoid transformation in early disease.

appearing large and blastic (Fig. 2.137B). There is hepatic periacinar and, to a lesser extent, periportal lymphocytic infiltration and, in addition, there are focal infiltrations of the hepatic capsule that give rise to the raised foci seen grossly. In some cases, there is periacinar hepatocellular necrosis and irregular canalicular cholestasis with foci of inspissated bile. There is early splenic lymphoid hypertrophy that is later followed by lympholysis. Germinal centers remain prominent and are surrounded by areas of hemorrhage. The hypocellular follicular centers are usually occupied by fibrinous or hyaline exudate similar to that seen in lymph nodes. The kidneys are remarkably congested with focal hemorrhage, and there is interstitial infiltration with lymphocytes. The lymphocytic infiltration is prominent around vessels, and often around the parietal layer of Bowman's capsule. There is a variable level of parenchymal necrosis with the formation of hyaline casts and brown pigmentation of the remaining epithelium. The pulmonary changes are characteristic and consist of lymphocytic infiltration of the septa and interstitial tissues, resulting in widespread severe interstitial alveolitis (Fig. 2.138). The bone marrow is hypocellular with early asynchrony of the granulocytic system and a less severely affected erythroid system accompanied by proliferation of large lymphocytes similar to those infiltrating other tissues.

An aberrant expression of the disease is described as "**turning sickness**," although it is not clear whether the responsible organism is *T. parva*, *T. mutans*, or another. The condition occurs occasionally in partially resistant cattle re-exposed to heavy infestations of infective ticks. *Parasitized lymphocytes localize by embolism or sequestration in cerebrospinal vessels* (Fig. 2.139) *and produce hemorrhagic infarcts*. The infarcts are of usual character, but muddy discoloration of tissues and meninges with hemosiderin is suggestive of repetitive minor episodes of infarction. Infarcts of various ages may be found in other organs, especially kidney and spleen, but are small and easily overlooked. Koch's bodies may be rare or not demonstrable in peripheral blood or lymphoid organs, but are numerous in the clumped cells in vessels in the infarcts.

Theileria lawrencei is the cause of **Corridor disease** of calves, so named because it occurred in cattle moved into an area called "the Corridor" lying between two game reserves in South Africa. *Rhipicephalus* ticks collected in the area were able to infect cattle, but ticks feeding on infected cattle were not able to transmit the infection further to other cattle. Thus, cattle were not infective for ticks. While the disease in cattle closely resembled East Coast fever clinically and morphologically, there were differences in parasitic behavior. In cattle affected with Corridor disease, less than 5% of red cells in the blood and less than 5% of lymphocytes in smears of lymph nodes contained the parasite, whereas in East Coast fever the corresponding figures would be about 50 and 80%. Cross immunity, however, exists between *T. parva parva* and *T. parva lawrencei*. *Theileria lawrencei* is endemic in buffalo, which may be carriers, some strains are transmissible from cattle

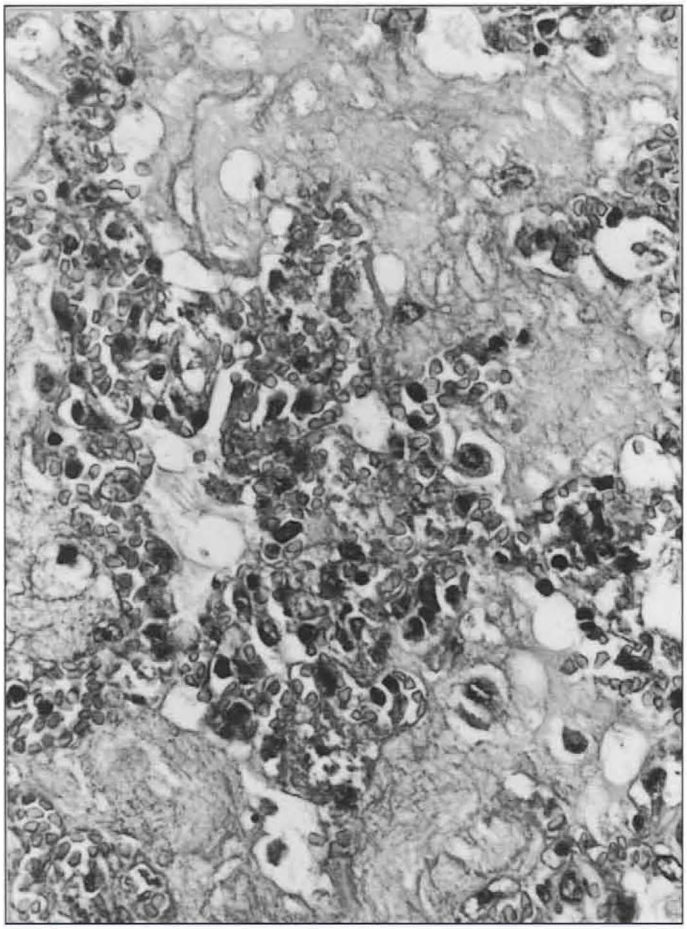

Figure 2.138 Theileriosis in an ox. Interstitial pneumonia with massive proteinaceous effusion.

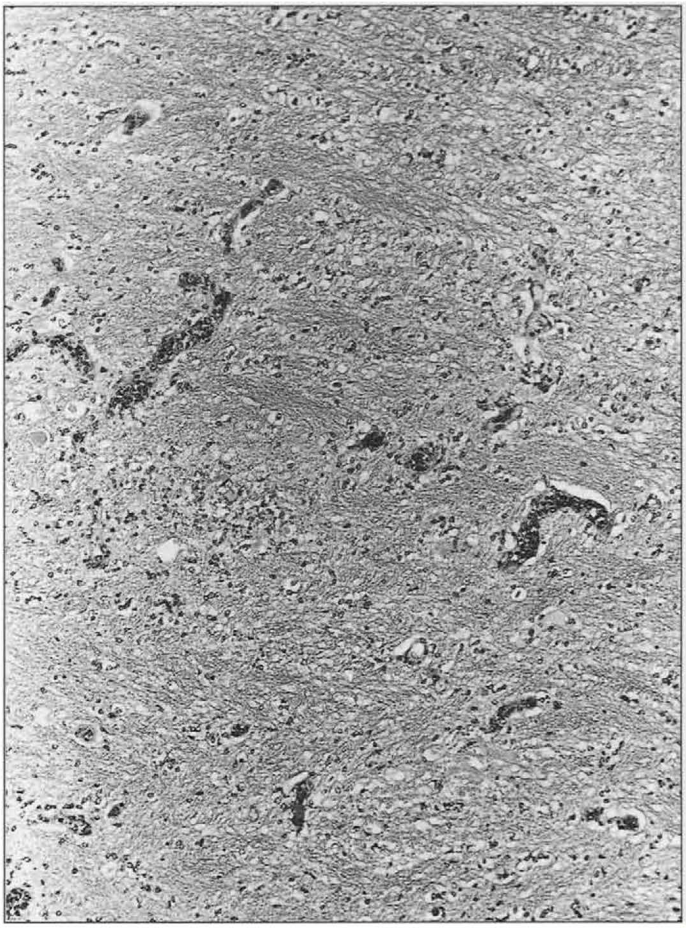

Figure 2.139 Theileriosis in an ox. Sequestration of parasitized cells in cerebral vessels in "turning sickness."

to cattle by ticks and, in these transmissions, *T. lawrencei* comes to behave like and to assume the morphological characters, particularly with respect to macroschizonts, of *T. parva*.

Theileria mutans is the cause of **Tzaneen disease** of cattle, usually a mild and inapparent infection. Sheep can be infected artificially, the infections remaining latent and persisting at least for some weeks; the organisms in sheep do not appear in smears of blood. *Theileria mutans* is widely distributed in tropical and subtropical countries and is transmitted naturally by ticks of the genera *Rhipicephalus*, *Amblyomma*, and *Haemaphysalis*, and possibly by ticks of other genera as well. The importance of the parasite lies in the need to differentiate it from *T. parva*. Cross-immunity trials are necessary for certainty, but it is useful that *T. mutans* can be readily transmitted by the inoculation of even small quantities of blood, and in this infection schizonts are rare or impossible to find. The phases in erythrocytes are rod-shaped and ring-shaped, in about equal numbers.

There are occasional reports of fatal *T. mutans* infections in adult cattle manifested as hemolytic anemia, icterus and hemoglobinuria. The lesions in lymphoid tissue are similar in type, but less severe than in East Coast fever. There is very heavy parasitism of erythrocytes, but schizonts are not observed. The pathogenesis of hemolysis is unclear, but there is some evidence that it is associated with the activities of macroschizonts in lymphocytes rather than with piroplasms in erythrocytes.

Theileria annulata is the cause of **tropical theileriosis** in North Africa, the Middle East, and central Asia. The vectors are ticks of the genus *Hyalomma*. Infection with *T. annulata* is persistent and latent, relatively benign, and often with no parasitemia detectable in smears of blood. It is, however, readily transmitted by inoculations of blood. Occasionally, acute cases do occur and these tend to be fatal, the disease closely resembling East Coast fever. The parasite, both within erythrocytes and forming Koch's bodies, becomes very numerous in the blood during acute attacks of the disease. The majority of the parasites in red blood cells are ring- or oval-shaped and only a few are bacilliform.

Theileria ovis is the ovine equivalent of *T. mutans*; it is benign. *Theileria hirci* is somewhat more virulent and is also pathogenic for goats, producing a disease closely resembling East Coast fever.

Jembrana disease

A severe acute disease occurs in Bali cattle (*Bos javanicus*) in Indonesia, with a case fatality rate of 20%; mild or subclinical disease occurs in other cattle types and buffalo. The cause is **Jembrana disease virus** (JDV), a bovine lentivirus that is closely related to *Bovine immunodeficiency virus*. Virus titers are high in blood in the acute disease, and virus is present in saliva and milk; direct transmission may then occur to susceptible cattle via conjunctival, intranasal or oral routes. During the height of viremia, virus may also be transmitted mechanically by hematophagous arthropods. Recovered cattle may have persistent low-level viremia, but are probably an infrequent source of infection. Cattle of European breeds and sheep are resistant to the disease, although subclinical carrier status may persist for many months.

Clinically, following an incubation period of 5–10 days after infection, there is transient fever, dullness and anorexia. Mild oculonasal discharge, pallor of the mucosae, and diarrhea with blood-stained feces are common. Superficial lymph nodes are visibly enlarged, whereas examination of the blood during the febrile period usually reveals anemia, leukopenia, thrombocytopenia, and in some cases which may be fatal, an elevated blood urea level. Basophilic cytoplasmic inclusions are occasionally seen in circulating mononuclear cells.

At autopsy, lesions may not be remarkable, but several are constant and of diagnostic value. *Enlargement of lymph nodes with slight edema and blurred corticomedullary junctions are widespread but most marked when regional to other affected organs, e.g., lungs and liver.* During the acute phase there is *splenomegaly* and on incision the surface shows small gray-red foci. Scattered petechiae or ecchymoses occur irregularly in the serosae of the heart, gastrointestinal tract, kidneys and below the endocardium. The myocardium and liver contain gray foci 1–3 mm in size. Pulmonary lesions are subtle but can be detected in the cranial lobes, which are firmer than normal, blue-red, finely mottled and slightly edematous. Adjacent lobules show mild overinflation. Shallow erosions may occur in the gastrointestinal tract and caudal tongue, where an occasional ulcer is also possible. The kidneys are consistently pale and have small numbers of gray foci.

The general picture may be complicated by *concurrent infections*, which have included *Pasteurella* pneumonia and helminths of the liver, pancreas, or alimentary tract.

Histologically, *three phases* can be recognized in the acute disease process of about 6 weeks. During the first week, there is a general response by the lymphoreticular system, but in the second phase, up to the fifth week approximately, there is intense nonfollicular proliferation of reticular and large lymphoid cells. A similar infiltrative process occurs in the liver, kidneys, adrenal medulla and choroid plexus systems of the brain, although the central nervous tissue shows little change. In the cranial lung lobes, alveolar cells are enlarged, pleomorphic and proliferative alongside infiltrating mononuclear cells. Mid-sized pulmonary veins and arteries may be filled with large numbers of intravascular macrophages. In the third phase, the follicular lymphoid system is reactivated and plasma cells appear progressively. *The sequence is consistent with a transient immunosuppressive disease.* Indeed, the humoral immune response can be suppressed and delayed in JDV-infected cattle. Histologic lesions regress, but traces of change can be seen up to 60 days after infection.

Pleomorphic basophilic cytoplasmic inclusions are present in all affected tissues. By light microscopy, clumps of minute coccoid bodies about 0.5 μm, and larger, pleomorphic intravacuolar structures occur in reticular and large lymphoid cells, macrophages including Kupffer cells, pulmonary alveolar cells, and occasionally in vascular endothelium.

Tick-borne fever

Tick-borne fever of sheep and goats and *pasture fever* of cattle is transmitted by the vector tick *Ixodes ricinus* and occurs in Great Britain, Ireland, The Netherlands, Norway, and Finland. The causative agent is ***Anaplasma phagocytophilum*** (formerly *Cytoecetes phagocytophila, Rickettsia phagocytophila, Cytoecetes bovis, Ehrlichia equi*), which is also the agent of human granulocytic ehrlichiosis in Europe and North America (where the vector tick is *Ixodes scapularis* or *I. pacificus*). The infection is transmitted stage to stage in ticks, but not hereditarily, and other blood-sucking arthropods may also transmit the agent. Similar diseases have been reported in sheep and cattle in North Africa. An agent in cattle identified as "*Ehrlichia bovis*" is thought to be transmitted by ticks of the genus *Hyalomma;* the infection in sheep is caused by "*Ehrlichia ovina*" transmitted by *Rhipicephalus* spp.

Tick-borne fever is a transient and mild illness that causes some loss of condition. The disease is, however, of some significance because it appears to predispose sheep to cerebrospinal inflammation in louping ill and to staphylococcal pyemia (tick pyemia), the virus of louping ill being conveyed by the ticks and *Staphylococcus aureus* being first established as an infection in the tick bites. Tick-borne fever also appears to predispose animals to pasteurellosis.

Clinically, adult ruminants are more susceptible to tick-borne fever than are the young. After incubation for 2–6 days, or a few days longer in cattle, there is sudden onset of moderate fever. The fever lasts 2–3 days if the agent is of relatively low virulence and subsides quickly. If more virulent organisms are involved, the febrile reaction may be prolonged for nearly 2 weeks, the decline to normal temperature being gradual. Ewes in late pregnancy may abort. In terms of laboratory diagnosis, *with the onset of fever, the organism is detectable in* *circulating granulocytes and large lymphocytes.* The most useful stains are Giemsa and polychrome methylene blue. As the fever declines, the organisms disappear from smears and there is progressive and quite severe neutropenia for a few days, after which the neutrophil count returns to normal. Organisms are no longer visible in smears unless there is a recrudescence with fever, but they do persist in the blood in some animals for a year or more. During fever, up to 95% of the neutrophils may contain parasites. The parasites are restricted to the cytoplasm and are of varied morphology, the variations probably representing developmental stages of the parasite. They may be round, rod-shaped or irregular masses measuring 0.75–3 μm in diameter present either singly or in clusters; ring-shaped bodies 2–3.5 μm in size breaking up into irregular fragments; round or oval morulae of 2.5–3.5 μm in diameter containing many small granules; or in occasional cells there are small masses of about 0.5 μm in diameter.

Persistence of infection after the febrile period is associated with a state of labile premunition, resistance to reinfection being demonstrable at ~5 weeks after the primary infection. Reactions to reinfection are usually much milder than those to the initial infection, but the situation is complicated by the immunologic differences and differences in virulence of strains of the organism. It is probable that in endemic areas sheep remain infected for life, reinfection occurring at each season of tick activity.

Salmon poisoning in dogs

Salmon poisoning is a disease of dogs in the northwestern United States and western Canada, with reports from other areas usually being from dogs imported from those regions. Salmon poisoning is caused by ***Neorickettsia helminthoeca***. The disease is caused by dogs eating raw salmon or trout from areas where the disease is endemic. The dog appears to be the definitive host with the rickettsial agent infecting macrophages in its lymphoid tissues. *The agent is transmitted to dogs in cysts of the fluke Nanophyetus salmincola contained within the tissues of salmon or trout.* The presence of fluke eggs in dogs with signs of the disease are suggestive of the diagnosis. Eggs of the fluke are shed in dog feces which develop into a *miracidium*, and in the proper circumstances, these infect the freshwater snail *Oxytrema silicula*. The miracidium develops into a *redia stage* within the snail which then develops into a *cercaria*. Salmon are infected by ingestion of snails or by skin penetration by the cercaria. Some become encysted in various tissues and widely distributed in various tissues including the eyes, kidneys, liver, intestinal wall, musculature, and fins of salmonidae. The flukes apparently cause minimal damage or clinical signs to dogs, which shed the fluke eggs within about a week after ingestion of infected salmon and continue to shed for approximately 8 months. The rickettsial organism is present in all stages of the fluke life cycle and gains access to other tissues of the dog by an unknown process, but most likely through the attachment of the fluke to the intestinal wall.

Dogs are apparently susceptible to the infection at all ages, with the disease characterized by *lethargy and pyrexia with splenomegaly, generalized lymphadenopathy, vomiting, and diarrhea.* At the time the dogs are showing acute signs of salmon poisoning, there are usually large numbers of operculated fluke eggs in fecal smears. Mortality rate is very high, and approaches 100% in untreated animals. Organisms are present in virtually all enlarged lymph nodes, but usually the submandibular nodes are enlarged and easily aspirated, with the organisms present in the cytoplasm of macrophages. *The neorickettsial organisms are coccoid, less than 1 μm in length, and appear blue-purple with blood stains and blue with Macchiavello's stain.* Dogs succumbing to infection with salmon poisoning have marked enlargement of spleen and lymph nodes with focal hemorrhages in the thymus and pale often swollen liver with an exaggeration of the lobular pattern visible through the capsule. Histologically, the lesions of the nodes in dogs dying early in infection are those of massive lympholysis and loss of germinal centers and generalized cortical depletion of cells (see Fig. 2.114A). In animals that survive 10 to 12 days when there is prominent node enlargement, there is diffuse paracortical hyperplasia with a prominent "starry-sky" appearance but without the development of germinal centers. Splenic lesions are characterized by follicular lympholysis in the acute phases of the disease, as well as loss of cells in the periarteriolar lymphoid sheaths. There is marked congestion of sinus areas with numerous macrophages containing ingested debris as well as the neorickettsial organisms. Thymic lesions are similar with marked involution particularly of cortical areas in the acute phases of the disease with foci of hemorrhage and edematous separation of the lobules. In animals that survive a week or longer, lympholysis is less apparent but there is only minimal restoration of cells in periarteriolar lymphoid sheaths and in the thymic cortex. Hepatic lesions consist of isolated foci of necrosis with macrophage reaction.

Salmon poisoning needs to be distinguished from a related disease known as "**Elokomin fluke fever**," named after the river in Washington State where the disease was first recognized. There are antigenic differences between the agent of salmon poisoning and Elokomin fever, which were initially distinguished on the basis of the specificities of the antibody reaction in surviving animals applied in fluorescent antibody staining of the infectious agents. The lesions in both diseases are similar.

Bovine petechial fever

Bovine petechial fever or **Ondiri disease** of Kenya and Tanzania is very similar to tick-borne fever in that the causative agent is rickettsial and parasitizes circulating neutrophils. The agent is most often identified as ***Ehrlichia (Cytoecetes) ondiri***. An arthropod vector is suspected, but unidentified. Several species of wild ruminants are susceptible to experimental infection, and the bushbuck and African buffalo may serve as amplifying and reservoir hosts.

Experimental transmission has been possible only by injecting blood, spleen or lymph node taken from affected animals, but transmission by these means is possible for only a limited number of passages. The disease occurs naturally only in restricted areas of Kenya at altitudes above 1500 m, and there appear to be some differences in breed susceptibility, with Borans susceptible but Ayrshires and Herefords resistant to experimental infection.

Clinically, the disease is often mild and, unless cattle are being closely observed, signs may not be noticed. After an incubation period of 5–14 days, the affected animals become febrile, and within 1–2 days *fine petechiae develop on the tongue, conjunctiva and the mucosa of the vulva.* The petechiae may persist for only 1–2 or up to 10 days. Occasionally the conjunctival lesions are severe, and the conjunctiva may become edematous and prolapse. Epistaxis and other hemorrhagic tendencies develop occasionally. Early in the course of the disease, affected animals have *leukopenia,* due to a drop in the numbers of circulating lymphocytes and monocytes, and *thrombocytopenia* of greater or lesser degree accounting for the variation in persistence of the petechiation. There follows in ~1 week a rebound leukocytosis produced by an increase in immature mononuclear cells. The organisms are found in neutrophils and lymphocytes, but are not common, and are not demonstrable in every case.

Grossly, the lymph nodes of affected animals are enlarged and congested. The petechial hemorrhages that are seen clinically are also found in the internal organs. The lungs are usually normal in experimental cases, but in severe field cases *death is often due to hemorrhage and edema of the lungs.* The folds of the abomasum are edematous and congested and the contents of the ileum and colon are tarry. The gallbladder is usually distended and the wall thickened by gelatinous edema. *The histologic appearance is nonspecific and the agent cannot be recognized in routine sections.*

Hemorrhagic diatheses

Patricia A. Gentry

Hemostasis is a complex process involving multiple interdependent interactions among platelets, endothelial cells, white cells and fluid-phase proteins that exert both procoagulant and anticoagulant functions. Under normal circumstances, the **anticoagulant system**, which is designed to ensure that the coagulation mechanism is tightly regulated, predominates over the **procoagulant system**. In response to perturbations of vascular endothelium, procoagulant activators are released locally and blood platelets and plasma proteins become exposed to extravascular tissue and soluble activators. This initiates the process of **blood coagulation** and **platelet-mediated primary hemostasis** that initially stems the loss of blood at the site of the vascular lesion. **Thrombin** *is the most important enzyme of the coagulation system.* It has many biological functions in hemostasis, including activation of platelets, conversion of fibrinogen to the fibrin meshwork that is essential for thrombus formation, positive feedback amplification of coagulation, as well as activation of anticoagulants and the fibrinolytic system to regulate the extent of thrombus formation (Fig. 2.140). In addition to its function in hemostasis, thrombin also has important biological roles in cell proliferation and inflammation that are mediated through thrombin's ability to activate specific surface membrane receptors (protease-activated receptors, PARs) on target cells.

Thrombin formation

Initiation of thrombin formation

The primary event that initiates thrombin formation is the exposure of circulating blood to *tissue factor (TF),* which becomes exposed on the plasma membrane of activated endothelial cells or activated monocytes at sites of vascular injury or inflammation. This pathway of thrombin generation is termed the **tissue factor pathway** and is also known as the **extrinsic pathway.**

TF is a lipid-dependent transmembrane glycoprotein that is sequestered in quiescent endothelial cells and monocytes. Upon activation, the extracellular domain of TF is expressed on the cell surface in a configuration that facilitates the binding of one molecule of TF to one molecule of factor VII (FVII), or the active form of the enzyme, FVIIa. Although FVII is the predominant form of the protein in the circulation, a small fraction of the protein circulates as FVIIa. The binding of FVIIa to TF triggers coagulation by activating

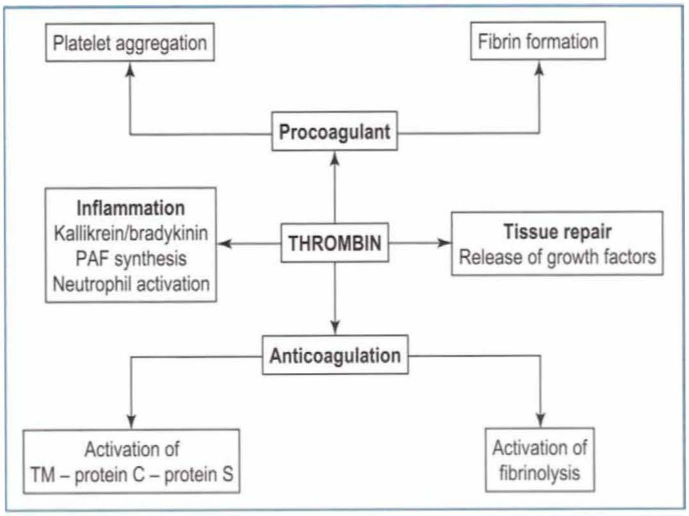

Figure 2.140 Selected multiple functions of **thrombin** that modulate coagulation, anticoagulation, inflammation and tissue repair. PAF = platelet activating factor. TM = thrombomodulin.

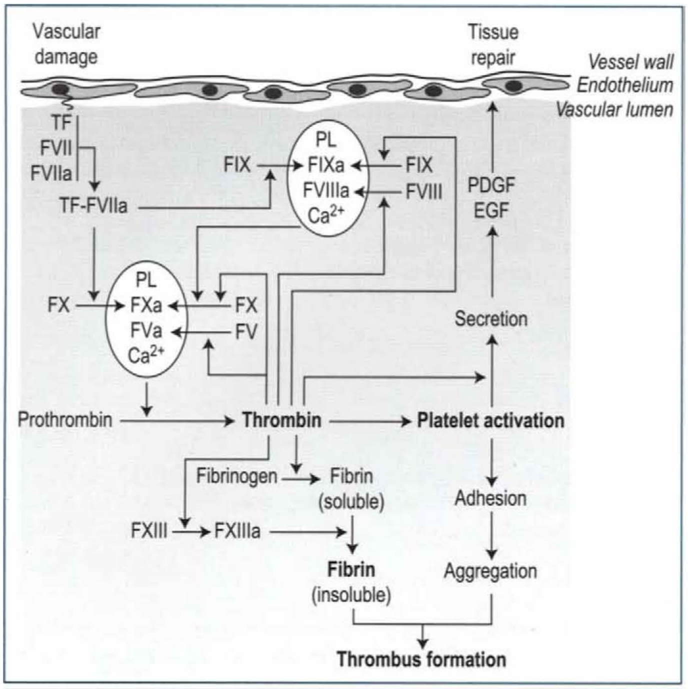

Figure 2.141 Schematic of the primary reactions of the **tissue factor pathway (extrinsic pathway)** leading to thrombin generation and platelet activation following vascular damage. EGF = epidermal growth factor. PDGF = platelet-derived growth factor. PL = phospholipid. TF = tissue factor.

additional TF-FVIIa molecules and by converting both factor IX (FIX) and factor X (FX) to their activated forms, FIXa and FXa, respectively (Fig. 2.141). Factors IXa and Xa can either remain associated with the TF-bearing cells or they can diffuse into the blood and bind to the surface of nearby activated platelets that have gathered around the site of vascular damage. Prothrombin is rapidly activated to thrombin by the "*prothrombinase complex*" that consists of FXa, phospholipid, calcium, and a protein cofactor, factor V (FV). During platelet activation, negatively charged phospholipids become exposed on the platelet surface. These phospholipids serve as binding sites for coagulation factors, protein cofactors and calcium to permit the assembly of the highly reactive enzyme–cofactor complexes that are essential for the rapid propagation of fibrin and thrombus formation. The platelet phospholipid contribution is also referred to as *platelet factor 3 (PF3).*

The first few molecules of thrombin generated by the "prothrombinase complex" initiate a positive feedback reaction that accelerates the rate of prothrombin activation and causes an increase in the amount of thrombin generated that, in turn, increases the rate of fibrin formation (Fig. 2.141). Thrombin directly increases the activity of the prothrombinase complex by activating FX to FXa and by proteolytic cleavage of FV to a more reactive form, FVa. Thrombin further facilitates thrombus formation at a site of vascular damage by promoting localized platelet activation, adhesion and secretory reactions that culminate in platelet aggregation (Fig. 2.141).

Maintenance of thrombin generation

The activation of prothrombin by the TF–FVIIa–FXa pathway initiates thrombin formation but it cannot sustain thrombin production long enough to ensure that sufficient fibrin can be formed to stem blood loss when a vessel wall is breached. This is due to the presence of a natural anticoagulant, *tissue factor pathway inhibitor (TFPI),* that circulates in blood bound to lipoproteins and platelets as well as being localized on endothelial cell surfaces in association with heparan sulfate. TFPI binds to FXa, and then forms an inactive quaternary complex, the FXa–TFPI–FVIIa complex, that effectively inhibits the TF pathway of thrombin generation. To circumvent the anticoagulant effect of TFPI, there are alternative pathways that result in activation of FX and hence thrombin production (Fig. 2.141).

Thrombin feedback not only activates FV but it also activates factor IX and converts FVIII to a more reactive form, FVIIIa (Fig. 2.141). Factor VIII normally circulates bound to *von Willebrand factor (vWF)*, an adhesive protein important for the generation of the initial platelet plug. After activation by thrombin, FVIIIa dissociates from vWF and forms a complex with FIXa, calcium and phospholipid molecules exposed on the surface of thrombin-activated platelets. The resulting highly reactive enzyme–cofactor complex, the "*tenase complex,*" proteolytically cleaves FX at the same reactive site as TF–VIIa and hence produces the same FXa product.

A reactive "tenase complex" leading to thrombin formation can also be generated by the **contact activation system**, also known as the **intrinsic pathway**. The contact activation system involves four components, *the proenzymes factor XII (FXII) and factor XI (FXI), prekallikrein (PK), and a protein cofactor, high molecular weight kininogen (HMWK)* (Fig. 2.142). This pathway is initiated when FXII interacts with a negatively charged surface, e.g., damaged endothelium or activated neutrophils, and undergoes a conformational change that results in its ability to cleave FXI to a proteolytically active form, FXIa, and to convert PK to kallikrein. This reaction is accelerated by the presence of HMWK. In plasma, FXI and PK each circulate separately as a complex with HMWK. FXIIa can convert HMWK to a modified form, HMWKa, that exhibits a high surface-binding affinity and thus brings large amounts of both FXI and PK to the charged surface in close proximity to the already adherent FXIIa. FXIa, in the presence of calcium, is a potent activator of circulating FIX and thus promotes thrombin formation. Direct activation of FXI by thrombin is another amplification loop, which, in turn, results in the generation of additional FIXa (Fig. 2.142).

The physiological role of the contact activation pathway is not fully understood because it does not appear to be important in trauma-mediated thrombin generation. However, kalllikrein not only functions as an activator of the fibrinolytic system, but it also stimulates both chemotaxis and degranulation of neutrophils attracted to an area of vascular perturbation (Fig. 2.142). Hence, *the contact activation pathway serves as a link between inflammation, thrombin formation and fibrinolysis.*

Fibrin formation

The final step in the coagulation pathway is the conversion of soluble fibrinogen to an insoluble fibrin meshwork in a multistep process mediated by thrombin and by activated factor XIII (FXIIIa) (Fig. 2.141). Fibrinogen is a large globular molecule composed of two sets of three identical protein chains ($A\alpha$, $B\beta$ and $\gamma\gamma$) forming a trinodular structure held together by disulfide bonds. Thrombin first interacts with fibrinogen by cleaving two small peptide chains, fibrinopeptides A and B, from the amino terminal end of the $A\alpha$ and $B\beta$ chains, respectively, thus altering the surface charge of the molecule. The

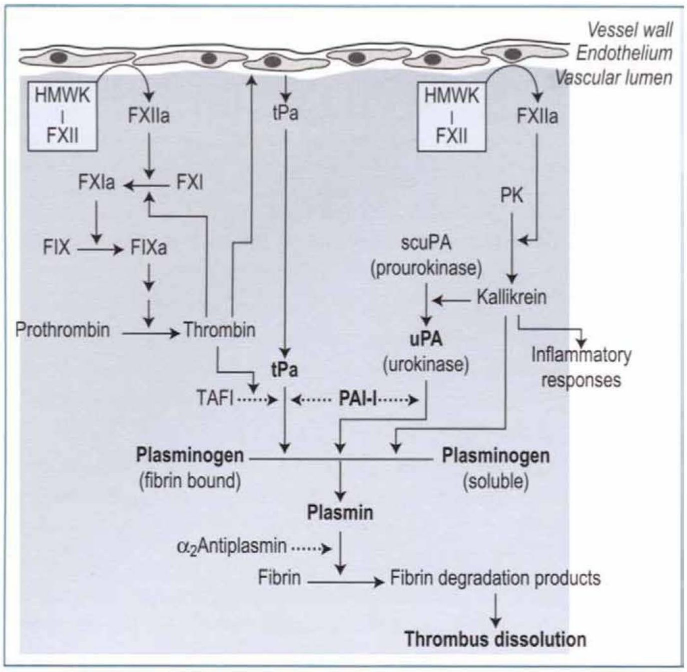

Figure 2.142 Schematic of interactions between the **contact activation pathway (intrinsic pathway)** system and activation of the fibrinolytic system that result in thrombus dissolution once tissue repair has occurred. Solid lines represent activation reactions; dashed lines represent inhibitory reactions. HMWK = high molecular weight kininogen; PAI-1 = plasminogen activator inhibitor-1, PK = prekallikrein, TAFI = thrombin-activatable fibrinolysis inhibitor, tPA = tissue-type plasminogen activator.

result is the formation of soluble fibrin monomers that can spontaneously polymerize by aggregating end-to-end and side-to-side to form a loosely knit mesh held together by covalent bonds. The transformation of this permeable structure to an insoluble fibrin mesh that forms the scaffolding for both thrombus formation and vascular repair requires the formation of stable peptide bonds between neighboring γ and α chains of the fibrin polymer. Factor XIIIa (FXIIIa), a transpeptidase enzyme activated by thrombin cleavage of the precursor, FXIII, catalyzes the formation of the internal peptide bonds between the fibrin chains in a calcium-dependent reaction.

Maximum thrombin generation occurs after the initial formation of fibrin strands. In addition to being important for the activation of FXIII, thrombin is important for activation of the protein known as *thrombin-activatable fibrinolysis inhibitor* (*TAFI*). This inhibitory protein not only prevents premature degradation of the fibrin clot but also participates in the activation of the *thrombomodulin-protein C-protein S (TM-protein C-protein S) anticoagulant system* that, in turn, prevents thrombin generation in the general circulation outside the fibrin clot (Figs 2.142, 2.143).

Evaluation of thrombin and fibrin formation

Circulating levels of procoagulant activity

Although the quantitative amounts of various coagulant proteins in circulating blood vary between species, qualitatively the pattern is similar and is related to the specific role of each protein in hemostasis. For example, the amount of fibrinogen in plasma is generally 50 000 times higher than that of FVIII. This reflects the need for relatively large amounts of fibrinogen for the formation of the fibrin network, whereas *only a small amount of FVIII is required to catalyze the conversion of FIX to FIXa at a physiologically adequate rate.* Similar variations are observed for the vitamin-K dependent proteins, prothrombin, FVII, FIX and FX. Prothrombin is present in the circulation at higher levels than either FIX or FX which, in turn, exhibit higher levels than FVII. Thus, *proteins that interact in the initial stages of thrombin generation circulate at lower concentrations than proteins that act at the later stages*, which is consistent with the multiple reactions and amplification potential of the system (Fig. 2.141). The assembly of enzyme–cofactor complexes on negatively charged phospholipid surfaces not only increases the local concentration of the coagulation components but counteracts the inhibitory potential of circulating anticoagulants. Among the procoagulants, FVII has the shortest half-life, being in the order of hours rather than days as is observed for the other proteins. Fibrinogen and prothrombin exhibit the longest circulating half-lives.

The clinical manifestation of hemorrhagic problems is variable, depending on the nature and cause of the coagulopathy. In domestic animals, as in people, *hemorrhagic episodes are rarely encountered unless the biological activity of a single coagulation factor is severely compromised or the biological activity of multiple coagulation proteins is reduced below 30% of normal circulating levels.* Hemorrhage is typically into body cavities or tissues and from wounds. Subcutaneous hematomas and hemorrhage into urogenital and gastrointestinal tracts are also common.

Laboratory procedures

Appropriate blood sample collection and handling techniques are essential for reliable in vitro evaluation of hemostasis. While blood anticoagulated with EDTA is required for accurate platelet counts in mammals, *citrated plasma* is essential for the screening of the coagulation system and measuring individual components of the coagulation, fibrinolytic and inhibitory pathways.

Routine hemostatic screening involves determination of *platelet numbers*, the *one-stage prothrombin time* (OSPT or PT), the *activated partial thromboplastin time* (APTT), and the *thrombin time*, which can also be used to determine fibrinogen values. The PT assay measures the overall competency of the tissue factor pathway. The procedure involves the addition of a thromboplastin (TF)–phospholipid mixture to test plasma and the determination of the time for a fibrin clot to form after the sample has been recalcified. For the APTT assay, a FXII activating agent, such as celite or ellagic acid, mixed with phospholipid is added to test plasma prior to recalcification. Hence, this assay determines the competency of the contact activation system, the formation of the "tenase" complex as well as the formation of the "prothrombinase" complex in the test sample. A simplified, but less sensitive, version of the APTT assay is the *activated clotting time* (ACT). For this assay, the contact activator is added directly to whole blood and the time for clot formation to occur is recorded. The PT and APTT assays will detect a severe deficiency of a single procoagulant factor or a moderately reduced activity of several factors, but are not sufficiently sensitive to detect a mild to moderate reduction in a single factor. The assays will also be prolonged if circulating inhibitors are present in the patient's plasma.

Plasma fibrinogen concentrations can be quantitated by several methods, including physical and immunological procedures. A modified thrombin time assay, which quantifies the amount of fibrinogen in a diluted test sample on the basis of the rate of formation of fibrin, is currently commonly used in veterinary medicine. The biological activity of the specific coagulation factors, FXII, FXI, FIX, and FVIII are determined in an assay system based on a modification of the APTT assay, while the activity of FVII, FX, and FV require a modification of the PT assay. The ability of the test plasma sample to correct the clotting time of a plasma sample obtained from an individual with a proven hereditary defect of the specific factor relative to a reference standard is used to quantitate the activity of the specific factor. Prothrombin and FX activity can also be quantified by colorimetric methods based on the ability of enzymes isolated from snake venoms to selectively cleave the inactive zymogen into a reactive serine protease in phospholipid-independent reactions. An extract, Ecarin, from the venom of the saw-scaled viper (*Echis carinatus*) cleaves both carboxylated and noncarboxylated prothrombin, whereas Russell's viper venom selectively cleaves FX.

Specific laboratory assays that have been used to detect plasma proteins that function as natural anticoagulants or in the fibrinolytic system are described in the appropriate section below.

Disorders of thrombin formation

Inherited disorders

Although FVIII and FIX are not involved in the initiation pathway of thrombin generation, inherited deficiencies in these factors are among the most commonly encountered in domestic animals and result in the most severe hemorrhagic episodes. The explanation for this apparent paradox has been obtained from studies with transgenic mice rendered deficient in a single coagulation protein. In mice, gene deletions for TF, FVII, FX, or prothrombin result in intrauterine death or fatal hemorrhage shortly after birth due, in part, to the role that thrombin plays in angiogenesis (Fig. 2.140). Murine gene deletions for any of FVIII, FIX or FXI result in viable offspring that exhibit various degrees of hemorrhage and mortality in the postnatal period. Both mice and people deficient in fibrinogen exhibit normal fetal development and moderate-to-severe bleeding incidents during later life.

Factor VIII deficiency (*hemophilia A*) is the most common of the naturally occurring inherited coagulopathies in veterinary medicine, being reported in many breeds of dogs, cats and occasionally in horses and cattle. It is an X-chromosomal recessively inherited disease that persists because *heterozygous females, carriers of the disease, are clinically asymptomatic.* In homozygous-deficient males, the clinical severity of the disorder can vary with the extent of reduction of circulating FVIII activity and with the size of the animal, with larger animals generally exhibiting more severe hemorrhagic problems. Unlike severely affected animals (<2% of normal FVIII activity), *mildly affected animals (5% of normal FVIII activity or above) seldom exhibit spontaneous bleeding.* Various types of stress, strenuous exercise, vaccination, surgery and trauma induce hemorrhagic episodes. In puppies, the first clinical signs may be cranial hematomas and gingival bleeding as permanent teeth erupt. As the dog matures, recurrent or shifting lameness due to intra-articular hemorrhage, particularly in the stifle joints, and subcutaneous and intramuscular hematomas are common clinical signs. Excessive bleeding resulting in large scrotal hematomas following castration is also typical.

Mildly affected male dogs can reach sexual maturity, and if they are mated with a heterozygous female, homozygous-deficient bitches can result. These animals may exhibit protracted estrus or postpartum hemorrhage.

In the laboratory, *FVIII deficiency is characterized by prolonged APTT, normal PT, and reduced plasma FVIII activity.*

Factor IX deficiency (*hemophilia B*) is another relatively common hemorrhagic disorder in dogs and cats. It has been described in several breeds of dogs and is the second most common inherited disorder in British shorthair cats. Like FVIII deficiency, it is inherited as an X-chromosomal recessive trait and has similar clinical characteristics, with both the circulating plasma levels of FIX and the size of the animal influencing the severity of hemorrhagic episodes. The reduced plasma FIX activity results in *prolonged APTT and normal PT laboratory results.*

A prolonged APTT and a normal PT is also the typical laboratory profile for animals with inherited defects involving proteins of the contact activation system, including, FXI, PK and FXII. The defect in each case is transmitted as an autosomal recessive trait.

- Among this group, **factor XI deficiency** is the only disorder in which affected animals can exhibit spontaneous bleeding episodes, most frequently associated with the urogenital tract. The disorder has been identified in English Springer Spaniels, Kerry Blue Terriers, and Great Pyrenees dogs, and in Holstein and Japanese Black cattle. Homozygous affected cattle have less than 5% of normal plasma FXI activity but the response to the trauma of surgery ranges from an uneventful cesarean delivery to catastrophic hemorrhage developing 12 to 48 hours after surgery.
- **Prekallikrein deficiency** is inherited as an autosomal recessive trait and is clinically asymptomatic. For example, PK deficiency was found fortuitously in a German Shorthaired Pointer who

subsequently underwent uneventful ovariohysterectomy surgery. Even in larger animals with PK deficiency, such as miniature and Belgian horses, hemorrhagic episodes are rare although bleeding has been reported in a horse following castration.

- **Factor XII deficiency** is inherited as an autosomal recessive trait, and has been observed in dogs and cats. No episodes of clinical bleeding occur in affected animals unless hemostasis is otherwise compromised. The absence of hemorrhage is consistent with observations that FXII has not been detected in plasma from birds, reptiles and amphibians.

Factor VII deficiency has only been reported in dogs and people. It is found in Beagles, Alaskan Malamutes, Boxers, Bulldogs, Miniature Schnauzers, and mixed-breed dogs, and is inherited as an autosomal trait. Dogs who survive to adulthood typically have plasma FVII activity of at least 5% of normal values, which is sufficient to initiate thrombin generation and induce adequate fibrin formation unless the animal is exposed to severe trauma. For example, FVII deficiency was diagnosed in a mixed-breed dog that exhibited abnormal bleeding following routine orchiectomy and failed to respond to vitamin K therapy. FVII deficiency is generally a mild disease, typified by easy bruising and a predisposition to demodicosis. Prolonged vaginal bleeding after whelping can occur in affected bitches. In the laboratory, *the PT is prolonged whereas the APTT is normal.*

As might be expected from its importance in the pathways of thrombin generation, severe **factor X deficiency** is lethal in severely affected dogs. It is inherited as an autosomal recessive trait, and dogs with >10% of normal plasma FX activity are usually stillborn or die as neonates from internal bleeding. The disorder has been reported in Jack Russell Terriers and in mixed-breed dogs. It has been eliminated from American Cocker Spaniels, the breed in which it was first identified. The *reduced plasma FX activity causes both the APTT and PT to be prolonged*. Both of these assays are also prolonged in canine **dysprothrombinemias**, which are characterized by reduced prothrombin coagulant activity and normal prothrombin antigen levels. This is a rare disorder that has been described in the Boxer, Otterhound, and English Cocker Spaniel breeds. Epistaxis and umbilical bleeding can occur in affected puppies, with mild mucosal bleeding being recorded in young adults.

Vitamin-K-dependent γ-glutamyl carboxylase deficiency has been identified in Devon Rex cats, Rambouillet sheep, and in a Labrador dog. In all species, the lack of adequate enzyme activity results in the synthesis of normal amounts of the vitamin-K-dependent coagulation proteins (FVII, FX, FIX, and prothrombin) but functional biological activity is depressed. In homozygous-deficient sheep, low levels of FIX (<16%), FX (<4%) and variably decreased prothrombin (11–36%) and FVII (20–33%) are typically found, whereas heterozygous carrier animals have normal vitamin-K-dependent coagulation factor activities. In affected sheep, lamb mortality is high and is associated with excessive blood loss at parturition through umbilical and subcutaneous tissue hemorrhages. Likewise, in affected kittens, bleeding episodes are severe or fatal and include hematomas and hemarthroses, as well as intrathoracic and intra-abdominal hemorrhages. In cats, administration of vitamin K_1 causes rapid recovery of circulating vitamin-K-dependent factor activity to near-normal levels. In an affected dog, circulating activity only rose to around 50–60% of normal canine values even after 3 months of vitamin K_1 therapy.

Acquired disorders

Poisoning by vitamin K antagonists

In mammals, the only known function of vitamin K is as a cofactor for γ-glutamyl carboxylase, an endoplasmic enzyme involved in the post-translational carboxylation of glutamate (Gla) residues into γ-carboxyglutamate. Vitamin K hydroquinone (KH_2) forms the active coenzyme and its oxidation into vitamin K 2,3 epoxide (KO) provides the energy to drive the carboxylation reaction. Vitamin K is fat soluble, is widely available in green leafy plants and vegetables oils and, like γ-glutamyl carboxylase, is widely distributed throughout body tissues. Thus, impaired carboxylation of vitamin-K-dependent coagulation proteins is rarely due to a dietary insufficiency or impaired gastrointestinal absorption of Vitamin K, but rather is associated with the *ingestion of coumarin and its derivatives, or sulfaquinoxaline*, which has been used as a coccidiostat in livestock and poultry. These vitamin K antagonists inhibit the recycling of KO back to KH_2 through specific inhibition of vitamin K epoxide reductase. The progressive reduction in KH_2 effectively leads to a reduction in the bioavailability of the active form of vitamin K. Because the sole function of Gla residues in Factors VII, IX, X, and prothrombin is to facilitate their binding to the negatively charged phospholipids on the surface of activated endothelium and activated platelets, the rate of thrombin formation is reduced when the number of Gla residues per protein molecule is reduced. The nonfunctional forms of Factors VII, IX, X, and prothrombin are collectively referred to as PIVKAs (proteins induced by vitamin K antagonism). These proteins can be detected in plasma by a commercial Thrombotest assay.

The period between ingestion of a vitamin K antagonist and the appearance of clinical signs varies depending on the amount and type of toxicant consumed, the rate of its metabolism, and the amount and bioavailability of functional vitamin K in the patient prior to intoxication. Rodenticide consumption is the most common source of vitamin K antagonists in dogs but it has also been reported as causing hemorrhagic episodes in cats, horses and swine. The first-generation rodenticides, such as *warfarin* and *indone*, had relatively low toxicity and biological half-lives of under 24 hours, which rendered vitamin K therapy quite effective. The development of rodent drug-resistance led to the introduction of 4-hydroxycoumarins such as *bromadiolone* and *brodifacoum*, and indan-1,3-dione rodentidices, such as *diphacinone*, which are not only more potent but also have longer biological half-lives requiring more aggressive vitamin K therapy in affected animals. Further, the clinical severity of anticoagulant rodenticide poisoning can be exacerbated by underlying disease conditions, such as uremia, or by co-ingestion of pharmacological agents. For example, sulfonamides, corticosteroids and phenylbutazone can displace anticoagulant binding to serum proteins effectively increasing the bioavailability of the vitamin K antagonists.

Cattle, pigs, and rabbits are susceptible to an apparent avitaminosis K if hay or silage containing *moldy sweet clover (Melilotus alba)* is ingested. *Sweet clover contains coumarin, which is converted to dicumarol.* Young calves are more susceptible to dicumarol than are their dams, while sheep and horses appear resistant to this form of vitamin K antagonism.

Because FVII has the shortest circulating half-life (~4–6 hours), it is the first coagulation protein to show a decrease in circulating biological activity. Hence, in the initial stages of intoxication of vitamin K antagonists, the PT result may be prolonged while the APTT remains within the representative range. However, the APTT rapidly begins to also show prolongation because FIX and FX both have plasma half-lives of 14–18 hours whereas that of prothrombin is ~40 hours. Clinical signs are often broad and nonspecific and range from hemorrhage after physical trauma to apparently spontaneous external hemorrhaging in the form of epistaxis, melena or hematuria. Hemorrhagic episodes may not occur until several days after ingestion of the anticoagulant and may be acute in onset when the functional activity of several of the coagulation proteins is depressed. Bleeding into joint spaces can be associated with anemia, weakness and pallor, while dyspnea can be associated with hypovolemia and bleeding into the thoracic cavity.

Liver dysfunction

Although it is recognized that ~75% of human patients with liver disease develop hemostatic problems, *clinical expression of bleeding diatheses is reported relatively infrequently in domestic animals.* Part of the explanation may be due to the fact that chronic hepatic disease, in which cell mass is reduced by at least 70%, must be present before the hepatic synthesis of coagulant proteins is sufficiently reduced to prolong the PT and the APTT assays. Further, the hepatic synthesis of thrombin inhibitory proteins, such as protein C, and the fibrinolytic proteins, such as antiplasmin, will also be reduced, resulting in the maintenance of the hemostatic balance among thrombin/fibrin formation and plasmin/fibrin degradation. Additionally, in certain inflammatory diseases, such as canine hepatitis, the liver can increase the rate of synthesis of specific clotting factors such as fibrinogen and vWF, which together can promote the efficiency of platelet plug and hence thrombus formation.

In a retrospective study of *cats* with liver problems, 60% exhibited laboratory coagulation test abnormalities and only 23% of this group demonstrated bleeding episodes, which in each case was associated with invasive treatments such as insertion of intravenous catheters or venipuncture. The more severe the progression of the liver disease, the more likely the cat was to develop a clinical coagulopathy. A comparison of the PT, APTT, fibrinogen values and PIVKA results indicated that *a PIVKA prolonged more than 20% beyond control was a more reliable indicator of cats at hemostatic risk than were the other parameters.* This correlation was also observed for cats with small bowel disease and pancreatic exocrine insufficiency.

Disorders of fibrin formation

Among domestic animals, hereditary **fibrinogen** defects have only been recognized in goats and dogs. **Afibrinogenemia** has been reported in one herd of Saanen goats, in which it was associated with severe umbilical bleeding, recurrent hemarthroses, and bleeding into subcutaneous tissues and from mucous membranes. **Hypofibrinogenemia** has been diagnosed in Bernese Mountain Dogs, Lhasa Apso, Vizsla, and Collie breeds. Like the **dysfibrinogenemia** that has been identified in an inbred Borzoi family and in a Border Leicester lamb, these fibrinogen abnormalities are expressed as a mild bleeding tendency that can be exacerbated by stress, trauma, or surgery.

Although fibrinogen responds as an acute-phase reactant in most domestic animals, with circulating levels rising several fold in response to inflammatory stimuli, thromboembolic problems are infrequently reported in veterinary medicine. Pulmonary thromboembolism occurs in dogs, usually as a secondary consequence of diseases such as *cardiac insufficiency, neoplasia, hyperadrenocorticism, or sepsis.* An elevation of plasma fibrinogen occurs in piglets in response to inoculation with *Actinobacillus pleuropneumoniae*, the causative agent of fibrinohemorrhagic pleuropneumonia in swine. Fibrinous pneumonia is a characteristic of shipping fever induced by *Mannheimia (Pasteurella)* in cattle. Hypercoagulation resulting in thrombosis of limb arteries has been reported in foals. In these animals, endotoxin-induced activation of thrombin generation was postulated to be a contributing factor along with elevated plasma fibrinogen. Similarly, elevated levels of fibrinogen, along with increases in circulating levels of prothrombin and FV, FVII, FIX, and FX, were observed in a study involving 56 dogs with Cushing syndrome. This increase in procoagulant activity was considered to be a contributing factor, along with a decrease in the circulating levels of the natural anticoagulant, antithrombin, in the development of a hypercoagulable state. In this group of Cushing syndrome dogs, a 4-fold increase in the incidence of pulmonary embolism and deep vein thrombosis and a higher mortality rate was observed.

Platelet activation and thrombus formation

When vascular endothelial cells are injured or exposed to inflammatory mediators, the plasma membrane undergoes biochemical and conformational changes that convert this vascular layer from presenting an anticoagulant surface to flowing blood to one that presents a *procoagulant surface*. The availability of platelet activators, as well as surface-binding proteins, integrins, such as vonWillebrand factor (vWF), initiates platelet adhesion and congregation of platelets at the site of vascular perturbation at the same time as TF and surface bound phospholipids are becoming available to initiate fibrin formation. *The response of platelet accumulation is referred to as* "**primary hemostasis**."

Platelet activation and adhesion

The cytoplasm of megakaryocytes fragments into individual platelets as a result of shear forces of the circulating blood, primarily in the pulmonary circulation. Upon activation, platelets undergo a morphological transformation from discoid cells into spiny spherical cells with numerous filopodia. This "*shape change*" is caused by interaction of actin and myosin filaments in the cytoplasm and is accompanied by alterations in membrane conformation that activate platelet membrane glycoprotein, or *integrin*, receptors. These receptors mediate the adhesion of single platelets to subendothelial tissue that, in turn, triggers a cascade of reactions leading to recruitment and adhesion of additional platelets.

Both fibrinogen and vWF are required for the adherence of platelets to each other and to damaged endothelium. Glycoprotein Ib-V-IX is a constitutively active receptor that causes rapid platelet attachment to exposed perivascular vWF. This receptor is particularly important in areas of the circulation with high shear forces as it facilitates the stabilization of the platelet aggregates. The most abundant platelet integrin, glycoprotein IIa/IIIb, requires a conformational change during platelet activation to express receptor function for fibrinogen, and to a lesser extent vWF. Additional pools of this receptor are available in the surface-connected open canalicular system that is a characteristic feature of most mammalian platelets. Once fibrinogen is bound to glycoprotein IIa/IIIb receptors, it forms bridges between adjacent platelets that are essential for the development of stable platelet aggregates.

While thrombin can bind to the N-terminal domain of the glycoprotein Ib receptor enhancing its reactivity, *platelets, like endothelial cells, possess specific membrane thrombin receptors*. These receptors are members of the G-protein-coupled receptor family characterized by a single polypeptide with a seven-transmembrane spanning domain. Thrombin receptors are frequently referred to as *protease-activated receptors*, or PARs, because the receptors only acquire transmembrane signaling functions after thrombin has cleaved a peptide from the extracellular domain of its receptor. This cleavage unmasks a new amino acid terminus that binds intramolecularly with the body of the PAR receptor to form a reactive molecule. *Thrombin is recognized as the most potent agonist for platelets of all species.*

Platelet aggregation

The continued recruitment of circulating platelets and their incorporation into platelet aggregates around the site of already adherent platelets depends on the local accumulation of platelet agonists and the generation of procoagulant activity in the form of integrin and phospholipid exposure on the surface of activated platelets. The agonists include ADP, serotonin and epinephrine that are released from platelet dense granules, and newly synthesized reactive molecules, such as platelet activating factor (PAF) and thromboxane A_2 (TxA_2). Each of these compounds, like thrombin, interacts with its own G-coupled protein receptor to initiate a process of "inside-out" signaling. The activator–receptor interactions not only increase the avidity of the glycoprotein-integrin receptors for their ligands but also initiate intracellular downstream signaling via several pathways involving the activation of phospholipases, protein kinase K (PKC), and adenylate cyclase.

The hypo-adhesive and hypo-aggregable state of unactivated circulating platelets is maintained by low cytosolic levels of calcium and cyclic AMP (cAMP). Following platelet activation, phospholipase C-mediated hydrolysis of the membrane phospholipid, phosphatidylinositol-4,5-bisphosphate (PIP_2), results in the release of two secondary messengers, inositol-1,4,5-triphosphate (IP_3) and diacylglycerol (DAG), while phospholipase A_2 hydrolyses phosphatidylcholine to PAF and the TxA_2 precursor, arachidonic acid. Intracellular IP_3 directly induces calcium release from storage pools in dense granules, while DAG indirectly induces the same response through activation of PKC. Elevation of free cytosolic calcium, coupled with a reduction in intracellular cAMP, is a universal response among mammalian platelets and explains why drugs that function as calcium channel blockers, e.g., verapamil, universally depress the rate and extent of aggregation. In contrast, drugs, such as aspirin, which inhibit the reactivity of the constitutive form of the cyclooxygenase enzyme (COX-1), do not interfere with the aggregation response in platelets from those species, e.g., cow, rat, and some dogs, that are relatively insensitive to TxA_2 as an agonist.

Because of the multiplicity of the intracellular responses to receptor activation and because of the synergy among products of the enzyme activations, *the physiological response of circulating platelets to vascular damage is similar in all animals despite species and breed differences being observed when a single agonist is used to induce platelet aggregation in vitro.*

In all species, platelets also function as an essential component of the endothelial repair process. During aggregation, growth factors, such as platelet-derived growth factor (PDGF) and epidermal growth factor (EGF), are released from their storage sites in α-granules (Fig. 2.141). Further, within the thrombus, the platelet cytoskeleton proteins, actin and myosin, in the presence of calcium, interact in a manner analogous to that of actin and myosin in muscle cells. *The activation of these contractile proteins results in the shrinkage of the platelet–fibrin meshwork, i.e., clot retraction.*

Platelet disorders

Bleeding episodes associated with a lack of sufficient numbers of functional platelets are typified by petechial and ecchymotic hemorrhages from unsealed small endothelial lesions of mucosal membranes or of the microvasculature. *Epistaxis, gastrointestinal and urogenital bleeding and cutaneous bruising are common phenomena.* This type of bleeding is not observed in disorders involving thrombin generation because the platelet adhesion and aggregation responses are adequate to seal small lesions in areas of low blood pressure. For larger wounds and in areas of high pressure, hemostasis requires both fully functional platelet aggregation and fibrin formation so that a stable thrombus can form to stop blood loss and promote wound healing. *Thrombopathies* associated with prolonged bleeding times, normal platelet counts and normal coagulation profiles may be due to defects in platelet adhesion, aggregation or secretion.

Evaluation of platelet function

The *buccal mucosal bleeding time* (BMBT) is a measure of the time for bleeding to stop after a standardized cut is made with a spring-loaded disposable device in the mucosal surface of the upper lip. The BMBT is prolonged if there are insufficient numbers of functional platelets in the circulation, or if there are reduced levels of functional adhesive proteins, such as vWF. Platelet numbers can be estimated from a blood smear and/or a platelet count. The ability of platelets to aggregate in response to in vitro stimulation with known agonists can be determined in citrated blood or plasma, but because this requires specialized instrumentation, its usefulness is limited in many diagnostic situations.

Thrombocytopenia

Clinical signs of thrombocytopenia include petechiation and ecchymosis in tissues or mucous membranes, epistaxis, hematuria and prolonged bleeding after venipuncture. In the absence of any other underlying coagulopathy, these clinical signs are generally not observed in domestic animals unless the platelet count falls below 25–50 $\times 10^9$ platelets/L. In healthy animals, approximately 30–40% of the total platelet pool is sequestered in the spleen, and hence transient thrombocytopenia may be observed in healthy animals when physiological conditions, such as hypothermia, induce an increase in the splenic platelet pool.

Hereditary thrombocytopenia has only been reported in Cavalier King Charles Spaniels. In this breed the autosomal recessive trait is asymptomatic and is characterized by *macrothrombocytopenia.*

Acquired thrombocytopenia is one of the most commonly recognized hematological disorders. Thrombocytopenia associated with *decreased platelet production* may be secondary to megakaryocyte hypoplasia or neoplasias, such as lymphoma. However, thrombocytopenia can also occur because of a *decreased rate of platelet survival* within the peripheral circulation that can be either immune-mediated or drug-induced. At present there are no noninvasive tests that can differentiate between an increase and a decrease in platelet production.

Immune-mediated thrombocytopenia has been reported in many breeds of dogs and in both young and old animals. *Primary idiopathic, or autoimmune thrombocytopenia,* is caused by the development of autoantibodies without an apparent associated disease. Prolonged bleeding may be observed during estrus, at whelping, and following venipuncture or surgery. Neonatal *alloimmune thrombocytopenia* has been reported in pigs and horses. In pigs, the disorder usually occurs after two or more pregnancies. Piglets are frequently born healthy but develop thrombocytopenia at one week of age. Diagnosis of the disorder is one of exclusion, sepsis being the usual differential, because *infections are the most common cause of thrombocytopenia.*

Secondary immune-mediated thrombocytopenia can be caused by *anti-platelet antibodies* or may be the result of *antibody binding to non-self-antigens* that become absorbed onto platelet membranes. These antibodies may be produced in the animal in response to infectious agents, drug exposure, or neoplasia. For example, an increase in antibody titer to *Rickettsia rickettsii* corresponds to thrombocytopenia and the development of petechiae and ecchymoses in dogs with canine Rocky Mountain spotted fever. Thrombocytopenia associated with systemic lupus erythromatosus (SLE) has been reported in dogs, cats and horses. Likewise, thrombocytopenia frequently accompanies immune-mediated hemolytic anemia in dogs, and has also been observed in cats and horses.

All domestic species are susceptible to **drug-induced thrombocytopenia** because of the broad spectrum of drugs that can either suppress pro-platelet production in the bone marrow or increase the rate of platelet destruction as a consequence of drug-dependent antibodies that bind to complementary antigenic sites on platelet membranes. Mononuclear phagocytes in the liver and spleen then destroy the modified platelets. In horses, as in people, *heparin administration* can induce transient thrombocytopenia through its interaction with preformed antibodies that have developed against the specific platelet protein, platelet factor 4 (PF4). PF4 is one of the proteins secreted from the α-granules into the circulation after platelets are activated. It is a positively charged molecule that binds tightly to negatively charged heparin. Not only can the complex of antibody-PF4-heparin enhance the rate of clearance of platelets from the circulation, but it can also induce platelet activation. To avoid thrombotic complications, low-molecular-weight (LMW) heparin preparations are becoming more widely used in the treatment of disseminated intravascular coagulation (DIC) in people. Preliminary results indicate that LMW heparin will also prove useful in veterinary medicine, as trials in dogs indicate that it is effective as an antithrombotic agent and appears not to induce thrombocytopenic complications.

von Willebrand disease

Although not an intrinsic platelet defect, *the primary cause of bleeding in von Willebrand disease (vWD) is failure of platelets to adhere and form aggregates around sites of vascular damage.* Although rare in cats, horses and cattle, *vWD is the most common canine inherited bleeding disorder.* In dogs, as in people, it represents a heterogeneous group of clinical disorders that are classified into *3 general types* on the basis of severity of bleeding, mode of inheritance, and biochemical abnormalities of the vWF protein. The vWF protein is primarily synthesized in endothelial cells as two subunits that subsequently undergo post-translational assembly into dimers and multimers ranging up to 100 vWF subunits that are stored in and subsequently released from endothelial cells. The high molecular weight subunits are most effective in promoting platelet-endothelial cell and intraplatelet bridges.

The release of vWF from cytoplasmic granules (Weibel-Palade bodies) occurs following endothelial cell stimulation with a variety of physiological compounds, such as thrombin, histamine, estrogen, thyroxine and the vasopressin analogue, 1-desamino-8-D-arginine vasopressin (DDAVP). Strenuous exercise also induces an increase in plasma vWF levels. In some species, such as people and cats, circulating platelets act as a secondary pool of circulating vWF because they contain megakaryocyte-derived vWF in their α-granules. However, canine platelets contain only very small amounts of vWF. Plasma vWF circulates in noncovalent complex with FVIII, which has the effect of prolonging the circulating half-life of the FVIII protein.

Based on breed studies in dogs, it appears that **type 1 vWD**, which is characterized by low circulating levels of vWF antigen and a proportional decrease in all multimeric forms, is transmitted in an incomplete dominant pattern. In contrast, the more clinically severe forms of vWD, **type 2 and type 3**, are recessive traits. In type 3, plasma vWF is absent whereas in type 2, high molecular weight multimers are absent and plasma vWF antigen levels are reduced (<50% of normal). In all forms of the disease, bleeding tendencies are exacerbated by concurrent thrombocytopenia or administration of drugs, such as nonsteroidal anti-inflammatory drugs (NSAIDs), that impair platelet function.

Acquired vWD has been reported in a dog as a secondary consequence of lymphangioma. In ponies, administration of hydroxyethylene starch solutions as blood volume expanders can also induce a transient decrease in circulating vWF levels.

A prolonged bleeding time accompanied by a normal platelet count and a normal coagulation profile is suggestive of vWD. Diagnosis can only be confirmed by specific assay of plasma vWF antigen and the determination of vWF multimer distribution. Both of these analytes are determined by immunological procedures. *Because vWF is antigenically distinct among mammalian species, plasma samples must be analyzed with reagents appropriate for the patient.* A semi-quantitative assessment of functional vWF activity can be determined by evaluating vWF-dependent platelet agglutination. A molecular test for vWF based on variation in DNA sequence is available for some breeds of dogs.

Inherited disorders of platelet function

Inherited thrombopathies are relatively rare in domestic animals compared to people, but they have been identified in several breeds of dogs and in cattle. *Four types of platelet dysfunction are recognized: disorders of platelet membrane glycoproteins, storage pool deficiencies, impairment of intracellular signaling, and a defect of platelet procoagulant activity.* Each of these disorders appears to be inherited as an autosomal trait. Clinical signs tend to be similar among the defects and involve mucosal bleeding that is more diffuse than the "pinpoint" hemorrhages observed with thrombocytopenia. Gingival hemorrhage can occur during shedding of deciduous teeth in puppies. Epistaxis, cutaneous ecchymoses, hematuria and prolonged or excessive bleeding at sites of surgery or trauma are common in older dogs. In cattle, subcutaneous hematomas and prolonged hemorrhage from puncture wounds, such as vaccination, ear tagging and insect bites, are typically encountered.

Thrombocytopenic thrombopathia, a variant of type I Glanzmann's thrombasthenia, has been documented in the Otterhound and Great Pyrenees breeds, and in a Boxer dog. The disorder is characterized by a decrease in the number of the platelet glycoprotein IIb/IIIa membrane receptors that serve as binding sites for vWF and fibrinogen. Thus, platelets from homozygous-deficient animals undergo a normal shape-change response following stimulation with agonists such as ADP, collagen, thrombin or PAF, but fail to form stable aggregates. Clot retraction is also impaired. Because platelet morphology is normal, a definitive diagnosis requires the analysis of platelet membranes by electrophoretic or flow cytometric techniques using antibodies specific for α- and β-subunits of the glycoprotein receptor.

The bleeding diathesis in **Chediak-Higashi syndrome** *(CHS) is due to a dense-granule storage pool deficiency.* The disease has been identified in Hereford, Brangus, and Japanese Black cattle, in Aleutian mink, Persian cats, and blue and silver foxes. The dense granules, the amine storage organelles, are either absent or ultrastructurally indistinct in platelets from affected animals. The in vitro aggregation response to ADP or collagen is reduced as a result of a decrease in the secretion of ATP, ADP and serotonin, which may or may not be accompanied by a decrease in intracellular calcium mobilization. Similar biochemical changes have been observed in several American Cocker Spaniels with normal platelet morphology.

Defective intracellular signaling pathways have been identified as the cause of platelet dysfunction in Basset Hounds, and Spitz dogs and in both purebred and crossbred Simmental cattle. In Basset Hounds, impaired cyclic AMP metabolism and abnormal phosphodiesterase activity result in elevations in basal platelet cAMP, which interferes with intracellular signaling following platelet activation. Platelet shape change is normal, but platelet adhesion and aggregation in response to most agonists is depressed. A similar response is observed in platelets from affected Spitz dogs, although the molecular basis for the defect in this breed has not been fully elucidated. In Simmental cattle, the platelet defect is characterized by a failure of platelets to form aggregates in vitro in response to ADP, collagen, PAF or other agonists that induce intracellular calcium mobilization. It has been proposed that the molecular basis for the dysfunction may be due to abnormal cytoskeleton interactions that prevent the assembly of the cytoplasmic domain of the GPIIb/IIIa receptors into the functional complexes necessary to support intracellular signaling.

A **defect in platelet procoagulant activity** has been identified in both male and female members of an inbred German Shepherd colony. As in the comparable human disorder known as Scott syndrome, platelet morphology is normal, as is platelet function as assessed by bleeding time, clot retraction, and aggregation. Total platelet phospholipid levels are normal but there is a reduction in the amount of phosphatidylserine that becomes exposed on the platelet surface during the activation process. Because of this, the platelets cannot provide an adequate phospholipid platform for the formation of the "tenase" and "prothrombinase" complexes, and consequently the rate of thrombin generation and fibrin formation is impaired. This delay in clot formation is clinically manifest by epistaxis, hyphema, intramuscular hematoma, and prolonged bleeding with cutaneous bruising after surgery.

Thrombopathies due to a combination of signaling and storage pool defects have been reported in a gray Collie and are associated with CHS in Japanese Black cattle.

Acquired platelet disorders

Considering the broad range of pharmacological agents that impair various biochemical aspect of platelet function, *it is probable that transient decrements in platelet hemostatic responses are relatively common in veterinary medicine but are rarely documented.* This is likely due to the relatively short half-lives of circulating platelets so that new, fully functional platelets are replenishing the circulating pool, and to the fact that a drug may selectively inhibit one intracellular signaling pathway thus reducing, but not completely blocking, platelet adhesion and aggregation. Further, in the absence of a preexisting coagulopathy, such as vWD or thrombocytopenia, a partial suppression of platelet reactivity is not, by itself, sufficient to induce clinical hemorrhage in the absence of trauma. However, hemorrhagic episodes are commonly observed when both thrombocytopenia and platelet dysfunction occur. For example, in calves infected with **type 2 *Bovine viral diarrhea virus***, spontaneous hemorrhages occur because of a decline in both circulating platelet numbers and their aggregation response. Dogs infected with *Ehrlichia canis* also develop thrombocytopenia and exhibit a reduction in both platelet adhesiveness and aggregation. The tendency to bleed and the alterations in platelet function in dogs with **canine ehrlichiosis** may be due to the appearance of anti-platelet antibodies.

Because of the subtle quantitative differences in the relative contributions of the various activation and intracellular signaling pathways among platelets from different species, it is difficult to make generalized statements about the inhibitory actions of anti-inflammatory and antibacterial agents. For example, nonsteroidal anti-inflammatory drugs, such as aspirin, that inhibit the endogenous platelet cyclooxygenase enzyme (COX-1), suppress platelet aggregation in most species. Bovine platelets are unresponsive to the inhibitory effects of aspirin and likewise are unresponsive to the β-lactam antibiotic, penicillin. In other species, this group of antibiotics binds to platelet membranes and inhibits glycoprotein receptor mediated adhesion and aggregation. The platelet inhibitory effects of barbiturates and cardiovascular drugs, such as diltiazem and verapamil, which act as calcium-channel blockers, also vary among species. Buccal mucosal bleeding time and platelet adhesion are prolonged in uremic dogs, but the molecular mechanisms involved have not been identified.

Regulation of coagulation: endogenous anticoagulants

It is essential for the maintenance of blood flow to tissues downstream from a site of vascular damage that thrombus formation be confined to the site of vascular damage, and that any procoagulant enzymes, such as FXa and thrombin, that escape from the thrombus into the circulation be neutralized by circulating inhibitors.

Antithrombin (AT, formerly called antithrombin III, or heparin cofactor) *is the major inhibitor of both thrombin and thrombin generation in plasma*. It is a member of the superfamily of "*serpins*" (serine protease inhibitors) that also includes α_1-antitrypsin, α_2-antiplasmin, and α_2-macroglobulin. Plasma AT is an α_2-globulin derived from both hepatocytes and endothelial cells. It preferentially inhibits the free forms of thrombin, FIXa and FXa, and thus has limited inhibitory activity against the "prothrombinase" and "tenase" complexes. The inhibitory action of AT is derived from the interaction of its reactive arginine residue with a serine residue at the reactive site of thrombin, or other serine proteases. The resulting thrombin–AT (TAT) complex prevents thrombin cleavage of fibrinogen to fibrin (Fig. 2.143). The inhibitory efficiency of AT is enhanced by heparan sulfate complexes exposed on the surface of activated endothelial cells. Either intravenously administered heparin, or heparin released from mast cells during an inflammatory reaction, also increases the rate of formation of TAT complexes. This mechanism forms the molecular basis for the therapeutic use of heparin as an anticoagulant. The TAT complexes are removed from the circulation either through clearance by the mononuclear phagocyte system or by becoming bound to the endothelial cell integrin, *vitronectin*, which results in their endocytosis and lysosomal degradation.

The **protein C anticoagulant system** regulates coagulation by modulating the activity of FV and FVIII. It represents a unique "on-demand" inhibitory system that is activated by thrombin generation. Protein C is synthesized in the liver as a vitamin-K-dependent zymogen of an anticoagulant protease. It is converted to an *activated form, APC*, on the surface of intact endothelial cells by thrombin that has become bound to the membrane protein, **thrombomodulin** (TM) in the T-TM complex (Fig. 2.143). Thrombomodulin is present on endothelial cells in arteries, capillaries, veins, and lymphatics. It is present in highest amounts in capillaries where blood flow is slower and thrombin concentrations highest. APC can cleave the phospholipid-membrane-bound cofactors to form the inhibitory products FVai and FVIIIai that, in turn, cause the suppression of both "prothrombinase" and "tenase" activity. The cleavage of FVa and FVIIIa within the phospholipid–enzyme complexes is facilitated by the vitamin-K-dependent cofactor, **protein S**, which forms a membrane-bound complex with APC. Only the free circulating form of protein S can complex with APC. This form represents about 30% of the total plasma concentration, as the major portion of protein S circulates bound to the complement regulatory protein C4b-binding protein.

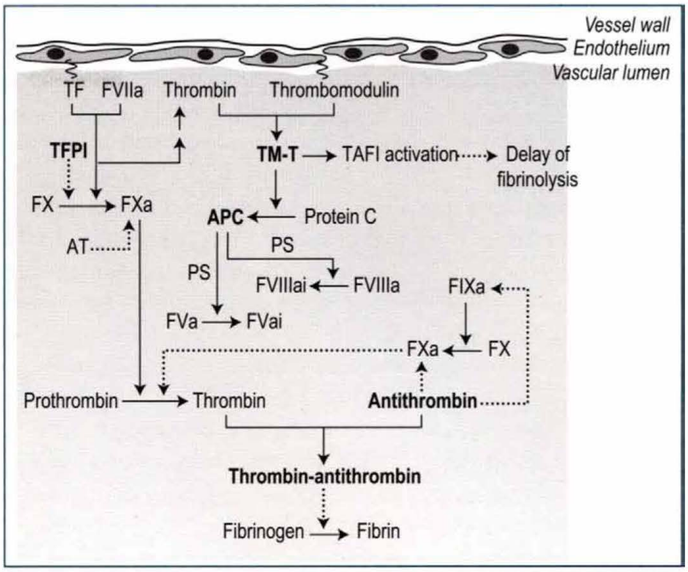

Figure 2.143 Schematic of the **major anticoagulant pathways**. Solid lines represent activation reactions and dashed lines represent inhibitory reactions. APC = activated protein C, AT = antithrombin, FVai = inhibitory form of FV, FVIIIai = inhibitory form of FVIII, PS = protein S, TAFI = thrombin-activatable fibrinolysis inhibitor, TFPI = tissue factor pathway inhibitor, TM-T = thrombomodulin–thrombin complex.

In vivo, APC does not cleave FVIII circulating bound to vWF, but it can cleave circulating FV and FVa, in part because both FV and FVa can bind to phospholipids in proximity to the APC-protein S membrane-bound complex. The cleaved FV can function in synergy with protein S as an APC cofactor in the degradation of FVIIIa. Thus, the anticoagulant potential of FV may be important in the regulation of the "tenase" complex by APC and protein S. Although few studies have been conducted with the APC-protein S system in domestic animals, its physiological importance is demonstrated by the severe thromboembolic disease that is associated with homozygous deficiency of protein C in both people and mice.

Disorders of endogenous anticoagulants

Although several types of inherited **antithrombin deficiency** have been characterized in people, this disorder has not been identified in domestic animals. Both functional and immunological laboratory assays have been developed to quantify AT levels in mammalian plasma. This has led to the recognition that, in many species, sepsis and DIC produce acquired deficiencies in circulating AT activity that are frequently accompanied by the appearance of circulating TAT complexes. One of the common hemostatic abnormalities observed in horses with colic is a decline in plasma AT activity. An acquired deficiency in AT activity has also been reported in dogs as a secondary consequence of protein-losing nephropathies or enteropathies. In dogs, the hypercoagulable state associated with these disorders, and the thrombosis that is an uncommon complication of hyperadrenocorticism, diabetes mellitus and cardiovascular disease, is attributed to reduced plasma AT activity. Reduced plasma AT was also one of the major hemostatic abnormalities found in a foal with thrombosis of the brachial artery. In contrast, increases in AT activity have been reported in cats associated with various inflammatory conditions. This is likely related to the fact that AT responds as a positive acute-phase reactant in cats.

Both immunological and functional laboratory techniques are available to quantify the protein C component of the thrombin–thrombomodulin–protein C–protein S system in animal plasma. As in human infants, foals exhibit lower functional protein C activity than do adult horses. Protein C activity is reduced in cases of vitamin K deficiency or antagonists, with protein C antigen levels being unaffected. DIC-induced consumption of protein C has been reported in dogs and primates. Lupus-like anticoagulants are phospholipids that promote thrombosis through inhibition of the protein C–protein S complex.

Fibrinolysis

The fibrinolytic system is an essential component of the hemostatic process. It is required for the dissolution of the thrombus through the proteolytic degradation of fibrin after tissue repair has occurred. The central enzyme in lysis of fibrin is **plasmin**, which is formed from its precursor, *plasminogen*, by one of two endogenous activators, tissue-type plasminogen activator (tPA) and urokinase (uPA) (Fig. 2.142). Plasminogen is synthesized by hepatocytes as a single chain glycoprotein and is the fibrinolytic component present in the highest concentration in the circulating blood. *Plasmin is a trypsin-like enzyme with broad substrate specificity*. In addition to degrading fibrin strands, it can degrade fibrinogen, FV and FVIII, various extracellular matrix components, and can activate other proteases, including matrix-degrading metalloproteinases. Like thrombin, both plasmin formation and its activity are highly regulated. For example, both tPA and uPA have short circulating half-lives relative to plasminogen, in part because of their rapid clearance via LDL-receptor related proteins (LRP) on cell surfaces. Further, *in healthy animals, the balance between circulating inhibitors and activators of plasminogen favors inhibition of plasmin formation.* The major inhibitor of plasminogen activation is *plasminogen activator inhibitor-1 (PAI-1)*, which can block the action of both tPA and uPA (Fig. 2.142). In normal plasma, PAI-1 is in five-fold excess over tPA, so most plasma tPA circulates as an inactive tPA-PAI-1 complex. This balance can be changed by the increased release of tPA from endothelial cells in response to exercise, vascular occlusion, or in response to locally generated thrombin at a site of vascular damage. In plasma, the primary inhibitor of plasmin activity is α_2-antiplasmin, with α_2-macroglobulin and α_1-antitrypsin capable of acting as "back-up" inhibitors.

Surface-mediated fibrinolysis

In the initial stages of thrombus formation, the activation of plasminogen is suppressed. Although thrombin is one of the potent promoters of the synthesis and secretion of tPA by endothelial cells, this profibrinolytic action is effectively opposed by the localized activation of TAFI (Figs 2.142 and 2.143). High concentrations of thrombin generated both by the positive feedback activation of FXI to FXIa and activation of the "tenase" complex, combined with the formation of thrombin–thrombomodulin complexes, enhance the activation of TAFI, which in turn inhibits tPA activation of plasminogen. Platelets represent the main circulating pool of PAI-1, which is locally released from α-granules during platelet activation. This platelet contribution of PAI-1 accounts, at least in part, for the premature fibrinolysis that has been observed in platelet-poor thrombi compared to platelet-rich thrombi.

Once an organized thrombus has been formed, plasmin formation and fibrinolysis is promoted. Most of the proteins of the fibrinolytic system appear in thrombi at final concentrations representing 10–30% of their concentration in plasma. This is consistent with simple trapping of plasma proteins in the thrombus. Fibrin potentiates fibrinolysis by bringing together plasminogen and tPA on its surface, which not only facilitates enzyme–substrate interactions but also protects tPA from inhibition by TAFI and PAI-1. Further plasmin, formed on a fibrin surface, interacts with fibrin strands at both its active site and at specific lysine-binding sites. This linkage has the effect of decreasing the ability of α2-antiplasmin to interact with and inhibit plasmin generated within the fibrin meshwork (Fig. 2.142).

Fluid-phase fibrinolysis

In contrast to tPA, uPA readily activates plasminogen in the fluid compartment of the circulation. At present, it is unclear how uPA participates in hemostasis, but it is evident from transgenic and knockout mouse studies that the tPA and uPA activators can compensate for each other. Fibrin is rapidly deposited after wounding, not only to prevent blood loss but also to provide a scaffold for the invasion of cells during the subsequent healing process. *Plasmin and uPA are known to be important in the slow dissolution of fibrin that occurs once tissue repair is complete.*

Single-chain urokinase-type plasminogen activator (scuPA, prourokinase) is synthesized in renal tissue and in macrophages as a zymogen. The molecule contains an EGF domain that is responsible for the binding of scuPA to specific receptors that are present on the surface of a variety of cells. *Kallikrein*, either generated at the site of vascular trauma or as part of an inflammatory response, is one of the important physiological mediators that selectively cleaves scu-PA to a proteolytically active two-chain form (uPA) (Fig. 2.142). Unlike tPA, uPA has no specific affinity for fibrin and thus can activate circulating and fibrin-bound plasminogen indiscriminately. Initially, plasmin generated outside a fibrin clot can be rapidly neutralized by α_2-antiplasmin. However, if the formation of plasmin exceeds the availability of this inhibitor, then plasmin can begin to degrade circulating plasma proteins such as fibrinogen, FV and FVIII. Different bacterial strains produce efficient plasminogen activators that can act as exogenous activators, frequently inducing inappropriate levels of plasmin formation. One of the best characterized compounds is *streptokinase*, which is produced by those strains of streptococci that use plasmin to their advantage in increasing the efficiency of their invasive capacity. In many mammalian species, streptokinase acts by forming a 1:1 stoichiometric complex with either plasminogen or plasmin. In this form, the general proteolytic action of streptokinase is decreased, but its plasminogen-activating activity is increased several fold.

Primary disorders of the fibrinolytic system have not been characterized in domestic animals. Unlike the situation in people, there appear to be no significant postoperative changes in the fibrinolytic system in dogs. However, alterations of the fibrinolytic system associated with inflammatory conditions are frequently recognized as a prelude to DIC.

Inflammation and neoplasia

Inflammatory mediators, released either from an infectious agent and/or by the host, can manipulate procoagulant/anticoagulant equilibrium and cause secondary hemorrhagic or thrombotic complications. *The role of the contact activation system as a link between hemostasis and inflammation has long been recognized.* In addition to initiating thrombin formation through the FXI-tenase pathway (Fig. 2.142), activation of FXII causes the conversion of PK to kallikrein that, in turn, converts HMWK to the inflammatory mediator *bradykinin*. A close connection between the tissue factor pathway and inflammation has more recently been elucidated.

An increase in TF expression on the plasma membrane of peripheral blood cells and endothelial cells occurs in response to products from both gram-negative and gram-positive organisms. Activated FVII, FX and thrombin, generated following exposure to TF, trigger intracellular signaling cascades in leukocytes by binding to PAR-type receptors that currently have no known role in hemostasis. *Among the inflammatory responses induced by these interactions are leukocyte recruitment, release of additional cytokines, and production of reactive oxygen species.* Systemic activation of thrombin generation can result in the cleavage of fibrinogen and the deposition of fibrin in the microvasculature of various organs. The formation of fibrinous exudates can benefit the host by encapsulating microorganisms. On the other hand, because the exudates can incorporate a large number of bacteria that are protected from phagocytosis once they are sequestered, bacterial proliferation can occur.

Blood platelets are also recognized as inflammatory mediators, either through release of their cytoplasmic granules, e.g., histamine and serotonin, or through the formation of cell membrane-derived neutrophil and monocyte agonists, e.g., PAF and leukotrienes. After activation, mononuclear phagocytes can produce and release a wide range of inflammatory mediators including: IL-6 that can stimulate increased hepatocyte fibrinogen synthesis, PAF and prostaglandins that can induce further platelet activation, and tumor necrosis factor (TNF), which can initiate fibrinolysis through the release of plasminogen activators. Thus, *in the initial phase of inflammation, a balance between procoagulant activity, fibrin formation, and the lysis of formed fibrin can be maintained.* However, within several hours of the initiation of an inflammatory response, the fibrinolytic system is suppressed due, in part, to the increased synthesis and release of PAI-1. The fact that thrombosis is not a consistent clinical observation during inflammation can be explained by the thrombin- and/or cytokine-induced activation of the TM–protein C–protein S anticoagulant system (Fig. 2.143). The suppression of both thrombin formation and plasmin generation maintains a hemostatic equilibrium.

Dysequilibrium among procoagulant, anticoagulant and fibrinolytic activity, similar in clinical manifestation to the situation that occurs in sepsis, is a common occurrence in people with various types of cancer. The association between hemostatic abnormalities and **neoplasia** is less well understood in domestic animals, although abnormal bleeding can be a clinical sign in animals with malignancies such as hemangiosarcoma, multiple myeloma and mast cell tumors. *Abnormal laboratory hemostatic profiles are frequently associated with untreated neoplasia in dogs and cats.* For example, in a study of 100 dogs, 83 exhibited at least one abnormal parameter with thrombocytopenia (36 dogs), prolonged APTT (32 dogs), and either elevated or reduced fibrinogen values (50 dogs) being the most common findings. *Anti-neoplastic drugs can also impair the hemostatic process.* For example, vincristine has been shown to inhibit canine platelet function. L-asparaginase, which inhibits protein synthesis, and actinomycin D, which directly antagonizes vitamin K, can produce transient reductions in the circulating activity of multiple hemostatic proteins. Functional inhibition of clotting factor activity by antibodies produced by neoplastic cells can also contribute to hemorrhagic problems. These pathological inhibitors, or circulating anticoagulants, may either be immunoglobulins directed against the functional epitopes of hemostatic proteins or antiphospholipid antibodies that interfere with the normal rate of formation of the "tenase" and "prothrombinase" complexes (Fig. 2.141). The presence of acquired plasma inhibitors is suspected when deficits in single or multiple coagulation factors cannot explain abnormal laboratory hemostasis profiles.

Disseminated intravascular coagulation (DIC) is an acquired syndrome that has been defined as "*the activation of intravascular* *coagulation up to intravascular fibrin formation, which may or may not be accompanied by secondary fibrinolysis or inhibited fibrinolysis.*" Due to the pathological activation of coagulation and inappropriate hypercoagulation with or without fibrinolysis, thrombosis and/or hemorrhage may occur at multiple sites, which in turn cause organ dysfunction or failure. It is a potential complication of several conditions, including sepsis and neoplasia. In horses, DIC has been reported as a complication of acute gastrointestinal tract disease. It is estimated that approximately 50% of dogs with *immune-mediated hemolytic anemia* exhibit evidence of a hypercoagulable state at the time of clinical presentation. Initially, an increased rate of thrombin generation can be compensated for by the circulating anticoagulant system, i.e., TFPI, APC and antithrombin (Fig. 2.143), resulting in a condition referred to as "*compensated DIC*." Variable laboratory results are obtained at this stage. Because of the increased amount of thrombin formation, PT and APTT results may be shortened and variable alterations observed for platelet counts and fibrinogen levels. Definitive laboratory diagnosis requires the evaluation of molecular markers such as TAT complexes (Fig. 2.143) and peptide fragments, such as prothrombin fragment 1 + 2, that are released during activation of procoagulant factors.

If the triggers to thrombin generation persist, the patient may progress to the *second phase of DIC*. When the reserve of circulating inhibitors is consumed, thrombin generation and fibrin formation are unrestrained. This results in the depletion of circulating platelets and the consumption of both procoagulant proteins and fibrinogen, hence the use of the terms "*consumptive coagulopathy*" *or* "*decompensated DIC*" to characterize this stage of DIC. The depletion of both circulating platelets and hemostatic proteins generally results in the development of either spontaneous hemorrhaging or hemorrhages in response to minor trauma. The abnormalities in the laboratory profile include *decreased platelet count, prolonged PT and APTT results, and decreased levels of fibrinogen, antithrombin, and protein C*. In dogs experimentally infected with *Angiostrongylus vasorum*, the consumptive coagulopathy that develops when the larvae migrate into the pulmonary circulation is marked by a decrease in plasma FV and FVIII activity along with an increased APTT.

Frequently, at some stage during DIC development, the fibrinolytic system is also activated resulting in increased amounts of intravascular plasmin being generated. Concurrent fibrin polymerization and fibrinolysis exacerbates the tendency for hemorrhage to occur. During plasmin proteolysis of fibrinogen and fibrin, peptide fragments, known as *D-dimers* and *fibrin degradation products (FDPs)*, respectively, are released into the circulation. Hence, *the evaluation of circulating levels of FDPs and D-dimers can be used as a diagnostic indicator of uncompensated DIC*. Excessive generation of plasmin and production of FDPs both contribute to *organ failure*, which is often the ultimate cause of death in animals with untreated DIC. For example, plasmin can induce vascular and cellular damage through activation of matrix metalloproteinases that degrade a wide range of cytoskeletal filaments. FDPs can enhance local inflammatory reactions by triggering the release of IL-1 and IL-6 from monocytes and macrophages.

There are a number of hemorrhagic conditions in which endothelial injury induced by infectious agents may be the underlying problem. One of the more severe and more commonly encountered disorders in this category is **purpura hemorrhagica**, a vasculitis syndrome, associated with *Streptococcus equi* infection in horses. In dogs, hemorrhage associated with *heartworm disease, Rocky Mountain spotted fever*, and *leishmaniasis* has been attributed, at least in part, to vascular damage. *Exercise-induced pulmonary hemorrhage* in horses is also likely due to an alteration in capillary permeability, because platelet function was found to be identical in horses that exhibited clinical bleeding and those that did not.

GENERAL CONSIDERATIONS

Endocrine glands are collections of specialized cells that synthesize, store, and release their secretions directly into the bloodstream. They are sensing and signaling devices located in the extracellular fluid compartment and are capable of responding to changes in the internal and external environments to coordinate a multiplicity of activities that maintain homeostasis.

Secretions of endocrine glands are peptide, steroid, catecholamine, or iodothyronine hormones that are transported by the blood to influence the functional activity of target cells elsewhere in the body. Other populations of cells are concerned with degradation of hormone after it has exerted its physiologic function. This is accomplished by peptidases on the cell surface, uptake by cells and degradation by lysosomal enzymes, or conjugation with glucuronide or sulfate and excretion in the bile or urine.

Endocrine glands are small compared with other organs, widely distributed in the body, and connected with one another by the bloodstream. They are richly supplied with blood, and there is a close anatomic relationship between endocrine cells and the capillary network. To facilitate rapid transport of raw materials and secretory products between the blood and endocrine cells, the peripheral cytoplasmic extensions of capillary endothelial cells have *fenestrae* covered by a single membrane.

Types of hormones

Polypeptide hormones

The primary site of action for polypeptide hormones is the plasma membrane of target cells. Receptor proteins for the hormone are present on the outer surface of the plasma membrane. These hormones are water soluble, have a *short half-life in blood* (usually measured in minutes), and lack specific plasma-binding proteins.

The receptors for polypeptide hormones on the plasma membrane of target cells perform two key functions. *First, they recognize the active hormone* from among many other proteins to which the cell is exposed. The concentration of hormone in extracellular fluids often is much lower than that of other proteins. The hormone binds to the receptor site and forms a reversible hormone-receptor complex. *Second, the receptor conveys the message of the bound hormone from the outside to the inside of the target cell.* The magnitude of this transmembrane signal depends on the concentration of hormone to which the target cell is exposed, the affinity of the receptor for the hormone, and the concentration of receptors on the target cell.

There appears to be a *single common intracellular pathway* for many different polypeptide hormones. It begins with the activation of an enzyme, *adenylate cyclase*, in the plasma membrane of target cells. Cyclic adenosine monophosphate (cAMP) is formed intracellularly from adenosine triphosphate (ATP) and activates cAMP-dependent protein kinases. These protein kinases activate or inactivate a variety of enzymes by phosphorylating them, using adenosine triphosphate as a source of phosphate. The intracellular pathway for each polypeptide hormone subsequently branches into a multiplicity of pathways leading to a variety of effects on any given target cell.

Endocrine cells that produce polypeptide hormones have a well-developed endoplasmic reticulum with many attached ribosomes where the hormone is assembled, and a prominent Golgi apparatus for packaging hormone into granules for intracellular storage and transport. *Secretory granules* are unique to polypeptide hormone- and catecholamine-secreting endocrine cells and provide a mechanism for intracellular storage of substantial amounts of preformed active hormone. These membrane-limited granules are macromolecular aggregations of active hormone, often associated with a specific binding protein. When the cell receives a signal for hormone secretion, secretory granules are directed by microtubules to the periphery of the endocrine cell, probably by the contraction of microfilaments. The limiting membrane of the granule then fuses with the plasma membrane of the cell. The hormone-containing granule core is extruded through a hiatus into the extracellular perivascular space by emiocytosis or exocytosis. The granule core is fragmented subsequently and hormone is rapidly transported through capillary fenestrae into the circulation. Hormone synthesized in excess of requirement is degraded by fusion of the hormone-containing granules with lysosomes, a process termed *crinophagy*.

Steroid hormones

Steroid hormone-secreting endocrine cells are characterized by large lipid bodies in the cytoplasm that contain cholesterol and other precursor molecules. The lipid bodies are in close proximity to an extensive tubular network of smooth endoplasmic reticulum and large mitochondria that contain the hydroxylase and dehydrogenase enzyme systems. These enzymes function to attach various side chains to the basic steroid nucleus. *Steroid-producing cells lack secretory granules and do not store significant amounts of preformed hormone.* They are dependent on continued biosynthesis to maintain the normal secretory rate for a particular hormone.

Steroid hormones having a basic nucleus of three cyclohexane rings and one pentane ring account for approximately 15% of mammalian hormones. *The primary site of their action is the nucleus of target cells.* Receptors are proteins that bind the hormone primarily in the nucleus resulting in *genomic activation of target cells*. The interaction of steroid hormones with the genetic information results in increased transcription of messenger ribonucleic acid (mRNA), which directs new protein synthesis by specific target cells. The steroid hormones are lipid-soluble, which facilitates their transport through the cell membrane. They have a *long half-life in blood* (typically measured in hours) and reversibly bind to high-affinity, specific binding proteins for transport in plasma.

Catecholamine and iodothyronine hormones

This chemical group of hormones are *tyrosine derivatives*. They account for approximately 5% of mammalian hormones and include the *catecholamines (epinephrine, norepinephrine)* secreted by the adrenal medulla, and *iodothyronines (thyroxine (T_4), triiodothyronine (T_3))* produced by follicular cells of the thyroid gland. Catecholamines share similar mechanisms of action with polypeptide hormones, whereas iodothyronines more closely resemble the steroid hormones.

Proliferative lesions in endocrine glands

Characteristics

Endocrinologically active (functional) neoplasms derived from polypeptide hormone-secreting endocrine cells consist of one predominant cell type and usually are associated clinically with the autonomous secretion of one polypeptide hormone. However, there is evidence from immunocytochemical and electron microscopic investigations that some endocrine tumors are composed of more than one type of neoplastic cell and are capable of synthesizing multiple hormones.

Neoplasms derived from steroid hormone-secreting endocrine cells are characterized by having large lipid bodies in their cytoplasm that contain cholesterol and other precursor molecules for hormone synthesis. The lipid bodies are in close proximity to an extensive tubular network of smooth endoplasmic reticulum and large mitochondria. Steroid hormone-producing cells lack secretory granules and are unable to store significant amounts of preformed hormone.

The histologic separation between nodular hyperplasia, adenoma and carcinoma often is more difficult in endocrine glands than in most other organs of the body. For many endocrine glands (especially thyroid C cells, secretory cells of the adrenal medulla, and specific trophic hormone-secreting cells of the adenohypophysis) there is a continuous spectrum of proliferative lesions between diffuse or focal hyperplasia and adenomas derived from a specific population of cells.

It is a common feature of endocrine glands that prolonged stimulation of a population of secretory cells predisposes to the subsequent development of a higher than expected incidence of tumors. Long-term stimulation leads to the development of clones of cells within the hyperplastic endocrine gland that grow more rapidly than the rest and are more susceptible to neoplastic transformation when exposed to the right combination of promoting carcinogens.

Nodular hyperplasia usually appears as multiple small foci, in one or both (for paired) endocrine gland(s), that are well demarcated but not encapsulated from adjacent normal cells. Cells comprising an area of nodular hyperplasia closely resemble the cell of origin; however, the cytoplasmic area may be slightly enlarged and the nucleus more hyperchromatic than in the normal endocrine cell.

Adenomas are solitary nodules, in one (or occasionally both for paired) endocrine gland(s), that are larger than the multiple foci of nodular hyperplasia. They are *sharply demarcated from the adjacent normal glandular parenchyma,* often by a thin, partial to complete, fibrous capsule. The adjacent parenchyma is compressed to varying degrees depending upon the size of the adenoma. Cells comprising an adenoma closely resemble the cell of origin morphologically and in their architectural pattern of arrangement; however, there often are histologic differences such as multiple layers of cells lining follicles or vascular trabeculae and solid clusters of secretory cells subdivided into packets by a fine fibrovascular stroma.

Carcinomas usually are larger than adenomas and produce enlargement in one (or occasionally both, for paired) endocrine gland(s). The separation between adenoma and carcinoma of an

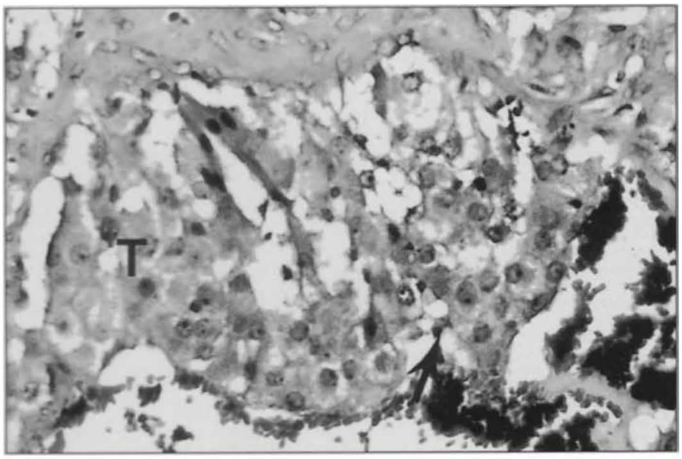

Figure 3.1 Subendothelial growth of tumor cells (T) in a **pheochromocytoma**, rat. The blood-filled space is lined by endothelial cells (arrow).

endocrine gland often is more difficult than in other tissues. *Histopathologic features that are suggestive of malignancy in an endocrine tumor include intraglandular invasion, invasion into and through the capsule of the gland with establishment of secondary foci of growth in the periglandular fibrous and adipose connective tissues, formation of tumor cell thrombi within vessels (especially muscular-walled), and particularly the establishment of metastases at distant sites.* The growth of neoplastic cells in a subendothelial location in highly vascular benign endocrine tumors should not be mistaken for vascular invasion and clusters of neoplastic cells may be artefactually forced into the lumen of thin-walled vessels and be misinterpreted as tumor cell emboli (Fig. 3.1). Malignant endocrine cells often are more pleomorphic (including oval or spindle-shaped) than normal, but nuclear pleomorphism is not a consistent criterion to distinguish adenomas and carcinomas. Mitotic figures may be frequent in malignant endocrine cells, but the significance of this criterion can vary considerably with the degree of background stimulation of the endocrine gland.

Functional aspects of endocrine tumors

Many neoplasms derived from endocrine glands are endocrinologically active (functional), secrete an excessive amount of hormone either continuously or episodically, and result in clinical syndromes of hormone excess. Many examples occur in different animal species including the hypoglycemia of beta cell neoplasms of the pancreatic islets in dogs, hyperthyroidism associated with adenomas and carcinomas derived from thyroid follicular cells in cats and dogs, hypercalcitoninism in bulls and other animal species with thyroid C-cell tumors, hyperadrenocorticism either associated with adrenocorticotropin (ACTH)-secreting pituitary corticotroph adenomas or neoplasms derived from the adrenal cortex (zona fasciculata) in dogs, among many others.

Measurement of hormone levels in serum or plasma in the basal, suppressed, or stimulated state and, in some instances, hormonal metabolites in the urine over a 24-hour period of excretion is essential to confirm that an endocrine tumor is releasing hormone at an abnormally elevated rate. An endocrine tumor also can be interpreted as being endocrinologically active if either the rim of normal tissue around the tumor or the opposite of paired endocrine glands undergoes atrophy due to negative feedback inhibition by the elevated hormone levels or an altered blood constituent. In response to the autonomous secretion of hormone by the tumor, these non-neoplastic secretory cells become smaller than normal, especially in the cytoplasmic area, and eventually the number of cells is decreased. Functional pituitary neoplasms secreting an excess of a particularly trophic hormone (e.g., adrenocorticotropin) will be associated with hypertrophy and hyperplasia of target cells in the adrenal cortex (zonae fasciculata and reticularis).

Mechanisms of endocrine disease

Primary hyperfunction of an endocrine gland

In primary hyperfunction of an endocrine gland, cells (often neoplastic and derived from the gland) synthesize and secrete hormone at an autonomous rate in excess of the body's ability to utilize and subsequently degrade the hormone, thereby resulting in *functional disturbances of hormone excess*. These include hyperfunction of parathyroid chief cells, thyroid C (parafollicular) cells, beta cells of the pancreatic islets, secretory cells of the adrenal medulla, follicular cells of the thyroid, among many others.

The *autonomous secretion of parathyroid hormone* results in progressive and generalized demineralization of the skeleton, leading to hypercalcemia, which results in soft tissue mineralization and the development of renal calculi. The accelerated osteoclastic resorption of bone results in marked thinning and osteoclastic tunneling of cortical bone, and predisposes bone to the development of pathologic fractures.

The *autonomous hypersecretion of thyroxine and triiodothyronine* is a common endocrinopathy in older cats. This hypersecretion is associated with a spectrum of proliferative lesions of thyroid follicular cells. Although the majority of the functional thyroid lesions are adenomas derived from follicular cells, other distinctly multifocal lesions in one or both thyroids are more consistent with multinodular hyperplasia. Functional thyroid lesions in cats should be considered potentially malignant because a few are adenocarcinomas that may metastasize to regional lymph nodes. The functional disturbances of hyperactivity, weight loss despite increased appetite, hyperthermia, and tachycardia reflect long-term stimulation of multiple populations of target cells by the abnormally elevated blood levels of thyroid hormones.

Secondary hyperfunction of an endocrine gland

In secondary hyperfunction of an endocrine gland, a lesion in one organ (e.g., adenohypophysis) secretes an excess of a trophic hormone that leads to long-term stimulation and hypersecretion of hormone by a target organ. An example of this pathogenic mechanism in animals is the adrenocorticotropic hormone (ACTH)-secreting tumor derived from pituitary corticotrophs in the pars distalis and intermedia of dogs (see Fig. 3.11).

The clinical signs and lesions in the animal primarily are the result of the elevated blood cortisol levels associated with the ACTH-stimulated hypertrophy and hyperplasia of the zonae fasciculata and reticularis of the adrenal cortex. The syndrome of cortisol excess in dogs is characterized by progressive alopecia, hyperpigmentation, and muscle wasting caused by the protein catabolic effects of glucocorticoids. Some dogs, particularly Poodles, have a similar marked adrenocortical enlargement and clinical evidence of cortisol excess, but without a tumor in the pituitary gland. These dogs may have a change in their set point to the negative feedback signal (e.g., blood cortisol). This can be caused by an abnormal accumulation of certain neurotransmitter substances (e.g., serotonin) near neurosecretory neurons in the hypothalamus that secrete corticotrophic hormone-releasing factor. The end result is corticotroph hyperplasia, elevated ACTH levels in the blood and long-term stimulation of the adrenal cortex, which results in hyperplasia of the zona fasciculata and zona reticularis and the clinical syndrome of cortisol excess (see Fig. 3.10).

Primary hypofunction of an endocrine gland

In primary hypofunction of an endocrine gland, *hormone secretion is subnormal* because of extensive destruction of secretory cells by a disease process, the failure of an endocrine gland to develop properly, or the result of a specific biochemical defect in the synthetic pathway of a hormone.

- *Immune-mediated injury* causes hypofunction of several endocrine glands in animals, including the parathyroid gland, adrenal cortex, and thyroid gland. Thyroiditis caused by this mechanism is characterized by marked infiltration of lymphocytes and plasmacytes, and deposition of electron-dense immune complexes along the follicular basement membranes with progressive destruction of secretory parenchyma.
- *Failure of development* also results in primary hypofunction of an endocrine gland. An example of this mechanism in animals is the failure of oropharyngeal ectoderm to differentiate into trophic hormone-secreting cells of the adenohypophysis in dogs, resulting in pituitary dwarfism and a failure to attain somatic maturation (see Fig. 3.9). A large, multicompartmented cyst is present on the ventral aspect of the brain in the pituitary region of these dogs. The cyst compresses the normally developed neurohypophysis and results in disturbances of water metabolism.
- Another form of primary hypofunction is *failure of hormone synthesis caused by a genetically determined defect in a biosynthetic pathway or lack of a specific enzyme.* One of the best-documented examples of this condition in animals is vitamin D-dependent rickets in pigs. It is caused by a lack of 25-hydroxycholecalciferol-1-α-hydroxylase in the proximal convoluted tubules of the kidney. This enzyme is needed to synthesize the hormonal form of vitamin D. Blood calcium and phosphorus levels progressively decrease due to the subnormal ability of the pig to convert 25-hydroxycholecalciferol to the biologically active, hormonal form (1,25-dihydroxycholecalciferol) in the kidney. The lowered blood concentrations of calcium and phosphorus lead to a failure of mineralization of osteoid and persistence of cartilage in the physes, leading to severe deformities in the skeleton (see Vol. 1, Bones and joints).

Congenital dyshormonogenetic goiter in sheep, goats, and cattle is another example of primary hypofunction caused by failure of hormone synthesis. The low blood thyroxine and triiodothyronine levels and clinical evidence of severe hypothyroidism in these animals are due to an inability of follicular cells to synthesize thyroglobulin. The molecular defect has been shown to be a defective processing of the primary transcripts for thyroglobulin messenger ribonucleic acid (mRNA) and aberrant transport of mRNA from the nucleus to ribosomes. This results in subnormal amounts of thyroglobulin mRNA in follicular cells, particularly mRNA that is attached to membranes of the endoplasmic reticulum in the cytoplasm.

Thyroglobulin is one of the major components of colloid in the lumen of thyroid follicles. This high molecular weight glycoprotein is synthesized on ribosomes of the rough endoplasmic reticulum in follicular cells. Thyroglobulin is packaged into apical granules that are secreted into the follicular lumen to serve as an extracellular matrix for the stepwise iodination of the tyrosyl residues incorporated into its structure, resulting in the formation of thyroxine and triiodothyronine. These animals do not have a defect in the ability of the thyroid to concentrate ^{131}I; however, there is a greatly reduced ability to iodinate tyrosyl residues and form thyroid hormones. The subnormal blood levels of thyroxine (T_4) and triiodothyronine (T_3) are detected by the hypothalamus and adenohypophysis, resulting in an increased secretion of thyroid stimulating hormone (TSH) or thyrotropin (TTH) and intense hyperplasia of follicular cells (see Fig. 3.66B).

Secondary hypofunction of an endocrine gland

In secondary hypofunction of an endocrine gland, *a destructive lesion in one organ, such as the pituitary, interferes with the secretion of trophic hormone*. This results in hypofunction of the target endocrine glands. Large, endocrinologically inactive, pituitary neoplasms in adult dogs, cats, and other animal species may interfere with the secretion of the multiple pituitary trophic hormones and result in clinically detectable hypofunction of the adrenal cortex, follicular cells of the thyroid, and gonads (see Fig. 3.15).

Target endocrine organs respond dramatically to a lack of normal production of pituitary trophic hormones. The adrenal glands of animals with large nonfunctional pituitary adenomas are small and often difficult to find at necropsy. The adrenals consist primarily of medullary tissue surrounded by a narrow zone of atrophic cortex. The adrenal cortex appears as a thin yellow-brown rim composed of a moderately thickened capsule and secretory cells of the outer (aldosterone-producing) layer, zona multiformis (glomerulosa), which is not under ACTH control. The zonae fasciculata and reticularis are severely atrophied compared with those in normal adrenal glands, secrete subnormal amounts of glucocorticoid hormones, and have a blunted increase in cortisol or corticosterone following the administration of exogenous ACTH. By comparison, thyroid glands in animals with large pituitary adenomas disrupting normal trophic hormone (e.g., TSH) production either are near normal size or only slightly reduced in size to a much lesser degree than is the adrenal cortex. The majority of thyroid follicles are large, lined by flattened (atrophic) cuboidal follicular cells, and distended with densely stained colloid with little evidence of endocytotic activity because of a lack of TSH. Calcitonin-secreting thyroid C cells function normally since they are not controlled by pituitary trophic hormones. Seminiferous tubules in the testis are small with little evidence of active spermatogenesis and the ovarian cortex is devoid of functional graafian follicles.

Secondary hypofunction of an endocrine gland also occurs when *insufficient iodide ion* is available for thyroid follicular cells to synthesize adequate amounts of thyroid hormones to meet the animal's daily requirements. The thyroid gland attempts to compensate by increasing the efficiency of iodide trapping and by preferentially synthesizing more T_3 than T_4, thereby saving a molecule of iodide for every molecule of thyroid hormone produced. *Dietary iodine deficiency resulting in diffuse hyperplastic goiter* (see Fig. 3.61) was common in many areas of the world before the widespread addition of iodized salt to animal diets and still occurs worldwide in domestic animals and human beings living in iodine-deficient areas. Marginally iodine-deficient diets that contain goitrogenic compounds may cause severe thyroid follicular cell hyperplasia and goiter. Goitrogenic substances include thiouracil, sulfonamides, anions of the Hofmeister series, and a number of plants of the family Brassicaceae. Offspring of females fed iodine-deficient diets are likely to develop severe thyroidal follicular cell hyperplasia and have clinical signs of hypothyroidism. The affected lobes are firm and dark red because an extensive interfollicular capillary network develops under the influence of long-term TSH stimulation. Follicles are irregular in size and shape in hyperplastic goiter because they contain various amounts of lightly eosinophilic and vacuolated colloid. Some follicles collapse because of the lack of colloid. Their lining epithelial cells are columnar and have deeply eosinophilic cytoplasm and small hyperchromatic nuclei that often are situated in the basilar portion of the cell. The follicles are lined by single or multiple layers of hyperplastic follicular cells that form papillary projections into the lumens of some follicles.

Endocrine hyperactivity secondary to diseases of other organs

A common example of endocrine hyperactivity secondary to diseases of other organs in animals is the **hyperparathyroidism** *that develops secondary to chronic renal failure or nutritional imbalances.* In the **renal form**, the retention of phosphorus early and subsequent progressive destruction of cells in the proximal convoluted tubules interferes with the metabolic activation of vitamin D_3 by the 1-α-hydroxylase in the kidney. This is the rate-limiting step in the metabolic activation of vitamin D_3 and is tightly controlled by parathyroid hormone (PTH) and several other factors. The impaired intestinal absorption of calcium results in the development of progressive hypocalcemia. Parathyroid stimulation in animals with chronic renal disease can be directly attributed to the hypocalcemia that develops. As the phosphorus concentration increases, blood calcium decreases reciprocally due largely to the suppressive effects of the hyperphosphatemia on the renal 1-α-hydroxylase resulting in an interference in production of the active form of vitamin D_3 ($1,25\text{-}(OH)_2D_3$), thereby reducing intestinal absorption of calcium. All 4 parathyroid glands are enlarged due initially to organellar hypertrophy and later to chief cell hyperplasia that results in an increased PTH synthesis and secretion in response to the hypocalcemia. Although skeletal involvement is generalized with hyperparathyroidism, it does not affect all parts uniformly. Bone lesions include resorption of alveolar socket bone and loss of *lamina dura dentes* that occur early in the course of the disease. This results in loose teeth that may be dislodged easily and interfere with mastication. Due to the accelerated rate of resorption, cancellous bones of the maxilla and mandible become weakened, are readily pliable ("rubber jaw"), and the jaws fail to close properly.

Nutritional hyperparathyroidism develops in animals fed abnormal diets that are low in calcium, high in phosphorus or oxalate, or deficient in cholecalciferol for certain non-human primates. Unsupplemented all-meat diets fed to carnivores fail to supply the daily requirements for calcium, leading to progressive hypocalcemia that stimulates the parathyroid gland to increased activity. The normal kidneys in these animals respond to the increased parathyroid hormone secretion by increasing phosphorus excretion and lowering blood phosphorus levels. After a carnivore is fed this imbalanced diet for several weeks to months, its skeleton becomes severely demineralized and predisposed to fractures. The cortices of long bones are thin and the medullary cavity widened due to intense osteoclastic resorption of bone that is stimulated indirectly by the increased secretion of parathyroid hormone (see Vol. 1, Bones and joints).

Hyperfunction of an endocrine organ also can be the result of hormonal imbalances induced by **xenobiotics**. For example, hyperactivity of the pituitary gland in rodents during chronic toxicity testing often results in increased development of tumors in the gonads or mammary glands. Excess production of luteinizing hormone (LH), usually due to disruption of negative feedback control by estrogen or testosterone, increases the incidence of tubulostromal adenomas and granulosa cell tumors in the ovary of mice, and Leydig (interstitial) adenomas of the testes in rats. The tubulostromal adenomas are the most important of the ovarian tumors in mice and they are the tumors whose incidence often is increased by various endocrine perturbations associated with chronic exposure to xenobiotics, senescence or inherited genic deletion. Tubulostromal adenomas are unique lesions that develop frequently in the mouse ovary, accounting for approximately 25% of naturally occurring ovarian tumors in this species. They are uncommon in rats, rare in other animal species, and are not recognized in the ovaries of women.

Factors that destroy or greatly diminish the numbers of ovarian follicles, such as senescence, genetic deletion of follicles, X-radiation, drugs and xenobiotics, and early thymectomy with the development of autoantibodies to oocytes all diminish sex steroid hormone secretion by the ovary. This results in elevated circulating levels of gonadotrophins, especially LH, due to decreased negative feedback on the hypothalamic–pituitary axis by estrogens and possibly other humoral factors produced by graafian follicles. The long-term stimulation of stromal (interstitial) cells, which have receptors for LH, and, indirectly, the ovarian surface epithelium appears to place the mouse ovary at increased risk for developing the unique tubular or tubulostromal adenomas.

Leydig (interstitial) cells of the testis frequently undergo proliferative changes with advancing age and following chronic exposure to large doses of xenobiotics that result in hormonal imbalances in rodents. Pathogenic mechanisms reported to be important in the development of proliferative lesions of Leydig cells include hormonal imbalances, irradiation, species and strain differences, and exposure to certain chemicals. Hormonal imbalances are important factors in the development of focal proliferative lesions of Leydig cells, including increased estrogenic steroids in mice and hamsters and elevated pituitary gonadotrophins in rats resulting from the chronic administration of xenobiotics. Many xenobiotics when administered chronically to rats disrupt the hypothalamic–pituitary–testis axis at one of several possible sites (e.g., androgen receptor antagonists, 5-α-reductase inhibitors, testosterone biosynthesis inhibitors, GnRH agonists, and aromatase inhibitors) interfering with negative feedback control, resulting in hyperfunctioning of the pituitary gland

and over-production of LH that leads to the proliferative changes (hyperplasia, adenoma) in Leydig cells.

Hypersecretion of hormones by nonendocrine tumors

Certain neoplasms of nonendocrine tissues in both animals and humans either secrete hormones or humoral substances that share chemical and/or biologic characteristics with the "native" hormones secreted by an endocrine gland. *Most of the recently discovered humoral substances secreted by nonendocrine tumors are peptides* rather than steroids, iodothyronines or catecholamines, which require more complex biosynthetic pathways. For example, **humoral hypercalcemia of malignancy (HHM, "pseudohyperparathyroidism")** is a clinical syndrome produced primarily by the autonomous hypersecretion of a new hormone, **parathyroid hormone-related peptide (PTH-rP)**, by cancer cells. PTH-rP is able to interact with the parathyroid hormone receptor in target cells (e.g., bone and kidney) and result in persistent, often life-threatening, hypercalcemia.

Humoral hypercalcemia of malignancy is associated with diverse malignant neoplasms in animal and human patients. Characteristic findings in patients with HHM include hypercalcemia, hypophosphatemia, hypercalciuria (often with decreased fractional calcium excretion), increased fractional excretion of phosphorus, increased nephrogenous cAMP, and increased osteoclastic bone resorption. *The direct effects of PTH-rP on bone and kidney, and indirect effects on the intestine produce hypercalcemia.* Increased osteoclastic bone resorption is a consistent finding in HHM with increased calcium release from bone. The kidney plays a critical role in the pathogenesis of hypercalcemia and hypophosphatemia, since renal calcium reabsorption is stimulated by PTH-rP and phosphorus reabsorption is inhibited due to binding to and activation of the renal PTH/PTH-rP receptors. PTH-rP binds to the N-terminal PTH/PTH-rP receptor in bone and kidney, but does not cross-react immunologically with native PTH. PTH-rP stimulates adenylate cyclase and increases intracellular calcium ion in bone and kidney cells by binding to and activating the cell membrane PTH/PTH-rP receptors. This results in stimulation of osteoclastic bone resorption, increased renal tubular calcium reabsorption, and decreased renal tubular phosphate reabsorption. In some forms of HHM, there are increased serum 1,25-dihydroxyvitamin D_3 levels that may increase calcium absorption from the intestine. Although excessive secretion of biologically active PTH-rP plays a central role in the pathogenesis of hypercalcemia in most forms of HHM cytokines such as interleukin-1, tumor necrosis factor-α, transforming growth factors, and 1,25-dihydroxyvitamin D_3 may have synergistic or cooperative actions with PTH-rP.

A well-characterized example of this disease mechanism in animals is the *adenocarcinoma derived from the apocrine glands of the anal sac in dogs.* Serum PTH levels are lower in dogs with apocrine carcinomas and hypercalcemia than in controls and PTH levels are undetectable in tumor tissue. The parathyroid glands are small and difficult to locate or not visible macroscopically in dogs with persistent cancer-associated hypercalcemia. Atrophic parathyroid glands are characterized by narrow cords of inactive chief cells with abundant fibrous connective tissue stroma and widened perivascular spaces. The inactive chief cells have markedly reduced cytoplasmic area, prominent hyperchromatic nuclei, relatively straight cell membranes with uncomplicated interdigitations, and are closely packed together. These morphologic findings indicate that the malignant neoplasms are not producing a substance that stimulates parathyroid hormone secretion by chief cells, but rather that the parathyroid glands are responding to persistent hypercalcemia by undergoing trophic atrophy. Thyroid parafollicular cells (C cells) often respond to the persistent elevation in blood calcium by undergoing diffuse or nodular hyperplasia.

Endocrine dysfunction due to failure of target cell response

Endocrine dysfunction due to a failure of target cell response has been recognized coincident with a more complete understanding of how hormones convey their biologic message. Steroid and iodothyronine hormones penetrate the cell membrane and are transported to the nucleus where they interact with the genetic information in the cell to increase new protein synthesis. Polypeptide and catecholamine hormones bind to receptors on the surface of target cells and activate a membrane-bound enzyme that generates one of several possible intracellular messengers (e.g., cAMP) which elicits the physiologic response. *Failure of target cells to respond to hormone may be due to a lack of adenylate cyclase in the cell membrane or to an alteration in hormone receptors on the cell surface.* Hormone is secreted in normal or increased amounts by cells of the endocrine gland.

Insulin resistance associated with obesity in both animals and humans can result from a decrease or "downregulation" of receptors on the surface of target cells. This develops in response to the chronic increased insulin secretion stimulated by the hyperglycemia that results from excessive food intake. Large pituitary neoplasms that extend dorsally out of the sella turcica destroy critical hypothalamic nuclei that regulate the intake of food. These animals often develop insulin-resistant hyperglycemia and glycosuria as a result of a downregulation of insulin receptors on target cells induced by the chronic excessive intake of food and hyperinsulinemia (Fig. 3.2). Secretory cells in the corresponding endocrine gland (i.e., pancreatic islets) undergo

compensatory hypertrophy and hyperplasia in an attempt to secrete additional hormone.

An interesting form of hypoparathyroidism has been reported in human patients in which the inability of target cells to respond is due to a defect in the cAMP-mediated signal transduction resulting from a lack of specific nucleotide regulatory protein in the cell membrane. Patients with "pseudohypoparathyroidism" develop hypocalcemia and hyperphosphatemia in spite of hyperplastic parathyroids and elevated blood levels of PTH. Similarly, animals and humans with nephrogenic diabetes have defects in the vasopressin receptor on cells of the distal nephron and collecting ducts in the kidney resulting in a lack of adenylate cyclase stimulation and generation of cyclic AMP after vasopressin binding to its receptor on target cells.

Failure of fetal endocrine function

Subnormal function of the fetal endocrine system, especially in ruminants, may disrupt normal fetal development and result in prolongation of the gestation period. In Guernsey and Jersey cattle, a genetically determined failure of development (aplasia) of the adenohypophysis results in a lack of fetal pituitary trophic hormone secretion during the last trimester and hypoplastic development of target endocrine organs (e.g., adrenal cortex, thyroid follicular cells, and gonads). Fetal development is normal up to approximately seven months gestation but subsequently fetal growth ceases irrespective of how long the viable fetus is retained in utero.

Prolongation of gestation also occurs in ewes that ingest the plant *Veratrum californicum* early in gestation. Toxins in the plant cause extensive malformations of the central nervous system (CNS) and hypothalamus in lambs. Although the adenohypophysis is present, it is unable to secrete normal amounts of trophic hormones (e.g., adrenocorticotropin (ACTH)) because it lacks the necessary fine control derived from the releasing hormones of the hypothalamus. Target endocrine organs in the fetus are hypoplastic and the adrenal cortex does not differentiate completely into the three distinctive zones that secrete corticosteroid hormones. The plant contains potent steroidal alkaloids that inhibit neural tube development when ingested by the ewe between days 9 and 14 of gestation. Cyclopia and extensive CNS malformations are found in lambs. Arrhinencephaly and lack of development of nasal bones accompany the formation of a proboscis-like structure. The lambs retained in the uterus continue to grow beyond the normal gestation period.

The concepts that have emerged from the study of these naturally occurring diseases are: *first*, fetal hormones are necessary for final growth and development in utero in certain animals; and *second*, normal parturition at term requires an intact fetal hypothalamic–adenohypophyseal–adrenal cortical axis in these species working in concert with trophoblasts of the placenta. Although the presence or absence of functional adenohypophyseal tissue determines whether the fetus continues to grow in utero, the pathogenesis of prolongation of the gestational interval is similar in these two examples. The subnormal development of the fetal adrenal cortex results in inadequate secretion of cortisol and failure to induce the 17-α-hydroxylase in the placenta that converts precursor molecules (e.g., progesterone) to estrogen. The fetal adrenal gland is small and there is incomplete development of the three distinct zones of the cortex (Fig. 3.3). The dam's circulating progesterone is maintained near mid-gestational concentrations, and there is a lack of the marked increase in estrogens that normally occurs near term and results in parturition by stimulating the local synthesis of prostaglandins in the uterus. This normally results in the smooth muscle contractions and biochemical changes in collagen along the birth canal that permit delivery of the fetus.

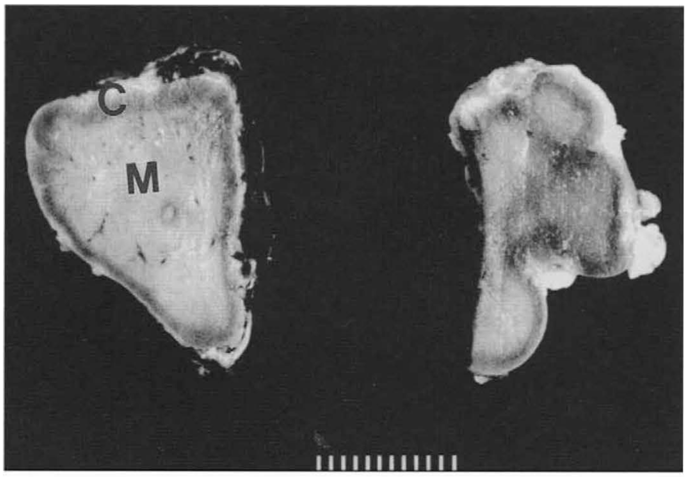

Figure 3.3 Failure of fetal endocrine function. **Adrenal cortical hypoplasia** in a calf with prolongation of the gestation period. The adrenal cortex (C) is markedly reduced in thickness and the adrenal medulla (M) is relatively more prominent. Scale in mm. (From Capen CC. Toxicol Pathol 2001;29:8–33.)

Endocrine dysfunction resulting from abnormal degradation of hormone

Increased degradation of hormone. The long-term administration of *various xenobiotics* (e.g., phenobarbital and others) results in the induction of liver enzymes (e.g., T_4–uridine diphosphate (UDP)-glucuronyl transferase) that increases the degradation of thyroxine, especially in laboratory rodents. Endocrine gland and target cell function are normal. The chronic disruption of the thyroid–pituitary axis and augmented TSH secretion in rodents, especially male rats, often increases the development of thyroid follicular cell tumors in chronic toxicity and oncogenicity studies with certain drugs and chemicals. Hepatic microsomal enzymes play an important role in thyroid hormone economy because glucuronidation is the rate-limiting step in the biliary excretion of T_4 and sulfation, primarily by phenol sulfotransferase for the excretion of T_3. Long-term exposure of rats to a wide variety of different chemicals induces these enzyme pathways and results in chronic stimulation of the thyroid by disrupting the hypothalamic–pituitary–thyroid axis. The resulting chronic stimulation of the thyroid by increased circulating levels of TSH in rats often results in a greater risk of developing tumors derived from follicular cells in chronic toxicity/carcinogenicity studies with these compounds (Fig. 3.4). The chronic administration of phenylbutazone, a nonhormonal antipyretic compound used in the medical management of inflammatory conditions of the musculoskeletal system, especially in horses, which is a hepatic microsomal enzyme inducer, often results in moderate thyroid enlargement by a similar mechanism described above.

Decreased degradation of hormone. The rate of secretion of hormone by an endocrine gland may be normal with this mechanism,

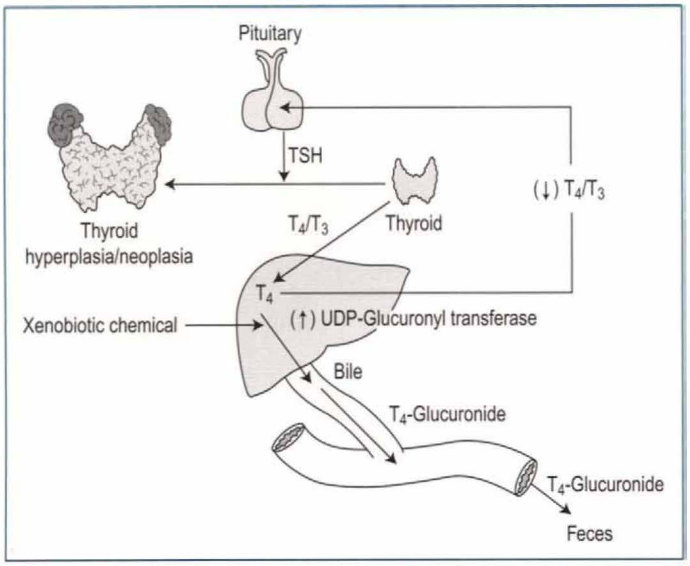

Figure 3.4 Hepatic microsomal enzyme induction by the chronic administration of xenobiotics in rodents leading to thyroid follicular cell hyperplasia and neoplasia in chronic studies with large doses of compound. (From Capen CC. Toxicol Pathol 2001;29:8–33.)

but blood hormone levels are persistently elevated, thereby simulating a syndrome of hypersecretion, due to a decreased rate of hormone degradation. The classic example of this pathogenic mechanism is the syndrome of feminization due to hyperestrogenism associated with cirrhosis and decreased hepatic degradation of estrogens. Chronic renal disease in dogs occasionally is associated with persistent hypercalcemia due, in part, to decreased degradation of PTH (along with decreased urinary excretion of calcium) by the diseased kidney.

Syndromes of iatrogenic hormone excess

Direct effects. The administration of hormone, either directly or indirectly, influences the activity of target cells with this mechanism and results in important functional disturbances. It is well recognized that the administration of potent preparations of adrenal cortical steroids at inappropriately high daily doses for prolonged intervals in the symptomatic treatment of various diseases can produce most of the functional disturbances associated with endogenous hypersecretion of cortisol. Similarly, the administration of excessively large doses of insulin can result in hypoglycemia, and an excess of exogenous T_4 or T_3 may result in hyperthyroidism, especially in certain species (e.g., cats) that have limited capacity to conjugate T_4 with glucuronic acid and enhance biliary excretion.

Indirect effects. *The administration of progestins to dogs indirectly results in a syndrome of growth hormone excess.* The injection of medroxyprogesterone acetate for the prevention of estrus in dogs appears to stimulate expression of the growth hormone gene in the mammary gland leading to an elevation in circulating growth hormone levels, and results in the classic clinical manifestations and lesions of acromegaly (e.g., excessive skin folds, respiratory stridor due to increased soft tissue in oropharyngeal region, expansion of interdental spaces, and hyperglycemia) (see Fig. 3.20).

It was assumed initially that the reversibly elevated circulating levels of growth hormone (GH) in response to the administration of synthetic progestins in dogs were from direct stimulation of somatotrophs in the pituitary gland; however, somatotroph hyperplasia or adenomas have not been found in the adenohypophysis of progestin-treated dogs. The elevated GH levels were associated with progressively increasing circulating concentrations of insulin-like growth factor (IGF) and insulin. The progestin-induced excessive GH secretion in dogs was characterized by disappearance of the pulsatile secretion pattern and insensitivity to stimulation of GH secretion by both growth hormone-releasing hormone and clonidine, as well as inhibition of GH release with a somatostatin analog. The stimulation of growth hormone release in dogs by progestins differs from the situation in humans in whom high prolactin levels result from treatment with these drugs.

Transphenoidal hypophysectomy 4–6 weeks after the last progestin injection in dogs with markedly elevated plasma GH concentrations did not change the circulating levels of GH. Subsequent removal of all mammary tissue in the progestin-treated dogs resulted in a rapid decline of plasma GH concentrations to values in the reference range. Measurement of GH immunoreactivity in tissue homogenates from progestin-administered dogs revealed the highest GH content was present in normal and neoplastic mammary tissue. Immunohistochemical evaluation further confirmed the mammary gland as the source of the excessive GH production. In the dogs treated with progestins, GH immunoreactivity was present in the cytoplasm of both normal active ductal epithelial cells and benign neoplasms derived from mammary ductal epithelium. There was no GH immunoreactivity in the stroma or in mammary tissue from control dogs. Interestingly, progestins therapy has been used successfully to treat dogs with juvenile-onset panhypopituitarism and dwarfism due to failure of development of the adenohypophysis and severe GH deficiency.

PITUITARY GLAND

Although the pituitary gland is derived from the oropharyngeal ectoderm, it is completely separated from the oral cavity in adult animals. It is situated in the sella turcica, a concavity of the sphenoid bone, and enveloped by an extension of dura mater. The pituitary gland (hypophysis) is subdivided anatomically into the **adenohypophysis** and **neurohypophysis**.

Development, structure, and function

Embryologic development of the pituitary gland

The pituitary gland develops embryologically from a dorsal evagination of oropharyngeal ectoderm (Rathke's pouch) (Fig. 3.5) and a ventral downgrowth of diencephalic neuroectoderm, as shown schematically in the diagram. The point of fusion of the two primordia develops into the pars intermedia. The pars distalis undergoes extensive proliferation to form the major part of the adenohypophysis and is responsible for the secretion of the multiple trophic hormones.

The pituitary gland has two preformed cavities, the residual lumen of Rathke's pouch (cleft) and the infundibular recess of the third ventricle (central cavity). Separation of the developing adenohypophysis from the oropharynx is completed by formation of the sphenoid bone.

Structure of the adenohypophysis

The adenohypophysis consists of three portions, the *pars distalis, pars tuberalis, and pars intermedia*. In many species, the adenohypophysis

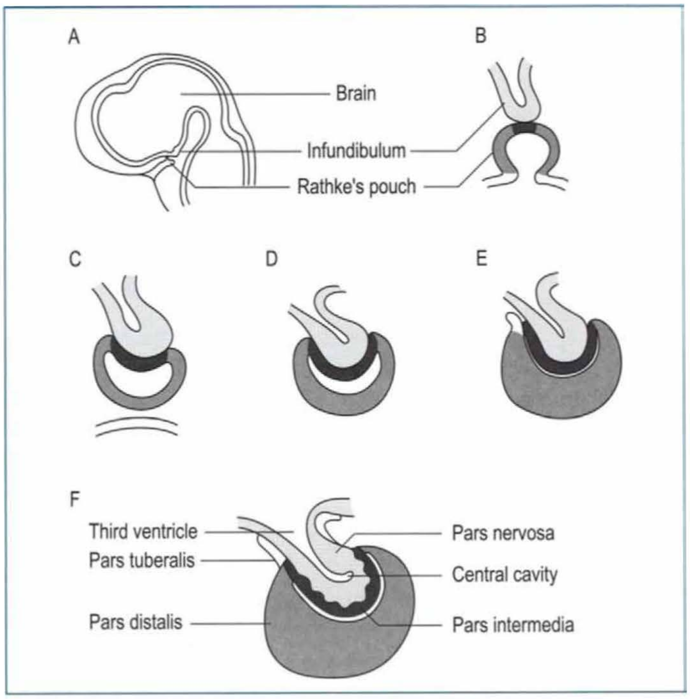

Figure 3.5 Embryologic development of the **pituitary gland**. (From Turner CD, Bagnara JT. In: General Endocrinology, 1971.)

completely surrounds the **pars nervosa** of the neurohypophyseal system.

- The **pars distalis** is the largest of the three parts of the adenohypophysis and contains the multiple populations of endocrine cells that secrete the different pituitary trophic hormones. The secretory cells are supplied with abundant capillaries that have fenestrae in their peripheral cytoplasmic extensions and are supported by the cytoplasmic processes of stellate (follicular or sustentacular) cells.
- The **pars tuberalis** consists of dorsal projections of cells along the infundibular stalk. It functions primarily as a scaffold for the capillary network of the hypophyseal portal system during its course from the median eminence to the pars distalis.
- The **pars intermedia** forms the junction between the pars distalis and pars nervosa. It lines the residual lumen of Rathke's pouch and contains two populations of cells. In the dog, one of these cell types synthesizes and secretes adrenocorticotropic hormone (ACTH), similar to corticotrophs in the pars distalis.

Functional cytology of the adenohypophysis

A specific population of endocrine cells is present in the pars distalis (and in the pars intermedia of dogs for ACTH) that synthesize and secrete each of the pituitary trophic hormones. Secretory cells in the adenohypophysis are subdivided into *acidophils, basophils, and chromophobes* based on the staining of their secretory granules with pH-dependent histochemical stains.

- **Acidophils** are further subdivided functionally into *somatotrophs* that secrete growth hormone (GH, somatotropin) and and *luteotrophs* that secrete uteotrophic hormone (LTH, prolactin). Their granules contain hormones that are simple proteins that stain with orange G, azocarmine or erythrosin.
- **Basophils** include both *gonadotrophs* that secrete luteinizing hormone (LH) and follicle stimulating hormone (FSH), and *thyrotrophs* that secrete thyrotrophic hormone (TSH). Secretory granules of basophils contain glycoproteins that react with the periodic acid-Schiff reagent.
- **Chromophobes** are pituitary cells that do not have obvious cytoplasmic secretory granules on light microscopic evaluation. They include the pituitary cells concerned with the synthesis of ACTH and melanocyte-stimulating hormone (MSH), nonsecretory follicular (stellate) cells, degranulated chromophils (acidophils and basophils) in the actively synthesizing phase of the secretory cycle, and undifferentiated stem embryonic cells of the adenohypophysis.

Specific immunocytochemical staining of the adenohypophysis in dogs has demonstrated that ACTH- and MSH-staining cells are polyhedral to round, sparsely granulated, and most numerous in the ventrocentral and rostral portions of the pars distalis. They are less frequent in the dorsal and caudal regions of the pars distalis and throughout the pars tuberalis. In the pars intermedia of dogs, most cells demonstrate immunoreactivity to either ACTH, or α-MSH.

Thyrotrophs are large polyhedral cells situated singly or in small groups ventrocentrally in the paramedian plane in the pars distalis of dogs. Gonadotrophs (cells reacting with antisera to human FSH and/or bovine LH) are oval to polyhedral and distributed singly in the pars distalis, particularly in the dorsocranial region and in the caudal extensions along the pars intermedia.

Immunoreactive prolactin cells occur in small groups of large polygonal cells with prominent granules in the ventrocentral and cranial portions of the canine pars distalis. A diffuse increase in this population of cells occurs in females near parturition. Growth hormone-secreting cells are present singly along capillaries in the dorsal region of the pars distalis near the pars intermedia. They are small, round to oval, and have numerous cytoplasmic granules. Somatotrophs frequently undergo diffuse hyperplasia and hypertrophy in old dogs, especially females with mammary dysplasia or neoplasia.

Hypothalamic control of the adenohypophysis

Each population of endocrine cells in the pars distalis is under the control of a corresponding releasing hormone from the hypothalamus (Fig. 3.6). These **releasing hormones** are small peptides synthesized via

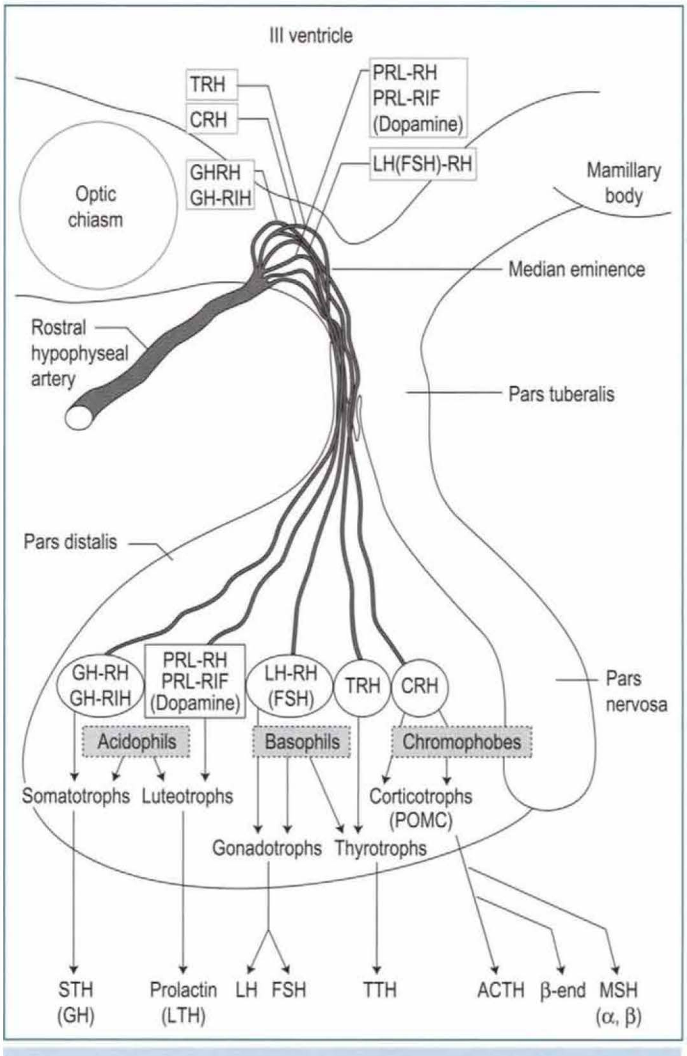

Figure 3.6 Separate **hypothalamic releasing hormones or factors** control the secretion of each trophic hormone by the adenohypophysis. Trophic hormones that do not act on a target endocrine organ to release a final endocrine product (e.g., somatotrophin and prolactin) also are regulated by a hypothalamic release inhibiting hormone (RIH) or factor (e.g., dopamine for prolactin).

neurosecretion by neurons in the hypothalamus. Axonal processes transport them to the median eminence where they are released into capillaries and conveyed by the hypophyseal portal system to specific endocrine cells in the adenohypophysis, where each stimulates the rapid release of secretory granules containing a specific preformed trophic hormone.

There are separate hypothalamic releasing hormones that regulate the rate of secretion of each trophic hormone secreted by the adenohypophysis. *For most pituitary trophic hormones,* **negative feedback control** *is accomplished by the blood concentration of the hormone produced by the target endocrine gland,* e.g., thyroid gland, adrenal cortex, ovary, or testis. The hormone produced by the endocrine glands exerts negative feedback control either on the neurosecretory neurons in the hypothalamus that synthesize the corresponding releasing hormone or on trophic hormone-secreting cells in the adenohypophysis or at both sites. However, GH, LTH, and MSH do not act on target endocrine organs to stimulate secretion of a hormone. *Negative feedback control of these three pituitary hormones is effected by production of a corresponding* **release-inhibiting hormone** *("factor") by neurons in the hypothalamus.* The relative local concentrations of the specific releasing hormone and release-inhibiting hormone appear to govern the rate of release of GH, LTH and MSH from the adenohypophysis. Growth hormone-release inhibiting hormone ("*somatostatin*"), which controls the release of somatotropin, also is produced by endocrine cells in the pancreatic islets. Dopamine is the principal release-inhibiting hormone for prolactin.

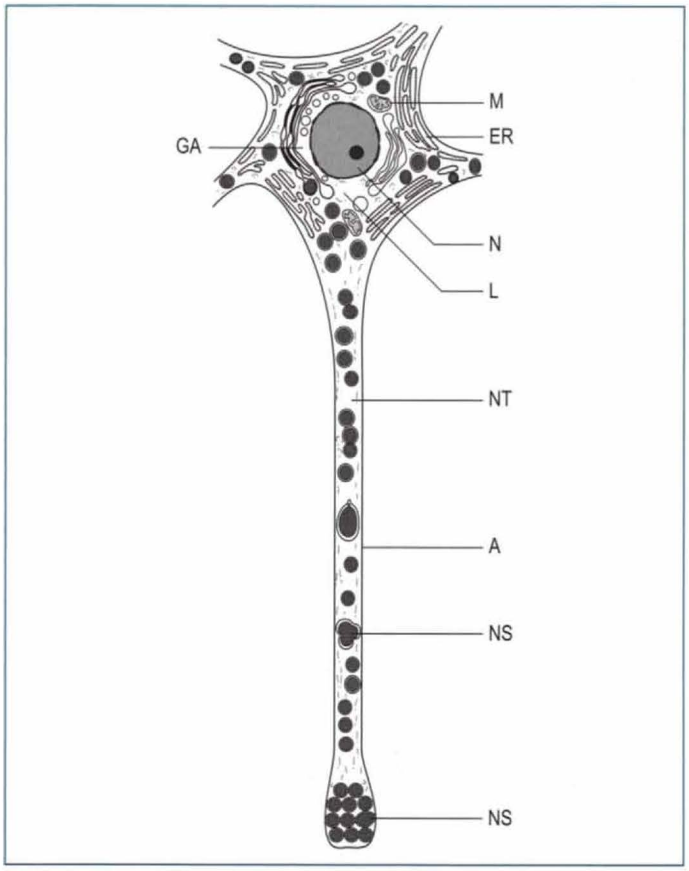

Figure 3.7 Structural characteristics of a **neurosecretory neuron**. Nerve cell body (N, nucleus) has dendritic and axonal (A) processes, arrays of rough endoplasmic reticulum (ER), a prominent Golgi apparatus (GA), and large mitochondria (M). Hormone-containing, membrane-limited neurosecretory granules (NS) are transported along axon to site of release in the pars nervosa. NT = neural tubules, L = lysosomes.

Structure and function of the neurohypophysis

The **neurohypophysis** has three anatomic subdivisions. The **pars nervosa** represents the distal component of the neurohypophyseal system. It is composed of numerous capillaries that are supported by modified glial cells (*pituicytes*). The capillaries in the pars nervosa are termination sites for the nonmyelinated axonal processes of neurosecretory neurons in the hypothalamus. Secretion granules that contain the neurohypophyseal hormones, *oxytocin* and *antidiuretic hormone*, are synthesized in **hypothalamic neurons** but are released into the bloodstream in the pars nervosa. The **infundibular stalk** joins the pars nervosa to the overlying hypothalamus and is composed of nonmyelinated axonal processes from neurosecretory neurons.

Neurosecretory neurons in the hypothalamus receive neural input from higher centers and translate this into endocrine output in the form of hormonal secretion. In addition to the usual structural features of neurons, they contain prominent lamellar arrays of rough endoplasmic reticulum, large Golgi apparatuses, and numerous membrane-limited neurosecretory granules in the cell body and axonal process (Fig. 3.7).

The neurosecretory neurons concerned with hormone synthesis are segregated into anatomically defined regions, termed *nuclei*, in the hypothalamus. The **supraoptic nucleus** is concerned primarily with the synthesis of antidiuretic hormone, whereas oxytocin is produced predominantly by neurons in the **paraventricular nucleus**.

Antidiuretic hormone and oxytocin are nonapeptides synthesized by neurons situated in either the supraoptic or the paraventricular nucleus. Antidiuretic hormone and its corresponding neurophysin appear to be synthesized as part of a common larger biosynthetic precursor molecule, termed propressophysin. The hormones are packaged into membrane-limited neurosecretory granules with a corresponding transport protein (*neurophysin*) and transported to the pars nervosa by axonal processes of the neurosecretory neurons. These axons terminate on fenestrated capillaries in the pars nervosa and release ADH or oxytocin into the circulation.

Antidiuretic hormone is transported by the bloodstream to its site of action in the kidney, where it binds to specific receptors on epithelial cells in the distal part of the nephron and collecting ducts. The overall effect of ADH on the kidney is to increase the active renal tubular reabsorption of water from the glomerular filtrate. The hormone (ADH)–receptor complex activates the membrane-bound enzyme, adenylate cyclase, resulting in the intracellular formation of cyclic adenosine monophosphate (cAMP) from ATP. The intracellular accumulation of cAMP activates protein kinases involved in the phosphorylation of proteins in the luminal membrane of distal tubular cells that increase their permeability to water.

Blood supply to the pituitary gland

The neurohypophysis in most animals is supplied directly by the caudal hypophyseal arteries that branch from the internal carotid arteries. Branches of the rostral hypophyseal arteries originate from the internal carotid arteries and form the caudal communicating arteries of the circle of Willis. Arteriolar branches penetrate the pars tuberalis, lose their muscular coat, and form a capillary plexus near the median eminence. These vessels subsequently drain into **hypophyseal portal veins** that supply the pars distalis and transport the hypothalamic releasing hormones to the pituitary. A small artery that arises from the caudal hypophyseal artery may provide a minor blood supply to the adenohypophysis.

Diseases of the pituitary gland

Hypophyseal changes associated with alterations in target organs

In response to surgical removal or disease processes in a target endocrine organ of the pituitary, there is a progressive decline in the circulating concentration of hormone produced by the target organ. This reduction in circulating hormone level is detected by the hypothalamic–adenohypophyseal system and results in structural changes in the specific trophic hormone-secreting cell population in the pars distalis.

The initial reaction is rapid release of storage granules containing preformed trophic hormone from one population of endocrine cells in the pars distalis. For example, only thyrotrophic basophils degranulate following thyroidectomy or thyroid disease, corticotrophic chromophobes degranulate after adrenalectomy, and gonadotrophic basophils release their secretory granules in response to gonadectomy. After an interval of several days following surgical ablation or extensive destruction of a target endocrine organ, the corresponding degranulated trophic hormone-secreting cell in the pars distalis undergoes hypertrophy with expansion of the cytoplasmic area in response to the sustained increased demand for the particular trophic hormone. The abundant cytoplasm contains extensive organelles concerned with hormonal synthesis (rough endoplasmic reticulum) and packaging into secretory granules (Golgi apparatus) plus large mitochondria.

If the demand for trophic hormone secretion is sustained for days or weeks, one specific population of endocrine cells in the pars distalis undergoes hyperplasia. Groups of hyperplastic trophic hormone-secreting cells are present, scattered as small nests throughout an otherwise normal pars distalis. In response to long-term (weeks to months) stimulation, the hypertrophied cytoplasm of the cells becomes vacuolated due to the extensive distention of profiles of rough endoplasmic reticulum with finely granular, moderately electron-dense material. The multiple small cytoplasmic vacuoles coalesce subsequently to form a large vacuole that may displace the nucleus eccentrically, characteristic of cells in the pituitary gland that degranulate following thyroidectomy, adrenalectomy, or gonadectomy.

Pituitary cysts

Cysts derived from distal ("sellar") end of the craniopharyngeal duct

Cysts may develop from remnants of the distal craniopharyngeal duct, which normally disappears by birth in most animal species. The cysts are lined by cuboidal to columnar, often ciliated, epithelium and contain mucin. In dogs, especially of the brachycephalic breeds, *cysts from these remnants are often found at the periphery of the pars tuberalis and pars distalis*. Cystic remnants of the craniopharyngeal duct in one survey were found in 53% of dogs of several breeds.

Craniopharyngeal duct cysts occasionally become large enough to exert pressure on the infundibular stalk and hypophyseal portal system, median eminence, or pars distalis. Structures adjacent to the cysts atrophy to varying degrees owing to compression and interference with the blood supply. Disruption of a large cyst with escape of the proteinaceous contents into adjacent tissues may incite intense, local inflammation with subsequent fibrosis that may interfere with pituitary function. Clinical signs can include visual difficulties due to pressure on the optic chiasm, diabetes insipidus, obesity, and hypofunction of the adenohypophysis leading to gonadal atrophy, decreased basal metabolic rate, and hypoglycemia.

Cysts derived from proximal end of craniopharyngeal duct (pharyngeal hypophysis)

The proximal portion of the adenohypophyseal anlage may persist in the dorsal aspect of the oral cavity in adults as undifferentiated remnants of cells along the craniopharyngeal canal or as differentiated cells similar to those of the definitive adenohypophysis. These remnants, called the **pharyngeal hypophysis**, have been described in dogs, cats, other animal species, and humans. The pharyngeal hypophysis is physically separated from the sellar adenohypophysis in dogs, but in cats these structures may be continuous due to persistence of the craniopharyngeal canal.

The pharyngeal hypophysis is seen most often in brachycephalic breeds of dogs. It is a tubular structure lined by ciliated columnar epithelium, located on the midline of the nasopharynx, and is frequently continuous with a multilocular cyst that is lined by ciliated cuboidal or columnar epithelium. The cyst contains colloid material and cellular debris. A mass of differentiated acidophilic, basophilic, and chromophobic cells, similar to those of the sellar adenohypophysis, usually extends from the cyst wall.

Cysts (up to several centimeters in diameter) may be derived from the oropharyngeal end of the craniopharyngeal duct and project as a space-occupying mass into the nasopharynx in dogs. The predominant clinical sign may be related to respiratory distress due to ventral displacement of the soft palate and occlusion of the caudal nares. The cyst wall may be hard on palpation due to the presence of partially mineralized woven bone. The contents of the cyst are often yellow-gray and caseous due to the accumulation of keratin and desquamated epithelial cells from the cyst lining. The squamous epithelial lining of the cyst is derived from metaplasia of the remnants of the primitive oropharyngeal epithelium.

Cysts resulting from failure of differentiation of oropharyngeal ectoderm of Rathke's pouch

Pituitary dwarfism in dogs usually is associated with a failure of the oropharyngeal ectoderm of Rathke's pouch to differentiate into trophic hormone-secreting cells of the pars distalis. This results in a progressively enlarging, multiloculated cyst in the sella turcica and absence of an adenohypophysis. The cyst is lined by pseudostratified, often ciliated, columnar epithelium with interspersed mucin-secreting goblet cells. The mucin-filled cysts eventually occupy the entire pituitary area in the sella turcica and severely compress the pars nervosa and infundibular stalk (Fig. 3.8A, B). Few differentiated, trophic hormone-secreting chromophils are present in the pituitary region that immunocytochemically stain for the

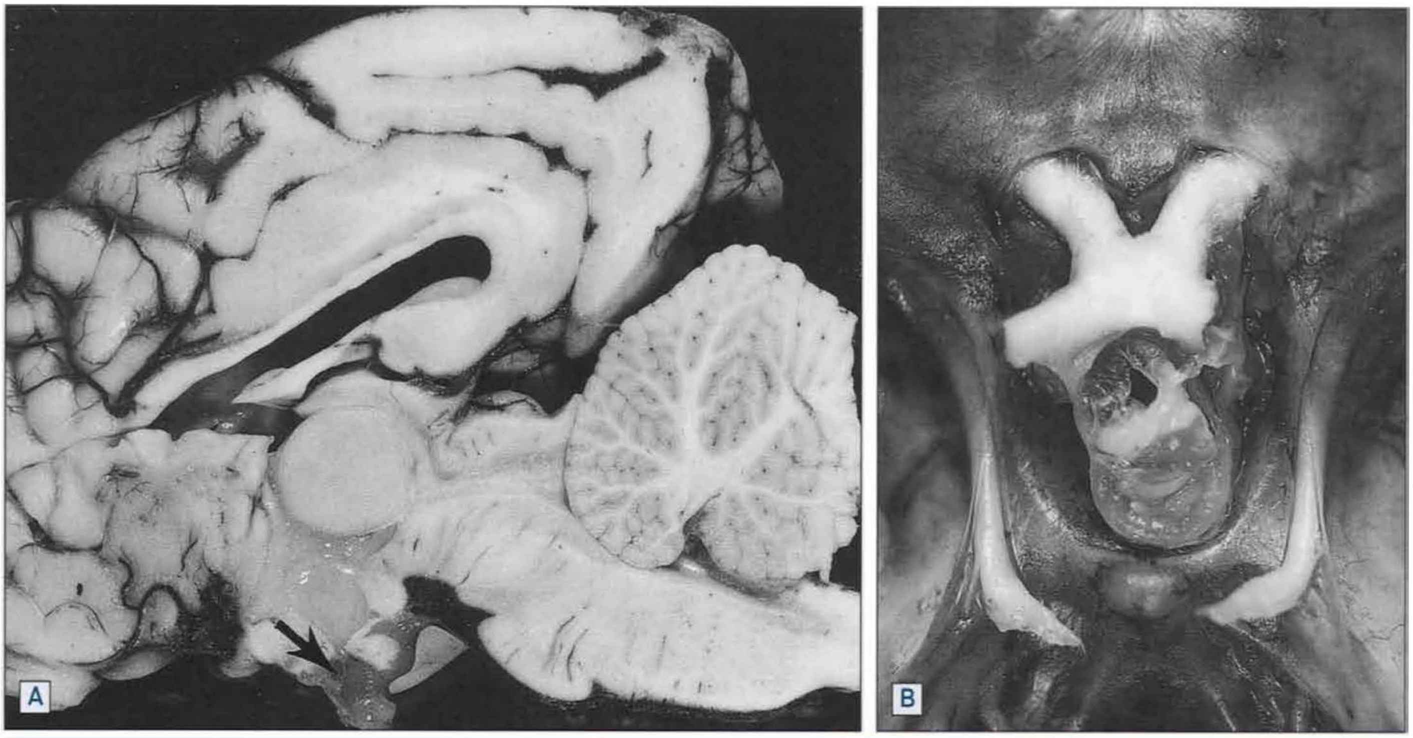

Figure 3.8 Failure of oropharyngeal ectoderm to differentiate into trophic hormone-secreting cells of the adenohypophysis in a German Shepherd Dog with **dwarfism**. **A.** Sagittal section. Pars nervosa compressed by mucin-filled cyst (arrow). **B.** Dorsal view of cyst.

specific trophic hormones. An occasional small nest or rosette of poorly differentiated epithelial cells is interspersed between the multiloculated cysts, but the cytoplasm of these cells is usually devoid of hormone-containing secretory granules.

Juvenile panhypopituitarism occurs most frequently in German Shepherd Dogs, but it has also been reported in other breeds such as the Spitz, Toy Pinscher, and Carelian Bear Dogs from Denmark. The dwarf pups appear normal or are indistinguishable from littermates at birth and until ~2 months of age. Subsequently the slower growth rate than the littermates, retention of puppy hair, and lack of primary guard hairs gradually become evident in dwarf pups. German Shepherd Dogs with pituitary dwarfism appear coyote- or fox-like due to their small size and soft woolly coat (Fig. 3.9). Bilaterally symmetrical alopecia develops gradually and often progresses to complete alopecia except for the head and tufts of hair on the legs. There is progressive hyperpigmentation of the skin until it is uniformly brown-black over most of the body. Adult German Shepherd Dogs with panhypopituitarism vary in size from as small as 2 kg up to nearly half normal size, depending upon whether the failure of formation of the adenohypophysis is nearly complete or only partial.

Permanent dentition is delayed or completely absent. Closure of epiphyses is delayed as long as 4 years, depending on the severity of hormonal insufficiency. There are few trabeculae in the primary and secondary spongiosa of the metaphysis of long bones, and osteoblasts are decreased in dwarf pups when compared with normal littermates. The external genitalia usually remain infantile. The testes and penis are small, mineralization of the os penis is delayed or incomplete, and the penile sheath is flaccid. In females the ovarian cortex is hypoplastic and estrus irregular or absent.

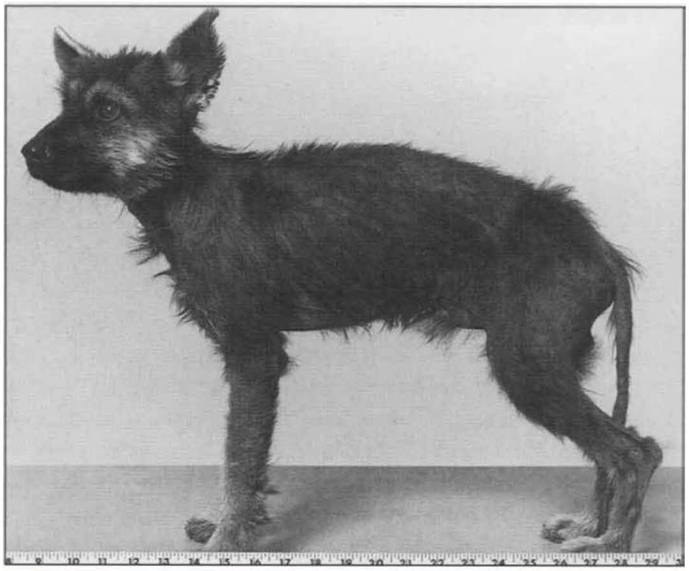

Figure 3.9 Panhypopituitarism ("pituitary dwarfism") in a 1-year-old German Shepherd Dog.

The shortened lifespan in dogs with pituitary dwarfism results not only from the panhypopituitarism but also from the resulting secondary endocrine dysfunction, such as hypothyroidism and hypoadrenocorticism. The increase in blood thyroxine and cortisol levels in response to challenge by exogenous TSH and ACTH are subnormal, owing to hypoplasia of thyroid follicular cells and the zonae fasciculata and reticularis of the adrenal cortex. The variation in severity and onset of the lesions in pituitary dwarfism appears to be related to the degree of penetrance of the defect. The degree to which the oropharyngeal epithelium fails to differentiate is variable as is the rapidity with which the mucin-filled cysts enlarge and exert pressure on adjacent structures.

Cutaneous lesions include hyperkeratosis, follicular keratosis, hyperpigmentation, adnexal atrophy and loss of elastin fibers, and the loose network of collagen fibers in the dermis. Hair shafts are absent and hair follicles are primarily in the telogen (resting) phase of the growth cycle.

Panhypopituitarism in German Shepherd Dogs often occurs in littermates and related litters, *suggesting a simple autosomal recessive mode of inheritance.* The activity of **somatomedin** (IGF-1) (a cartilage growth-promoting peptide whose production in the liver and plasma activity is controlled by somatotropin) is low in dwarf dogs. Intermediate somatomedin activity is present in phenotypically normal ancestors suspected to be heterozygous carriers. Useful diagnostic aids for pituitary dwarfs include comparison of height with littermates, radiographs of open epiphyseal lines, thyroid function tests, and skin biopsy.

Assays for somatomedin (a non-species-specific, somatotropin-dependent peptide) provide an indirect measurement of circulating growth hormone activity in dogs suspected to be heterozygous carriers. Basal levels of circulating canine growth hormone are detectable but low (normal range: 1.75 ± 0.17 μg/L) in pituitary dwarfs and fail to increase following a provocative test for growth hormone secretion provided by clonidine injection as in normal dogs. Insulin hypersensitivity has been demonstrated in pituitary dwarf dogs, most likely due to a change in insulin receptor numbers or affinity of binding in response to the low growth hormone levels. Dwarf dogs develop more profound hypoglycemia following an insulin injection than do normal dogs. Their response is similar to that in experimentally hypophysectomized dogs.

Cysts associated with pituitary dwarfism morphologically are distinct from the cysts that develop following the abnormal accumulation of colloid in the residual lumen of Rathke's pouch. The normally developed pars distalis and pars nervosa are compressed to various degrees by the abnormal accumulation of colloid in a normal cavity of the pituitary.

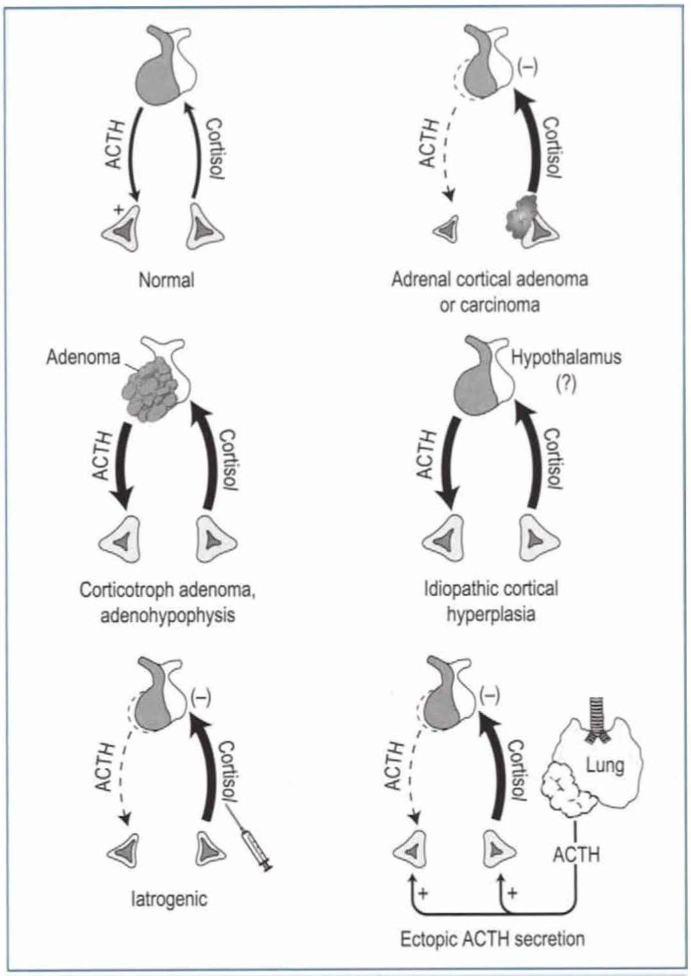

Figure 3.10 Multiple pathogenic mechanisms of **cortisol-excess** in dogs.

Neoplastic diseases of the pituitary

Corticotroph (ACTH-secreting) adenoma of the adenohypophysis

Functional tumors arising in the pituitary gland may be derived from corticotroph (ACTH-secreting) cells in either the pars distalis or the pars intermedia of dogs. *They are the most common cause the clinical syndrome of cortisol excess* **(Cushing's disease)** in dogs (Fig. 3.10). These neoplasms are encountered most frequently in dogs and infrequently in other animal species. Corticotroph adenomas develop in adult-to-aged dogs and have been reported in a number of breeds. Boxers, Boston Terriers, and Dachshunds appear to have a higher incidence of ACTH-secreting pituitary tumors than other breeds. *The spectrum of clinical manifestations and lesions that develop is primarily the result of long-term overproduction of cortisol by hyperplastic adrenal cortices.* These changes are the result of the combined gluconeogenic, lipolytic, protein catabolic, and anti-inflammatory actions of glucocorticoid hormones on many organ systems of the body. In horses pituitary tumors arise almost exclusively from the pars intermedia and are associated with dramatic clinical signs due primarily to space-occupying effects on the hypothalamus and other parts of the pituitary gland.

The pituitary gland is consistently enlarged in dogs with corticotroph adenomas (Fig. 3.11). Neither the occurrence nor the severity of functional disturbances appears to be directly related to the size of the neoplasm. Small corticotroph adenomas are as likely to be endocrinologically active as are larger neoplasms. The larger adenomas are often firmly attached to the base of the sella turcica but without evidence of erosion of the sphenoid bone. In the dog, the diaphragma sellae is incomplete. Therefore, the line of least resistance favors dorsal expansion of the gradually enlarging pituitary mass and invagination into the infundibular cavity, dilation of the infundibular recess and the third ventricle, with eventual compression or replacement of the hypothalamus, and possible extension of the tumor into the thalamus.

Dorsal expansion of larger corticotroph adenomas results in either a broadbased indentation and compression of the overlying hypothalamus, or extension into and replacement of the parenchyma of the hypothalamus and occasionally the thalamus. In the larger neoplasms, there are often focal areas of hemorrhage, necrosis, mineralization, and liquefaction. Growth of the pituitary tumor along the basilar aspects of the brain may result in incorporation of the

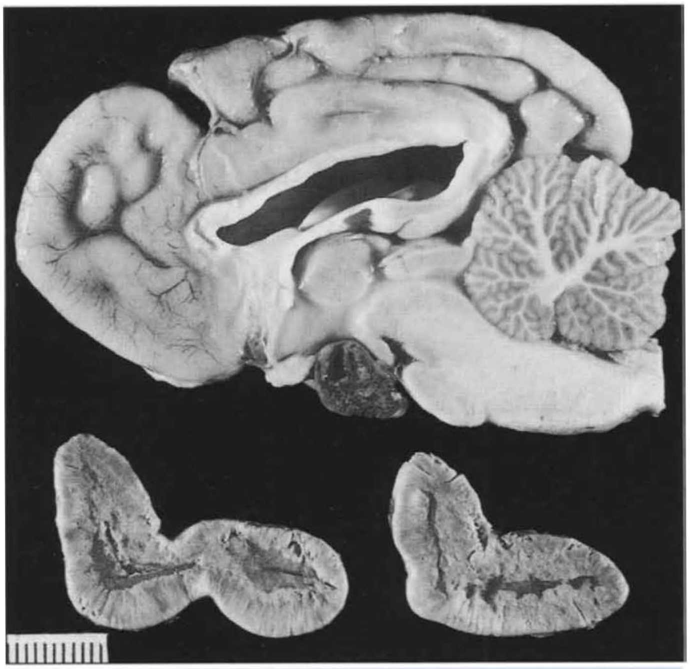

Figure 3.11 Corticotroph (ACTH-secreting) chromophobe adenoma of the pituitary with bilateral adrenal cortical hyperplasia, dog. Scale in mm.

second, third, and fourth cranial nerves, leading to disturbances of their function.

Bilateral enlargement of the adrenal glands occurs in dogs with functional corticotroph adenomas (Fig. 3.11). This enlargement often is striking and is due to increased cortical parenchyma, primarily in the zonae fasciculata and reticularis. Nodules of yellow-orange cortical tissue often are found outside the capsule in the periadrenal fat, as well as extending down into the adrenal medulla. The corticomedullary junction is irregular and the medulla is compressed.

Pituitary corticotroph adenomas are composed of well-differentiated, large or small, chromophobic cells supported by fine connective tissue septa. They can be divided into *sinusoidal* and *diffuse types* on the basis of the predominant pattern of cellular architecture. The cytoplasm of the tumor cells usually is devoid of secretory granules detectable by routine histochemical procedures used for pituitary cytology. However, pituitary corticotroph adenomas arising in both the pars distalis and the pars intermedia associated with the syndrome of cortisol excess in dogs are composed of polyhedral cells that immunocytochemically stain selectively for ACTH and MSH. *Nodules of focal hyperplasia* and microadenomas, composed of similar ACTH/MSH cells, often are present in the adenohypophysis of older dogs.

Pituitary adenomas arising in both the pars distalis and pars intermedia of dogs have positive immunocytochemical staining for ACTH, β-lipotrophin, and β-endorphin. Immunocytochemical studies have demonstrated that ACTH- and MSH-staining cells are polyhedral to round, sparsely granulated, and most numerous in the ventrocentral and cranial portions of the pars distalis in normal dogs. Corticotrophs are less numerous in the dorsal and caudal regions of the pars distalis and throughout the pars tuberalis.

Although remnants of the pars distalis can be identified near the periphery of corticotroph adenomas, the demarcation between the neoplasm and pars distalis often is not distinct. The pars distalis either is partly replaced by the neoplasm or severely compressed. The pars nervosa and infundibular stalk either are infiltrated and disrupted by tumor cells or completely incorporated within the larger neoplasms.

Cells constituting functional corticotroph adenomas have definite ultrastructural evidence of synthetic and secretory activity. Organelles concerned with protein synthesis (endoplasmic reticulum) and packaging of secretory products (Golgi apparatus) are well developed in tumor cells. *Hormone-containing secretory granules can be demonstrated by electron microscopy in functional corticotroph adenomas of dogs.* This is in contrast to the absence of demonstrable secretory granules within neoplastic cells observed with light microscopy. The granules vary in number from cell to cell, are spherical, and are surrounded by a delicate limiting membrane. They are small (mean diameter, 170 nm), electron-dense, often situated peripherally in the cell, and may have a prominent submembranous space.

A number of distinctive clinical and functional alterations develop in dogs with corticotroph (ACTH-secreting) adenomas, resulting in the **syndrome of hyperadrenocorticism** (*hypercortisolism*). Centripetal redistribution of adipose tissue leads to prominent fat pads on the dorsal midline of the neck, giving the neck and shoulders a thick appearance. Appetite and intake of food often are increased, either as a direct result of the hypercortisolism or involvement of hypothalamic appetite control centers by a large pituitary tumor. The muscles of the extremities and abdomen are weakened and atrophied. The loss of abdominal muscles and muscles of the appendicular skeleton results in gradual abdominal enlargement ("pot belly"), lordosis, muscle trembling, and a straight-legged skeletal-braced posture in order to support the body's weight. Profound atrophy of the temporal muscles may result in concave indentations and readily palpable prominences of underlying skull bones. Hepatomegaly due to increased fat and glycogen deposition plus vacuolation of hepatocytes produces a distended, often pendulous, abdomen. Functional alterations of the skin, muscle, lung and other tissues are the direct effects of elevated blood cortisol levels. They also are similar to those resulting from a primary cortisol-secreting adrenal cortical tumor and will be described elsewhere in this chapter.

Adenoma of the pars intermedia

Adenomas derived from cells of the pars intermedia are *the most common type of pituitary tumor in horses*, the second most common type in dogs, and rare in other species. They develop frequently in older horses, with females affected more frequently than males. Nonbrachycephalic breeds of dogs develop adenomas in the pars intermedia more often than brachycephalic breeds.

Adenomas of the pars intermedia in dogs result in only moderate enlargement of the pituitary gland. The pars distalis is readily identifiable and sharply demarcated from the rostral margin of the neoplasm. The tumor may extend across the residual hypophyseal lumen and result in compression atrophy, but usually does not invade the parenchyma of the pars distalis (Fig. 3.12A). The neurohypophysis is incorporated within the tumor, but the infundibular stalk is intact. Degenerative changes within the neoplasm are minimal.

Adenomas of the pars intermedia in dogs appear to arise from the lining epithelium of the residual hypophyseal lumen covering the pars nervosa. They often are relatively small and more strictly localized than corticotroph adenomas arising in the pars distalis of dogs.

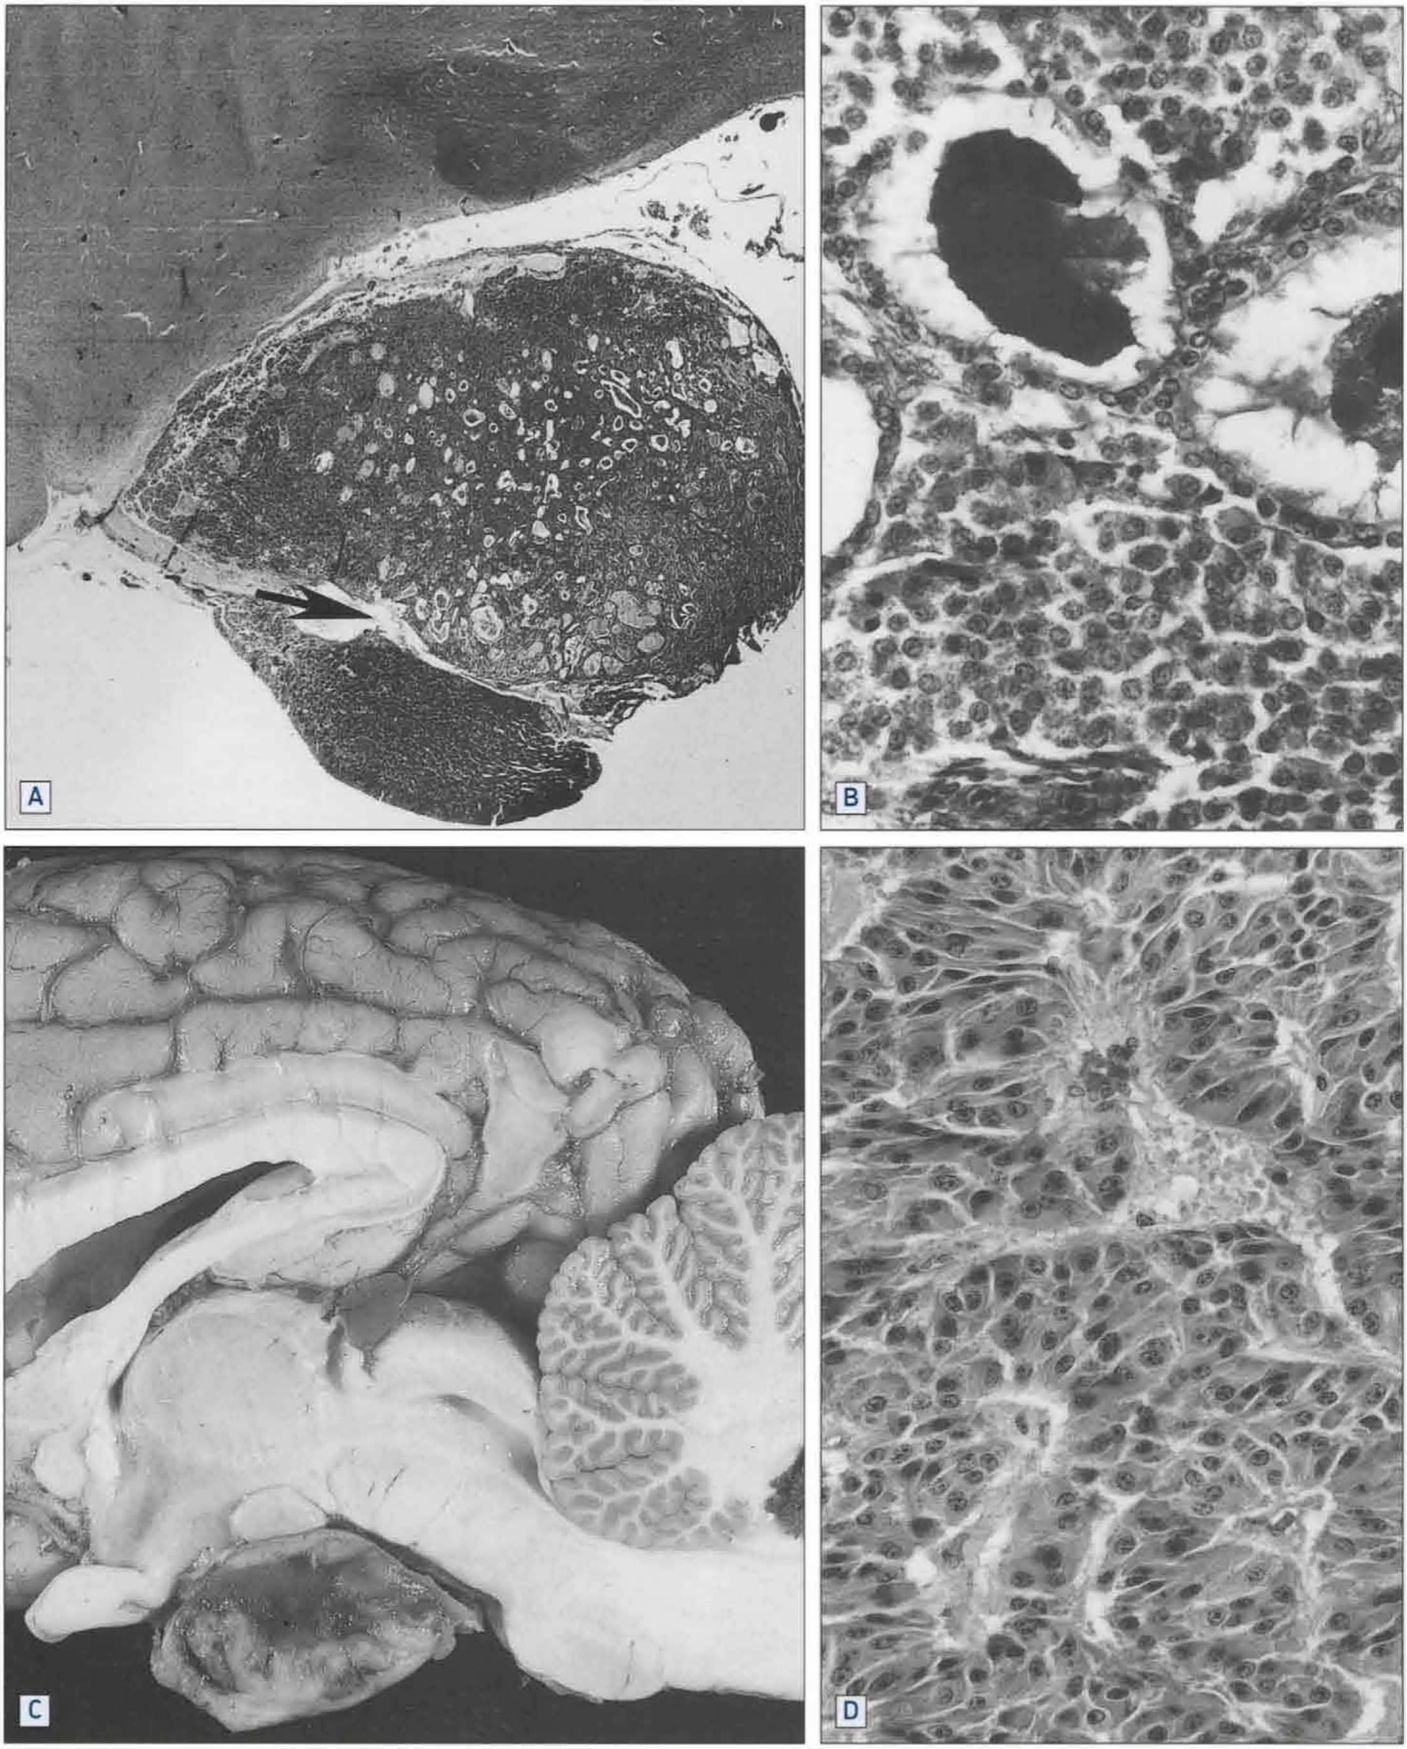

Figure 3.12 Corticotroph adenoma of pars intermedia in a dog. **A.** Neoplasm sharply demarcated from pars distalis. Arrow indicates the residual hypophyseal lumen. **B.** Nests of chromophobic cells interspersed between colloid-filled follicles. **Adenoma of pars intermedia** in a horse. **C.** Dorsal extension of tumor compressing hypothalamus and optic nerves with invasion of pars nervosa. **D.** Spindle-shaped tumor cells arranged in cords.

Adenomas of the pars intermedia are sharply demarcated from the pars distalis, usually by an incomplete layer of condensed reticulum and focal accumulations of lymphocytes, but are not encapsulated. The histologic appearance is different from corticotroph adenomas of the pars distalis, in that *there are numerous colloid-filled follicles interspersed between nests of large chromophobic cells* (Fig. 3.12B). The follicles are lined by simple columnar epithelium, which is partly ciliated, and contain interspersed mucin-secreting goblet cells. The follicular colloid is densely eosinophilic and periodic acid-Schiff (PAS) positive. The nests of cells between the follicles are primarily chromophobic, but occasional cells contain secretory granules of simple protein (acidophilic) or mucoprotein (basophilic). Endocrinologically active (ACTH-secreting) adenomas of the pars intermedia in dogs have prominent groups of large corticotrophs with abundant eosinophilic cytoplasm interspersed with variable numbers of smaller, more basophilic, cells and widely scattered follicles. Dense bands of fibrous connective tissue are occasionally interspersed between the follicles and nests of chromophobic cells, particularly in the endocrinologically inactive adenomas of the pars intermedia. Mitotic figures are observed infrequently. The neoplastic cells compress and often invade the pars nervosa and infundibular stalk.

Adenomas of the pars intermedia in dogs either are endocrinologically inactive and associated with various degrees of hypopituitarism and diabetes insipidus, or endocrinologically active and secrete excessive ACTH, leading to bilateral adrenocortical hyperplasia and a syndrome of cortisol excess. The clinical signs in the dogs with functional adenomas are similar to those described for corticotroph adenomas of the pars distalis.

Two cell populations have been identified in the pars intermedia of normal dogs by immunocytochemistry. The predominant cell type (**A cell**) stains strongly for α-MSH as in the pars intermedia of other species. A second cell type (**B cell**) in the canine pars intermedia stains intensely for ACTH but not for α-MSH. This second cell population accounts for the high bioactive ACTH concentration found in the pars intermedia of dogs, and appears to be the cell of origin of corticotroph adenomas of the pars intermedia in dogs with cortisol excess.

Adenomas of the pars intermedia in horses can be large tumors that extend out of the sella turcica and severely compress the overlying hypothalamus (Fig. 3.12C). The adenomas are yellow to white, multinodular, and incorporate the pars nervosa. On sectioning of the pituitary mass, the pars distalis usually can be identified as a compressed subcapsular rim of tissue on the rostral margin. A sharp line of demarcation remains between the neoplasm, which is partly encapsulated, and the compressed and atrophic pars distalis. The tumors are subdivided into nodules or compartments by fine septa of connective tissue that contain numerous capillaries and rare inflammatory cells. Tumor cells are large cylindrical, spindle-shaped or polyhedral, with an oval hyperchromatic nucleus (Fig. 3.12D). The histologic pattern is often reminiscent of the prominent pars intermedia of normal horses. Occasionally, cuboidal cells form follicular structures that contain dense eosinophilic colloid. In other areas, the spindle-shaped cells may assume a more sarcomatous pattern and palisade around vessels. The cytoplasm is lightly eosinophilic and granular.

Electron microscopy of the large cells comprising adenomas of the pars intermedia in horses reveals that the rough endoplasmic reticulum and Golgi apparatus are particularly well developed suggesting they are synthesizing and packaging considerable amounts of protein (pro-opiomelanocortin for secretion). The neoplastic cells contain numerous membrane limited secretory granules in their cytoplasm with a mean diameter of ~300 nm that are surrounded by a closely applied limiting membrane.

The *clinical syndrome* associated with tumors of the pars intermedia in horses is characterized by polyuria, polydipsia, increased appetite, muscle weakness, somnolence, intermittent hyperpyrexia, and generalized hyperhidrosis. The affected horses often develop striking *hypertrichosis* (*hirsutism*) because of failure of the seasonal shedding of hair (Fig. 3.13). The hair over most of the trunk and extremities is long (up to 9–10 cm), abnormally thick, wavy, and often matted together. Biopsy of skin reveals normal hair follicles uniformly in the anagen phase, normal epidermis and dermal collagen, and absence of the characteristic skin lesions observed in dogs with Cushing's disease due to cortisol excess.

Horses with larger tumors may have hyperglycemia (insulin-resistant) and glycosuria, most likely the result of downregulation of insulin receptors on target cells induced by the chronic excessive intake of food and hyperinsulinemia (see Fig. 3.2). *The disturbances in carbohydrate metabolism, ravenous appetite, hypertrichosis, and hyperhidrosis are considered to be primarily a reflection of deranged hypothalamic function caused by the compressive and destructive effects of the large pituitary tumors.* Adenomas of the pars intermedia in horses often extend out of the sella turcica and expand dorsally because of the incomplete diaphragma sellae, severely compress the overlying hypothalamus, and result in localized necrosis of nuclei in this important regulatory center. The hypothalamus is the primary autonomic center for homeostatic regulation of body temperature, appetite, cyclic shedding of hair, among many other functions.

Plasma cortisol and immunoreactive adrenocorticotropin (ACTH) levels are either normal or only modestly elevated in horses with adenomas of the pars intermedia. The cortisol levels often lack the

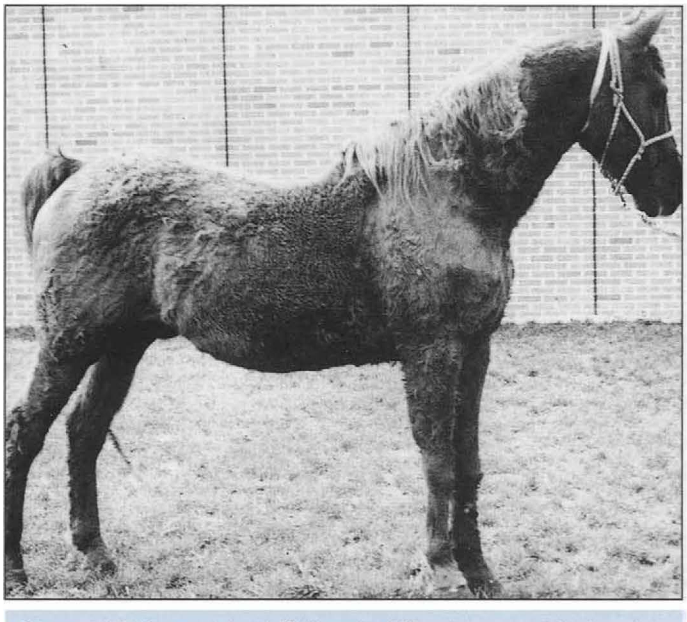

Figure 3.13 Hypertrichosis ("hirsutism") in a horse, resulting from failure of the cyclic shedding of hair associated with an adenoma of the pars intermedia. (From Capen CC. In: Special Veterinary Pathology, 3rd ed., 2001.)

normal diurnal rhythm and are not suppressed by either high or low doses of dexamethasone.

Tumor tissue and plasma from horses with adenomas of the pars intermedia contain high concentrations of **immunoreactive peptides** (*corticotropin-like intermediate lobe peptide (CLIP), α- and β-melanocyte-stimulating hormones (α- and β-MSH),* and *β-endorphin (β-END)*) derived from *pro-opiomelanocortin (pro-OMC)* and processed in the pars intermedia (Fig. 3.14). This biosynthetic precursor is a high molecular weight (31 000–37 000 daltons) glycoprotein that undergoes different post-translational processing in the pars distalis and pars intermedia. In the normal pars distalis, pro-OMC is processed to ACTH (4500 daltons), β-lipotropin (β-LPH) and γ-LPH, whereas in the normal pars intermedia the same precursor molecule is cleaved into α-MSH, CLIP (that contains amino acids 18–39 of the ACTH molecule), β-MSH, and β-END. Plasma cortisol strongly inhibits ACTH secretion by the pars distalis but has much less effect on peptides secreted by the pars intermedia, which are under tonic dopaminergic inhibitory control (Fig. 3.14).

The modest elevation of plasma immunoreactive adrenocorticotrophin appears to be due to the different processing of pro-OMC in tumors derived from cells of the pars intermedia. This may explain the normal or slightly elevated blood cortisol levels and normal or mildly hyperplastic adrenal cortices observed in some horses with adenomas of the pars intermedia. The plasma and tumor levels of pars intermedia-derived peptides (CLIP, α- and β-MSH, β-END) are disproportionately elevated (40 times or more) compared to those of ACTH, apparently as the result of selective post-translational processing of pro-OMC in a similar manner as the normal pars intermedia. Extracts of adenomas derived from pars intermedia also contain immunoreactive peptides of larger molecular weight than those present in the normal pituitary tissue. The smallest (38 500 daltons) of these peptides could represent pre-pro-OMC with an attached signal or leader sequence of ~26 amino acid residues. The larger peptides (47 000 and 63 000 daltons) may be derived from improper intranuclear processing of pro-OMC mRNA with retention of additional coding nucleotide sequences.

Horses with pituitary adenomas derived from pars intermedia develop a clinical syndrome that is associated, in part, with the autonomous production of excess pro-OMC-derived peptides. Immunocytochemical evaluation of adenomas of the pars intermedia reveals a diffuse moderate-to-strong staining for pro-OMC, α-MSH, and β-END. Although many of the functional disturbances in horses with pituitary adenomas (e.g., diabetes insipidus, polyphagia, hyperpyrexia, hyperhidrosis, and hypertrichosis (Fig. 3.13)) appear to be the result of hypothalamic or neurohypophyseal dysfunction, other signs (e.g., docility and diminished responsiveness to painful stimuli) may be related to the elevated plasma and cerebrospinal levels of β-END. Although ACTH is demonstrable in adenomas of the pars intermedia, the staining intensity is patchy and considerably weaker than that of pro-OMC, α-MSH, and β-END. These findings are in accord with biochemical studies that report markedly elevated concentrations of immunoreactive pro-OMC and pro-OMC-derived peptides including α- and β-MSH, corticotrophin-like intermediate lobe peptide, and β-END in adenomas and plasma of affected horses relative to ACTH. The overall processing of peptides in adenomas in the pars intermedia appears to be similar to that in the normal equine pars intermedia. *The clinical syndrome in horses with pituitary tumors leading to hypothalamic and neurohypophyseal derangement as well as autonomous production of excess amounts of pro-OMC-derived peptides is distinctly different from Cushing's disease that occurs in dogs, cats, and human patients.*

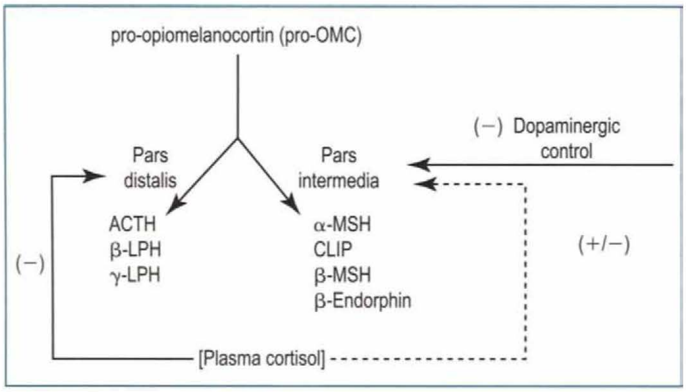

Figure 3.14 Post-translational **processing of pro-opiomelanocortin** (pro-OMC) produced by corticotrophs in pars distalis and pars intermedia. The plasma concentration of cortisol regulates processing in the pars distalis, whereas the pars intermedia is primarily under dopamine control.

Corticotrophs in the pars distalis of horse have strong immunostaining for ACTH, whereas only a few cells stain for α-MSH. These immunocytochemical findings illustrate the differences between adenomas of the pars intermedia in horses and corticotroph adenomas of the pars distalis (also pars intermedia in dogs) that result in the classical Cushing's disease with cortisol excess in humans and dogs. Corticotroph adenomas associated with Cushing's disease are characterized by strong immunostaining for ACTH and weak-to-moderate immunostaining for α-MSH.

Hormonally inactive chromophobe adenoma of the pars distalis

Nonfunctional pituitary tumors occur in dogs, cats, laboratory rodents, and parakeets, but are uncommon in other species. *Although chromophobe adenomas appear to be hormonally inactive, they may cause significant functional disturbances and clinical signs by compression of adjacent portions of the pituitary gland and dorsal extension into the overlying brain.*

Nonfunctional pituitary adenomas result in clinical disturbances either by interfering with secretion of pituitary trophic hormones and diminishing target organ function or dysfunction of the central nervous system. Affected animals often are depressed, have incoordination and other disturbances of balance, are weak and may collapse with exercise. In long-standing cases, there may be evidence of blindness with dilated and fixed pupils due to compression and disruption of optic nerves by dorsal extension of the pituitary tumor (Fig. 3.15).

Animals with hormonally inactive pituitary adenomas often have progressive loss of weight (*pituitary cachexia*), with muscle atrophy due to a lack of the protein anabolic effects of growth hormone. Compression of the cells that secrete gonadotrophic hormones or the corresponding hypothalamic releasing hormone(s) results in atrophy of the gonads, resulting in decreased libido or anestrus. Affected animals appear dehydrated, as evidenced by a lusterless dry haircoat, and they consume increased amounts of water.

Hormonally inactive pituitary adenomas often attain considerable size before they cause obvious signs or kill the animal. The proliferating tumor cells incorporate the remaining structures of the

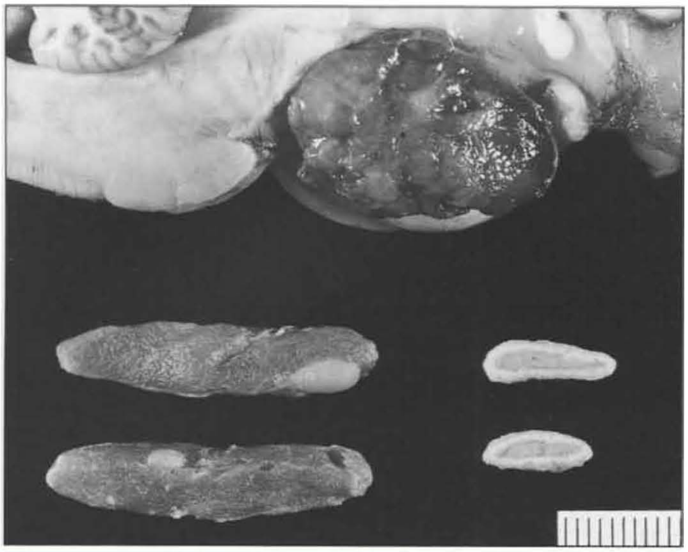

Figure 3.15 Destruction of pituitary by **nonfunctional adenoma** with trophic atrophy of adrenal cortex and thyroid follicular cells. Accumulation of colloid in involuted follicles prevents marked reduction in thyroid gland size. Scale in mm.

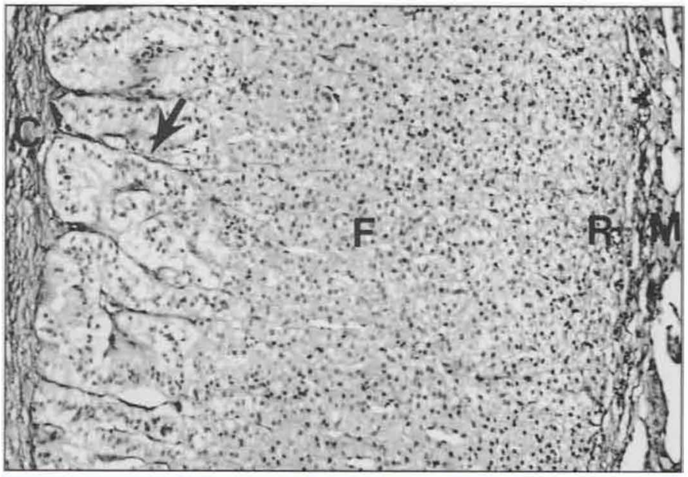

Figure 3.16 Adrenal cortex from a dog with a large **nonfunctional pituitary adenoma**. The inner zonae fasciculata (F) and reticularis (R) are atrophic due to subnormal production of ACTH. The outer zona glomerulosa (arrow) is normal but relatively more prominent. C = adrenal capsule, M = medulla.

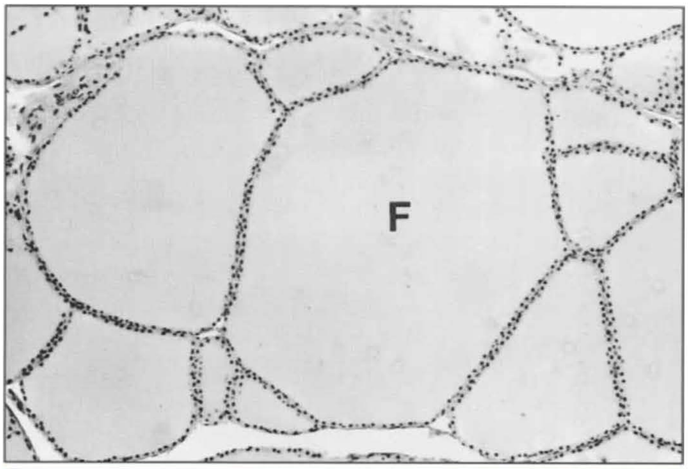

Figure 3.17 Colloid involution of thyroid follicles due to subnormal production of TSH by the adenohypophysis in a dog with a large **nonfunctional pituitary adenoma**. The follicular cells have undergone trophic atrophy and are low cuboidal because of a lack of TSH, and the follicles (F) are greatly distended by the accumulation of colloid. (From Capen CC. Toxicol Pathol 2001;29:8–33.)

adenohypophysis and infundibular stalk. The neoplasms attach firmly to the base of the sella turcica, but cause no erosion of the sphenoid bone. The incomplete diaphragma sellae permits dorsal growth of the adenoma along lines of least resistance. The entire hypothalamus may become compressed and replaced by the tumor.

The adrenal glands in animals with large nonfunctional pituitary adenomas are small and consist primarily of medullary tissue surrounded by a narrow zone of cortex. The adrenal cortex appears as a thin yellow-brown rim composed of a moderately thickened capsule and secretory cells of the outer zona glomerulosa (Figs 3.15, 3.16), which are not predominantly under the control of ACTH. The zonae fasciculata and reticularis are severely atrophied. Thyroid glands in animals with large pituitary adenomas are either normal size or smaller than normal, though less atrophied than the adrenal cortex (Fig. 3.15). Most of the atrophic thyroid follicles are large, lined by flattened cuboidal epithelium, and have few endocytotic vacuoles near the interface between the colloid and luminal aspect of the follicular cells (Fig. 3.17). The thyroid lesion is due to lack of TSH-induced endocytosis of colloid. Seminiferous tubules of the testes are small and show little evidence of active spermatogenesis.

The cells comprising nonfunctional pituitary adenomas are cuboidal to polyhedral and either arranged in diffuse sheets or subdivided into small packets by fine connective tissue septa. Special histochemical techniques for pituitary cytology fail to demonstrate specific secretory granules within the cytoplasm of tumor cells. The histogenesis of nonfunctional chromophobe adenomas often is difficult to define precisely, but they appear to be derived from less differentiated pituitary cells that neither store nor secrete a specific hypophyseal trophic hormone.

The daily administration of calcitonin to Sprague-Dawley, and to a lesser degree Fischer 344, rats for 1 year has been reported to increase the incidence of nonfunctional pituitary adenomas. Immunohistochemical analysis revealed that the tumor cells were negative for all of the major pituitary hormones, and serum levels of growth hormone, prolactin, ACTH, LH, and FSH were unchanged in calcitonin-treated rats. Immunohistochemistry and in situ hybridization analysis demonstrated that the nonfunctional pituitary tumors expressed the glycoprotein hormone α-subunit and serum levels of α-subunit were markedly increased (approximately 20-fold).

Acidophil adenoma of the pars distalis

Although **growth hormone-secreting acidophils (somatotrophs)** are one of the major cell types in the adenohypophysis, *development of functional adenomas from this population of acidophils is infrequent in animals.* Neoplasms derived from granulated acidophils are uncommon in all domestic animal species, but have been reported in the cat, dog and sheep; however, they are common in many strains of old laboratory rats.

Acidophil adenomas enlarge the pituitary gland and indent the overlying hypothalamus or extend into the overlying brain to various degrees. The enlarged hypophysis is composed of irregular columns of acidophils interspersed between numerous large blood-filled sinusoids. The fibrous stroma is sparse. Although the degree of cytoplasmic granulation of acidophils varies from cell to cell, the predominating type of neoplastic acidophil usually contains many secretary granules. The nuclei of the densely granulated acidophils are small, oval, and hyperchromatic. Sparsely granulated ("chromophobic") cells are interspersed between the densely granulated acidophils. Their cytoplasm is more abundant and lightly eosinophilic but contains only an occasional secretory granule. Secretory granules of acidophils are bright red when stained with acid fuschin-aniline blue and with Crossman's modification of Mallory's trichrome. Orange-G stains the granules an intense yellow-orange, but they are PAS-negative.

Colloid-containing follicles lined by follicular cells are found occasionally within **acidophil adenomas in dogs**. The colloid is intensely PAS-positive. Numerous sinusoids are distended with erythrocytes, detached neoplastic cells, and large masses of fibrin. The pars nervosa and infundibular stalk are infiltrated at the periphery by neoplastic cells, compressed, and partly replaced by fibrous astrocytes.

Electron microscopic evaluation reveals that *two types of acidophils* occur within pituitary acidophil adenomas. The *predominant type of acidophil* is smaller and contains many secretory granules. The granules are spherical to oval, uniformly electron-dense, finely granular, and surrounded by a delicate limiting membrane. The submembranous space of the granule is narrow. The mean diameter of mature secretory granules in the neoplastic acidophils is 420 nm (range 320–600 nm). The plasma membranes of adjacent cells are relatively straight with uncomplicated interdigitations and are connected by an occasional desmosome. The Golgi apparatus is comparatively small and associated with few prosecretory granules. The rough endoplasmic reticulum is composed of small, flattened membranous sacs with attached ribosomes. A few mitochondria are randomly distributed throughout the cytoplasm. Acidophils of this type are interpreted to be in the "storage phase" of their secretory cycle.

The *less common type of neoplastic acidophil* has a greater cytoplasmic and nuclear area but contains numerous organelles and few mature secretory granules. The rough endoplasmic reticulum is extensive and consists of aggregates of lamellar arrays of granular membranes. The Golgi apparatus is prominent and associated with numerous small prosecretory granules. Mitochondria are observed more often in the cytoplasm of this type of acidophil. These hypertrophied acidophils are considered to be secretorily active cells. Cells with various amounts of organellar development and numbers of mature secretory granules are present between the extremes of storage and actively synthesizing acidophils.

In the pars distalis of normal dogs immunoreactive prolactin cells occur as small groups of large polygonal cells with prominent granules in the ventrocentral and rostral portion. A diffuse increase in this population of cells occurs in female dogs near parturition. In comparison, growth hormone-secreting acidophils are present singly along capillaries in the dorsal region of the pars distalis near the pars intermedia. They are small, round to oval, and have fine cytoplasmic granules. Somatotrophs frequently undergo hypertrophy and diffuse hyperplasia in old dogs, especially females with mammary dysplasia or neoplasia.

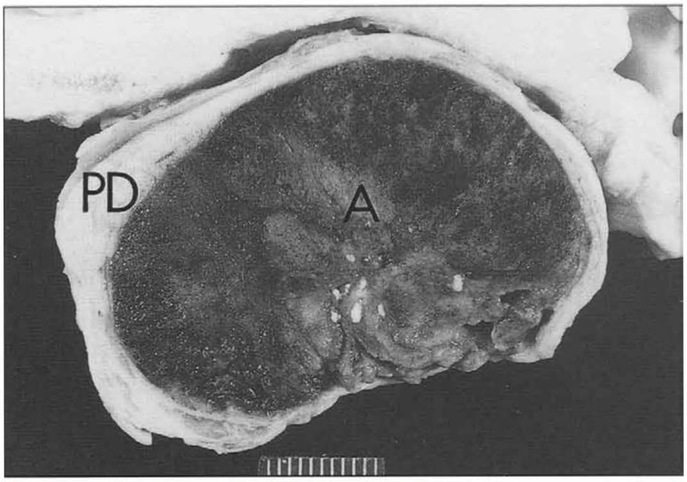

Figure 3.18 Acidophil adenoma (A) from a ewe with severe compression of the pars distalis (PD) and overlying brain. Scale in mm. (From Capen CC. In: Tumors of Domestic Animals, 4th ed., 2002.)

In none of the reported acidophil tumors of dogs has conclusive evidence been presented that there were functional disturbances resulting from hypersecretion of somatotropin or prolactin. **Acromegaly** is a disease characterized by an overgrowth of connective tissue, increased appositional growth of bone, coarsening of facial features, and enlargement of viscera due to chronic excessive secretion of growth hormone (somatotropin). However, acidophil adenomas in dogs have been associated with thickened cranial bones and metahypophyseal diabetes with fewer than normal pancreatic islets.

Acidophil adenomas in cats have been associated with clinical signs of diabetes mellitus with degranulation of pancreatic islets and vacuolar changes in beta cells. The persistent elevation of serum somatotropin in cats also is associated with proliferation of joint cartilage, leading to degenerative arthropathy, and with kidney disease due to periglomerular fibrosis and mesangial proliferation.

Functional acidophil adenomas in cats secrete excess growth hormone, which results in downregulation of insulin receptors and resistance to the action of insulin at the target cell level. Several reports have described acidophil adenomas in cats associated with **insulin-resistant diabetes mellitus** and acromegalic features with immunocytochemical localization of growth hormone in the cytoplasm of tumor cells. The circulating growth hormone levels were approximately 100 times normal and were nonsuppressible by an exogenous glucose load. Clinical evidence of acromegaly included an enlarged abdomen and prognathia inferior.

Acidophil adenomas in **sheep** may attain considerable size (Fig. 3.18) and remain confined to the sella turcica because sheep have a complete diaphragma sellae separating the pituitary fossa from the brain. The remaining adeno- and neurohypophysis are compressed severely (Fig. 3.18), and the sella turcica is enlarged and deepened due to pressure-induced osteolysis (Fig. 3.19).

Changes in plasma growth hormone, prolactin, cortisol, and progesterone levels in beagles following intramuscular injection of 75 mg/kg medroxyprogesterone acetate (6 α-methyl-17-acetoxyprogesterone) every 3 months for 17 months have been correlated with the development of acromegalic features and mammary nodules. Medroxyprogesterone acetate increased mean growth hormone levels, incidence of acromegaly-like changes (Fig. 3.20),

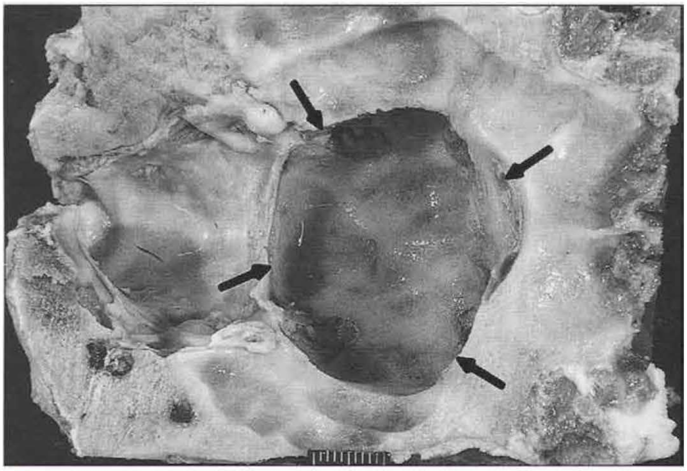

Figure 3.19 Enlargement and deepening of sella turcica (arrows) associated with a large **acidophil adenoma** (prolactin-secreting cells) of the pituitary gland that remained confined to this region due to the complete diaphragma sellae. Scale in mm. (From Capen CC. In: Tumors of Domestic Animals. 4th ed., 2002.)

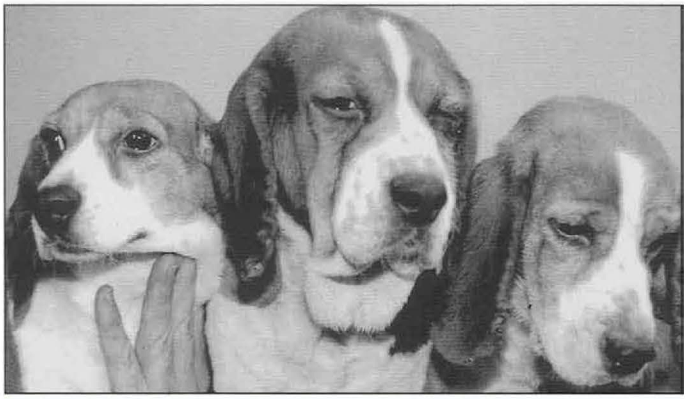

Figure 3.20 **Iatrogenic acromegaly** in a beagle (center) compared with unaffected littermates (left and right). Note the coarseness of facial features and marked thickening and folding of the skin of the face. These characteristic changes are the result of the protein anabolic effects of somatotropin, produced in excess by hyperplastic mammary ductular epithelial cells that have been stimulated by the exogenous administration of medroxyprogesterone acetate. (Courtesy of P Concannon.)

and frequency of palpable mammary nodules in beagles under controlled conditions. The growth hormone increase is the result of increased expression of the growth hormone gene in ductal cells of the mammary gland and not by stimulation of somatotrophs in the pituitary gland.

Growth hormone levels were elevated (2.5 μg/L and above) in all female beagles with acromegalic features compared with placebo controls and dogs receiving crystalline progesterone implants. All dogs with elevated growth hormone levels had multiple mammary nodules. The elevation in growth hormone levels and development of acromegalic features was greater in older than in younger dogs. Initial elevations of growth hormone occurred after 8 months of medroxyprogesterone acetate treatment. Serum prolactin levels were not changed by either medroxyprogesterone acetate or crystalline progesterone implants, but serum cortisol levels were suppressed significantly compared with those in controls. The latter most likely was the result of medroxyprogesterone-induced suppression of pituitary ACTH secretion and corresponding decrease in cortisol synthesis by the adrenal cortex. Elevated growth hormone levels also are reported in dogs with spontaneous mammary tumors.

Craniopharyngioma (intracranial germ cell tumor)

Craniopharyngioma *is a benign tumor that is derived from epithelial remnants of the oropharyngeal ectoderm of the craniopharyngeal duct (Rathke's pouch)*. It occurs in animals younger than those with other types of pituitary neoplasm and is present in either a suprasellar or infrasellar location. It is one cause of *panhypopituitarism and dwarfism* in young dogs due to subnormal secretion of somatotropin and other trophic hormones beginning at an early age, prior to closure of the growth plates.

Pleomorphic tumors in the suprasellar region often are large and grow along the ventral aspect of the brain where they can incorporate several cranial nerves. In addition, they extend dorsally into the hypothalamus and thalamus. The *clinical signs* resulting from this type of rapidly growing tumor in the pituitary region often are a combination of

1. lack of secretion of pituitary trophic hormones resulting in trophic atrophy and subnormal function of the adrenal cortex and thyroid, gonadal atrophy, and failure to attain somatic maturation due to a lack of growth hormone secretion;
2. disturbances in water metabolism (polyuria, polydipsia, low urine specific gravity and osmolality) from an interference with the release and synthesis of antidiuretic hormone by the large tumor;
3. deficits in cranial nerve function; and
4. central nervous system dysfunction due to extension into the overlying brain.

Histologically, the tumors have alternating solid and cystic areas. The solid areas are composed of nests of epithelial cells (cuboidal, columnar, or squamous) with focal areas of mineralization. The solid areas are composed of nests of epithelial cells (cuboidal, columnar, or squamous cells) with prominent focal areas of keratinization and occasional mineralization that compress the overlying hypothalamus. The areas of keratinization are densely eosinophilic and frequently are associated with fragments of nuclear chromatin. The neoplastic epithelial cells are large and pleomorphic with vesicular nuclei and prominent nucleoli, and frequently have discrete vacuoles in their cytoplasm. There frequently is an admixture with smaller cuboidal to polyhedral cells that have acidophilic secretory granules that stain positive for either prolactin or growth hormone by immunocytochemistry. The cystic spaces are lined by either columnar or squamous cells and contain keratin debris and colloid. Colloid-containing follicles may be formed that are lined either by cuboidal or by columnar cells and contain variable amounts of eosinophilic colloid.

It has been proposed that pleomorphic neoplasms in the suprasellar region of younger dogs be classified as **germ cell tumors** *rather than craniopharyngiomas*. The diagnosis of germ cell tumors was based upon three criteria:

1. midline suprasellar location,
2. presence within the tumor of several distinct cell types (one population resembling a seminoma or dysgerminoma, and

others suggesting teratomatous differentiation into secretory glandular and squamous elements), and

3. positive staining for α-fetoprotein.

This interpretation suggests that these suprasellar pleomorphic neoplasms in dogs are of germ cell origin and that the secretory (glandular) and squamous elements represent teratomatous differentiation. Additional cases need to be studied utilizing a spectrum of immunocytochemical stains for the protein and glycoprotein pituitary hormones, alpha subunit, chorionic gonadotrophin, α-fetoprotein, and placental alkaline phosphatase to determine which of the pleomorphic neoplasms in the suprasellar region are derived from remnants of the oropharyngeal epithelium of the craniopharyngeal duct and which have their origin from multipotential germ cells.

Basophil adenoma of the pars distalis

Tumors composed of granulated basophils are one of the least common pituitary tumors in all animal species. Cushing's disease in human beings was initially attributed to a hypersecretion of ACTH by small basophilic adenomas in the pars distalis. Current evidence suggests they are a possible cause for a small percentage of patients with Cushing's disease. Several of the early reports on ACTH-secreting pituitary tumors in dogs with hyperadrenocorticism reflected this concept and interpreted them to be basophil adenomas. Corticotroph (chromophobic) adenomas of the pars distalis and pars intermedia are responsible for the great majority of cases of Cushing's-like disease in dogs.

Basophil adenomas in people also may secrete thyrotropin (TTH) resulting in bilateral enlargement of both thyroid lobes ("goiter"). Serum thyroxine, triiodothyronine, and TTH are elevated and may be responsive to TRH from the hypothalamus. The neoplastic cells contain small secretory granules (diameter less than 150 nm) with prominent rough endoplasmic reticulum and Golgi apparatus, characteristic of pituitary thyrotrophs.

Pituitary chromophobe carcinoma

Pituitary chromophobe carcinomas are uncommon compared with pituitary adenomas, but have been seen in older dogs and cows. They are usually endocrinologically inactive but may result in significant functional disturbances by destruction of the pars distalis and neurohypophyseal system, leading to panhypopituitarism and diabetes insipidus.

Pituitary carcinomas are large and extensively invade the overlying brain, along the ventral aspect of skull, and into the sphenoid bone of the sella turcica inducing resorption of the bone. Metastases may occur to regional lymph nodes or to distant sites, such as the spleen or liver.

Malignant tumors of pituitary chromophobes are highly cellular and often have large areas of hemorrhage and necrosis. Giant cells, nuclear pleomorphism, and mitotic figures are encountered more frequently than in chromophobe adenomas.

Tumors metastatic to the pituitary gland

The pituitary gland occasionally is either partially or completely destroyed by metastatic tumors from distant sites. Examples include malignant lymphoma in cattle and dogs; malignant melanoma in horses and dogs, transmissible venereal tumor and adenocarcinoma of the mammary gland in dogs. In addition, the pituitary may be compressed or destroyed by local infiltration from osteosarcomas of the sphenoid bone, ependymomas arising in the infundibular recess of the third ventricle, by abscesses (Fig. 3.21A), meningiomas (Fig. 3.21B), and gliomas ("infundibuloma") of the infundibular stalk.

Granular cell tumors of pituitary

Granular cell tumors (GCT) *are uncommon in most animal species*, but have been reported in dogs, horses, and cats. They are encountered most commonly in the oral cavity; occasionally in the heart, lymph nodes, brain, and skin; and rarely involving the pituitary gland in a parasellar location. A recent report describes involvement of the pituitary, optic chiasm, and ventral pyriform lobes by a GCT resulting in blindness, seizures, ataxia, weakness, and behavioral changes.

The neoplastic cells in GCT have abundant eosinophilic granular cytoplasm with round-to-oval eccentrically placed nuclei (Fig. 3.22A). The cytoplasm stains diffusely positive with the PAS reaction, but immunohistochemical staining for pancytokeratin, vimentin, S-100 protein, glial fibrillary acidic protein, neuron-specific enolase, and synaptophysin is uniformly negative. Ultrastructurally, the neoplastic cells contain numerous membrane-bound lysosomal bodies that displace the nucleus to an eccentric location and obscure other cytoplasmic organelles (Fig. 3.22B). A similar entity in this region of human patients is referred to as parasellar or pituitary symptomatic GCT.

Mechanisms of pituitary tumor induction

Pituitary tumors can be induced readily by sustained uncompensated hormonal derangements leading to increased synthesis and secretion of pituitary hormones. The absence of negative feedback inhibition of pituitary cells leads to unrestrained proliferation (hyperplasia initially, neoplasia later). This effect can be potentiated by the concurrent administration of *ionizing radiation* or *chemical carcinogens*. The administration of *estrogens* is a reproducible method for inducing pituitary tumors in certain experimental animals. The effect of exogenous estrogen on the rat pituitary includes stimulation of prolactin secretion and the induction of prolactin-secreting tumors. The administration of estrogens in susceptible strains results in elevated serum prolactin levels, increased numbers of prolactin cells within the pituitary, enhanced incorporation of tritiated thymidine within the gland, and increased mitotic activity. Other agents, including caffeine, have been implicated in the development of pituitary adenomas in rats.

The *high frequency of spontaneous pituitary adenomas in laboratory rats* is a well-recognized phenomenon that must be considered in any long-term toxicological study. The incidence of pituitary tumors is determined by many factors including strain, age, sex, reproductive status, and diet. Both hereditary factors and the levels of circulating sex steroids have been suggested as important etiological mechanisms. The hypothalamus has also been incriminated in the development of these tumors. Age-related hypothalamic changes may result in diminished activity of dopamine, the major prolactin-inhibitory factor. Numerous studies have demonstrated the striking degree of strain variation in the incidence of pituitary tumors in rats, which has been reported to range from 10% to more than 90%. Rapid body growth rates and high levels of conversion of feed to body mass in early life, or high protein intake in early

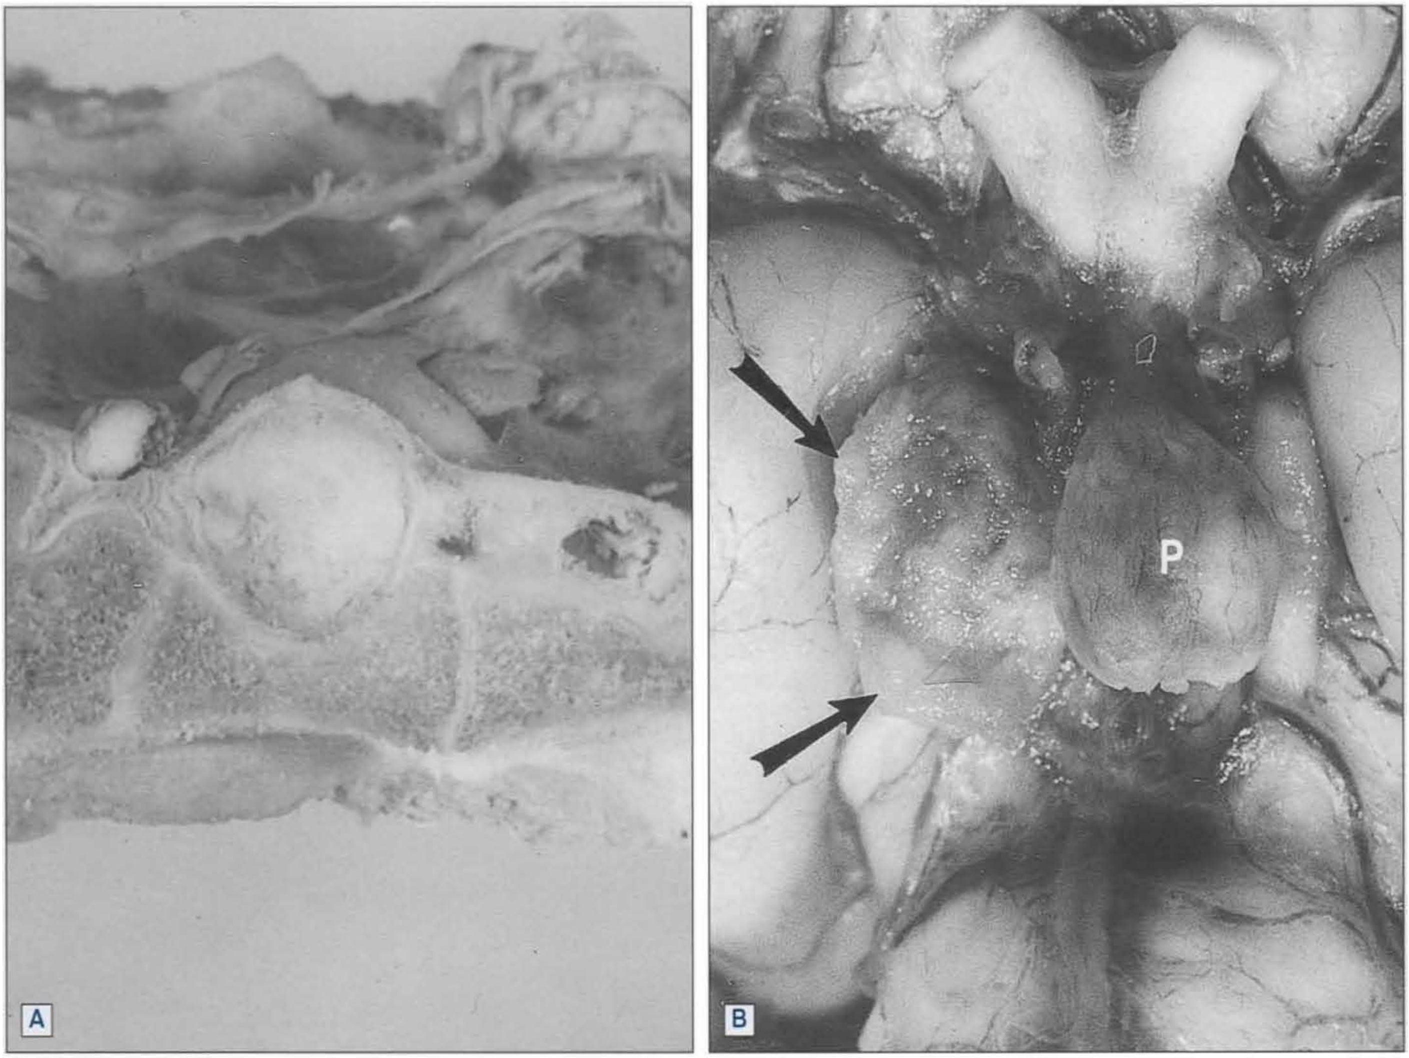

Figure 3.21 A. Pituitary abscess in a calf, mid-sagittal section. **B. Meningioma** (arrows) on ventral aspect of brain exerted pressure on the hypothalamic-hypophyseal portal system in a dog. P = pituitary gland.

adult life, predispose any strain of rat to the development of pituitary adenomas.

Diseases of neurohypophysis

Diabetes insipidus is a disorder in which inadequate antidiuretic hormone (ADH) is produced (*hypophyseal form*), or target cells in the kidney are unable to respond to the secretion of normal or elevated circulating levels of hormone (*nephrogenic form*).

The **hypophyseal form of diabetes insipidus** develops as a result of compression and destruction of the pars nervosa, infundibular stalk, or supraoptic nucleus in the hypothalamus. The lesions responsible for the disruption of ADH synthesis or secretion include large pituitary neoplasms (endocrinologically active or inactive), dorsally expanding cysts or inflammatory granulomas, and traumatic injury to the skull with hemorrhage and glial proliferation in the neurohypophyseal system. The neurohypophysis, infundibular stalk, and hypothalamus are compressed or disrupted by neoplastic cells. This interrupts the nonmyelinated axons that transport ADH from its site of production, primarily in the supraoptic nucleus of the hypothalamus, to the site of release in the capillary plexus of the pars nervosa. Compression of neurosecretory neurons in the supraoptic nucleus of the hypothalamus by the dorsally expanding neoplasm may also result in decreased ADH synthesis. Axons in the compressed pars nervosa with hypophyseal diabetes insipidus associated with pituitary neoplasms are depleted of ADH-containing, dense neurosecretory granules, unlike those in normal animals (Fig. 3.23A, B). Sporadic cases of hypophyseal diabetes insipidus may be the result of an *inherited biochemical defect in the synthesis of ADH* and its corresponding neurophysin I, as has been described in the Brattleboro strain of rat.

In the **nephrogenic form of diabetes insipidus**, blood levels of ADH are normal or elevated, but target cells in the distal nephron and collecting ducts are unable to respond due to a lack of adenylate cyclase in the plasma membrane.

Animals with diabetes insipidus excrete large volumes of hypotonic urine, which in turn obliges them to take in equally large amounts of water to prevent hyperosmolality of body fluids and dehydration. Urine osmolality is decreased below normal plasma osmolality (~300 mmol/L) in both hypophyseal and nephrogenic

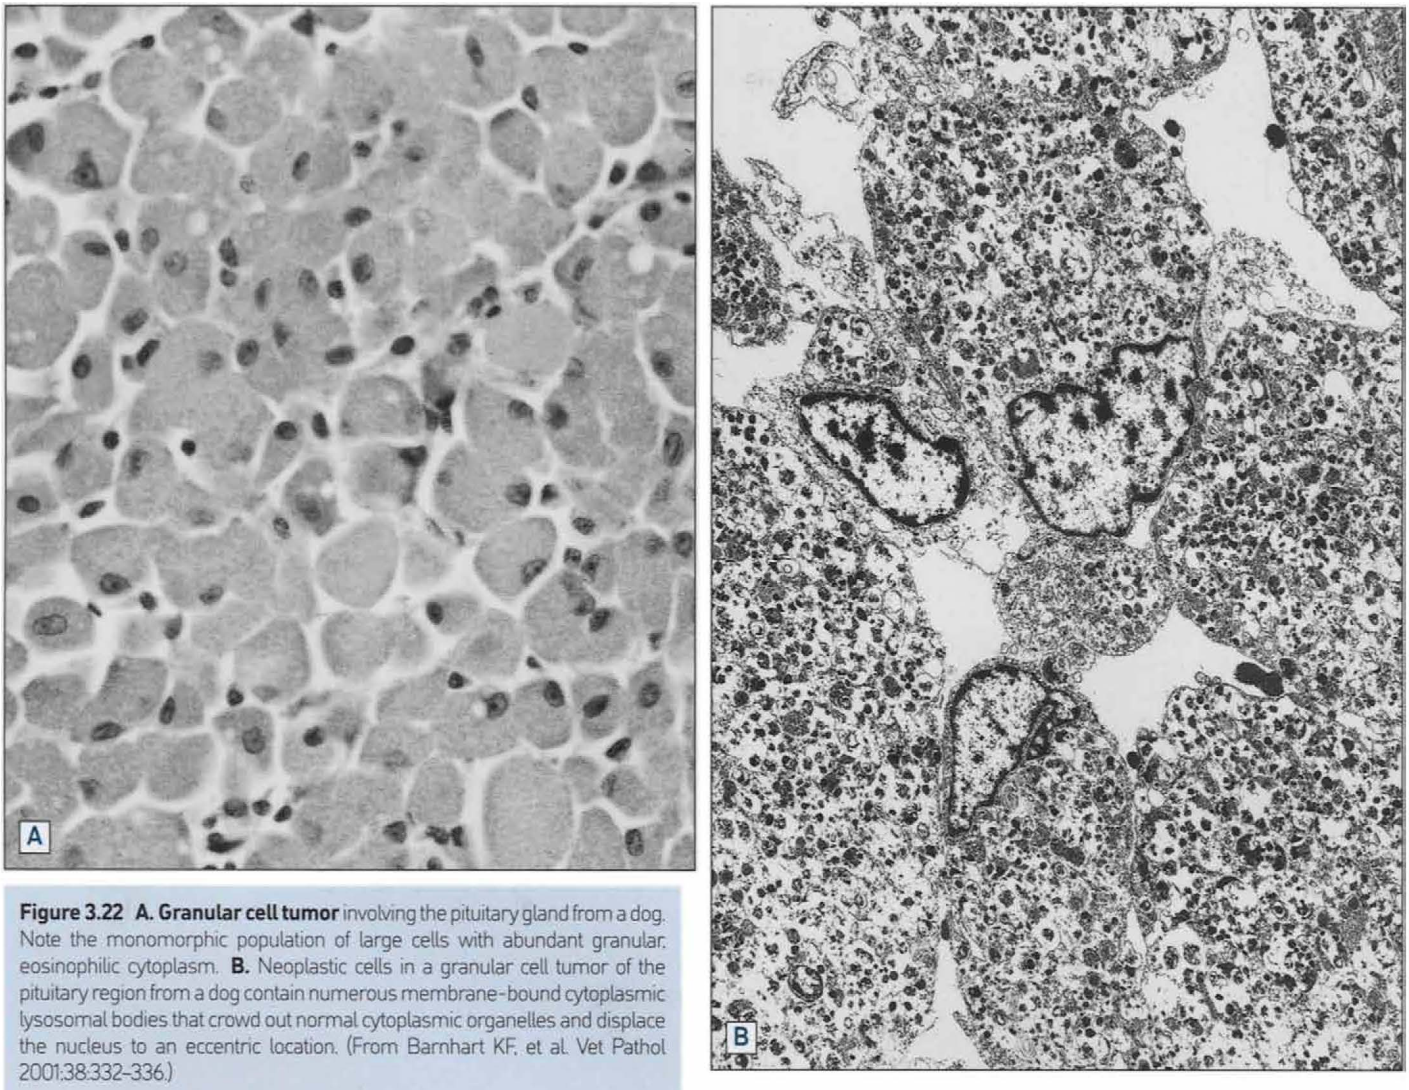

Figure 3.22 **A. Granular cell tumor** involving the pituitary gland from a dog. Note the monomorphic population of large cells with abundant granular, eosinophilic cytoplasm. **B.** Neoplastic cells in a granular cell tumor of the pituitary region from a dog contain numerous membrane-bound cytoplasmic lysosomal bodies that crowd out normal cytoplasmic organelles and displace the nucleus to an eccentric location. (From Barnhart KF, et al. Vet Pathol 2001;38:332–336.)

forms of diabetes insipidus. In response to water deprivation, urine osmolality remains below that of plasma in both forms in contrast to what is observed in normal animals. *The elevation of urine osmolality above that of plasma in response to exogenous ADH in the hypophyseal form, but not in nephrogenic diabetes insipidus, allows separation of these two forms of the disease.*

CALCIUM-REGULATING HORMONES

Calcium ion plays a key role in many fundamental biologic processes including muscle contraction, blood coagulation, enzyme activity, neural excitability, hormone release, and membrane permeability, in addition to being an essential structural component of the skeleton. To maintain a constant concentration of calcium, despite variations in intake and excretion, endocrine control mechanisms have evolved that primarily consist of the interactions of three major hormones (Fig. 3.24). Although the direct roles of *parathyroid hormone, calcitonin, and vitamin D* frequently are emphasized in the control of blood calcium, *other hormones such as adrenal corticosteroids, estrogen, thyroxine, somatotropin, and glucagon, also contribute to the maintenance of calcium homeostasis under certain conditions.*

Calcium (Ca) serves two primary functions in the body: *(1) structural integrity of bones and teeth, and (2) as a messenger or regulatory*

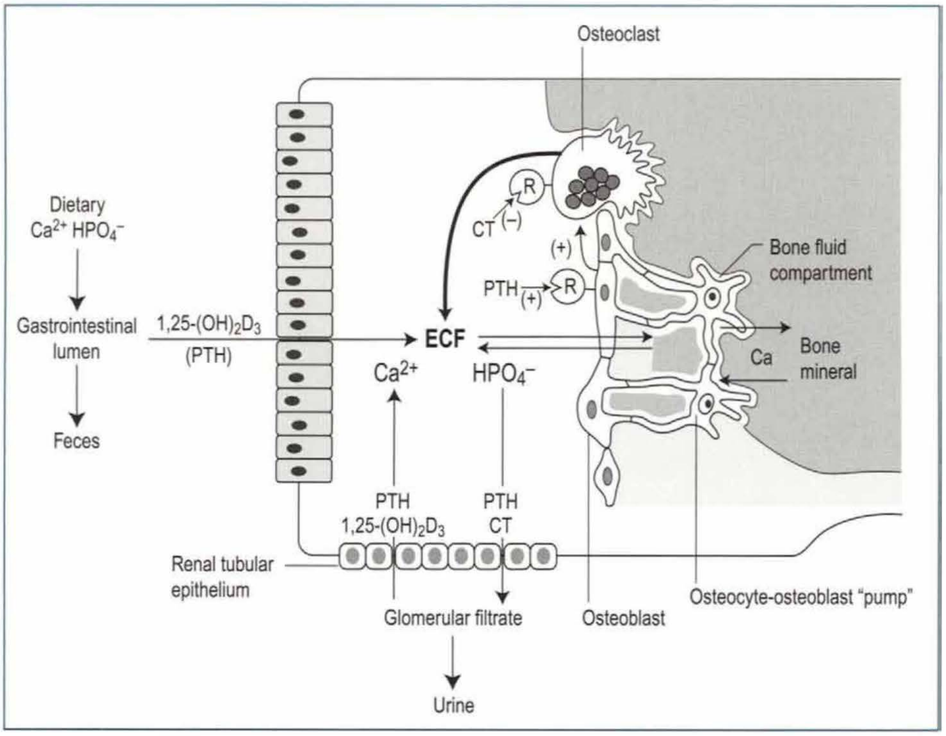

Figure 3.24 Interrelations of parathyroid hormone (PTH), calcitonin (CT), and 1,25-dihydroxycholecalciferol (1,25-$(OH)_2$ D_3) in the **hormonal regulation of calcium and phosphorus** in extracellular fluids (ECF). (From Rosol TJ, Capen CC. In: Clinical Biochemistry of Domestic Animals, 5th ed., 1997.)

ion. The 10 000-fold concentration gradient of calcium ion (Ca^{2+}) between the extracellular fluid (1.2 mmol/L) and the cytoplasm (100 nmol/L) permits Ca^{2+} to function as a signaling ion to activate intracellular processes. The lipid bilayer of the cell membrane has a low permeability to Ca^{2+}; therefore, influx of Ca^{2+} into the cytoplasm is controlled by a heterogeneous group of *Ca channels* regulated by membrane potential, cell membrane receptors or intracellular secondary messengers. Influx of Ca^{2+} into cells can: (1) regulate cellular function by interactions with Ca-binding proteins (e.g., calmodulin) and Ca-sensitive protein kinases, and (2) stimulate biologic responses such as neurotransmitter release, contraction, and secretion. *Ionized calcium (Ca^{2+}) also plays an important role in cell adhesion and blood coagulation.* In addition, Ca^{2+} may regulate cellular function by binding to a G-protein-linked Ca^{2+}-sensing receptor in the cell membrane, such as in parathyroid chief cells or renal epithelial cells.

It is critical for cells to maintain the normal low level of intracellular Ca^{2+}. If cellular calcium homeostasis fails due to anoxia, an energy-deprived state or perturbed membrane integrity, cell viability is threatened due to uncontrolled entry of Ca^{2+} through the plasma membrane or from intracellular stores.

There are two sources of calcium in bone that can enter the circulation: (1) readily mobilizeable Ca salts in the extracellular fluid, and (2) hydroxyapatite crystals that require digestion by osteoclasts before Ca^{2+} can be released from bone. The nature and regulation of the readily mobilizable Ca in bone is poorly understood; however, it is present in small amounts and likely plays a role in the fine regulation of serum Ca concentration. If there is a significant need for Ca from bone it must come from osteoclastic resorption of hydroxyapatite crystals. In adult animals, there is a stable balance between Ca deposition associated with bone formation by osteoblasts and Ca release associated with osteoclastic bone resorption. In young animals, bone has a positive Ca balance due to the relative excess of bone formation. Conditions that result in excessive bone resorption (e.g., humoral hypercalcemia of malignancy, osteolytic bone metastases, or primary hyperparathyroidism), can release large amounts of Ca from bone and contribute to the development of life-threatening hypercalcemia.

Parathyroid glands and parathyroid hormone

Development and structure

Parathyroids are of entodermal origin and derived from the third and fourth pharyngeal pouches in close association with the primordia of the thymus (Fig. 3.25). Anatomic location of parathyroid glands in relation to thyroids and related structures in several species of animals is shown in Fig. 3.26.

The parathyroid glands contain a single basic type of secretory cell, the chief cell, which is concerned with the elaboration of a single hormone. The chief cells are in different stages of secretory activity, and in certain species are in transition to oxyphil cells. Chief cells interpreted to be in an inactive (resting or involuted) stage of their secretory cycle predominate in the parathyroid glands under normal conditions. Inactive chief cells are cuboidal and have uncomplicated interdigitations between contiguous cells. The relatively electron-transparent cytoplasm contains poorly developed organelles and secretory granules are sparse. The cytoplasm often has either numerous lipid bodies and lipofuscin granules or aggregations of glycogen. Chief cells in the active stage of the secretory cycle are in the minority in the parathyroid glands of most species. The cytoplasm of active chief cells has increased electron density due to the close proximity of organelles and secretory granules, increased density of the cytoplasmic matrix, and loss of glycogen particles and lipid bodies.

The second cell type in the parathyroid glands of certain species, including humans, is the **oxyphil cell**. These cells are absent in rats,

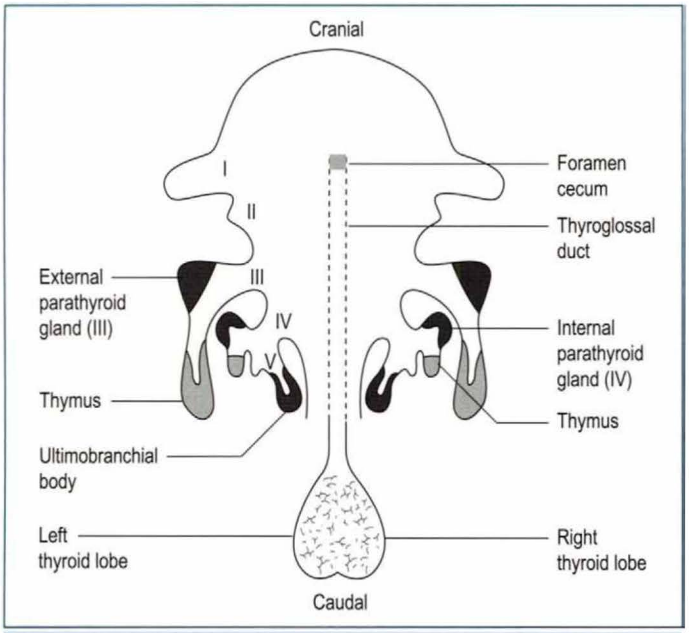

Figure 3.25 Embryologic development of thyroid and parathyroid glands.

chickens, and many species of lower animals. Oxyphil cells occur either singly or in small groups interspersed between chief cells. They are larger than chief cells and their abundant cytoplasm is filled with numerous large, often bizarre-shaped, mitochondria. Glycogen particles and free ribosomes are interspersed between the mitochondria. Granular endoplasmic reticulum, Golgi apparatuses, and secretory granules are poorly developed in oxyphil cells of normal parathyroid glands, *suggesting that oxyphil cells do not have an active role in the biosynthesis of parathyroid hormone.* Oxyphil cells have a higher oxidative and hydrolytic enzyme activity than chief cells, associated with the marked increase in numbers of mitochondria.

Cells are observed with cytoplasmic characteristics intermediate between those of chief and oxyphil cells. These **transitional oxyphil cells** have numerous mitochondria but other organelles are present, including rough endoplasmic reticulum, Golgi apparatuses, and secretory granules.The significance of oxyphil cells in the pathophysiology of the parathyroid glands is not completely understood. They are not altered in response to either short-term hypocalcemia or hypercalcemia in animals, but both oxyphil cells and transitional forms may be increased in response to long-term stimulation of human parathyroid glands.Therefore, oxyphil cells do not appear to be degenerate chief cells, but rather are derived from chief cells as the result of aging or some other metabolic derangement.

Biosynthesis and secretion of parathyroid hormone

The production of parathyroid hormone involves the biosynthesis of a large precursor on ribosomes of the rough endoplasmic reticulum in chief cells. This initial translation product is **pre-proparathyroid hormone** (pre-proPTH). It is composed of 115 amino acids and contains a hydrophobic signal sequence of 25 amino acid residues that facilitates the penetration and subsequent vectorial discharge of the nascent peptide into the cisternal space of the rough endoplasmic reticulum. Pre-proPTH is rapidly converted (within 1 min or less) to **proparathyroid hormone** (proPTH) by the proteolytic cleavage of 25 amino acids from the NH_2-terminal end of the molecule. The intermediate precursor, proPTH, is composed of 90 amino acids and moves within the membranous channels of the rough endoplasmic reticulum to the Golgi apparatus. Enzymes within membranes of the Golgi apparatus cleave a hexapeptide from the NH_2-terminal (biologically active) end of the molecule forming active parathyroid hormone. Active PTH is packaged into membrane-limited, macromolecular aggregates **(secretion granules)** in the Golgi apparatus for subsequent storage in chief cells. Under certain conditions of increased demand, PTH may be released directly from chief cells without being packaged into secretion granules.

Biologically active parathyroid hormone secreted by chief cells is a straight chain polypeptide consisting of 84 amino acid residues with a molecular weight of 9500. Although the principal form of active parathyroid hormone secreted from chief cells is a straight chain peptide of 84 amino acids, the molecule is rapidly cleaved into amino-and-carboxy-terminal fragments in the peripheral circulation and especially in the liver. The purpose of this fragmentation is uncertain since the biologically active amino-terminal fragment is no more active than the entire (1-84) PTH molecule. The plasma half-life of the N-terminal fragment is considerably shorter than that of the biologically inactive carboxy-terminal fragment of parathyroid hormone. The C-terminal and other portions of the PTH molecule are degraded primarily in the kidney and tend to accumulate in the circulation with chronic renal disease.

Chief cells synthesize and secrete another major protein termed **"parathyroid secretory protein (I)"** or **chromogranin A**. It has a higher molecular weight than PTH being composed of 430–448 amino acids, and is *co-stored and secreted with parathyroid hormone.* A similar molecule has been found in secretory granules of a wide variety of peptide–hormone-secreting cells (e.g., thyroid C cells, pancreatic islets, adrenal medulla, endocrine cells of the gastrointestinal tract, among others) and in neurotransmitter secretory vesicles of sympathetic nerves. An internal region of the parathyroid secretory protein or chromogranin A molecule is identical in sequence to **pancreastatin**, a C-terminal amidated peptide that inhibits glucose-stimulated insulin secretion. This 49 amino acid proteolytic cleavage product (240–280 amino acids) of parathyroid secretory protein *inhibits low calcium-stimulated secretion of parathyroid hormone and chromogranin A from parathyroid cells.* These findings suggest that one function of chromogranin A-derived peptides is to act locally in an autocrine manner to inhibit the secretion of active hormone by endocrine cells, such as those of the parathyroid gland.

Chromogranin A (CGA) shares considerable homology between species. Immunologic cross reactivity to mammalian proteins has been observed in reptiles, amphibians, fish, and *Drosophila* tissues. Chromogranin A is synthesized as a pre-protein and is directed to the internal cavity of the rough endoplasmic reticulum (RER) by the N-terminal pre-region of the peptide. Once inside the RER, the pre-region is cleaved by a signal peptidase. *Although the functions of CGA are still under investigation, several roles have been postulated.* Chromogranin A is suspected to play an important role in the maturation of secretory granules. Inside the Golgi apparatus, CGA is involved in the packaging of contents into newly formed vesicles. Chromogranin A precipitates as it diffuses into the trans-Golgi network. Other secretory products such as parathyroid hormone become entrapped in the growing CGA conglomerate and subsequently are packaged into a secretory granule. Chromogranin A has a large calcium-binding capacity that may enhance vesicle stability. As secretory granules mature, they accumulate large amounts of calcium (up to 40 mmol/L), which also may serve as a route of Ca^{2+} secretion. However, free (ionized) calcium concentrations remain in the micromolar range since most Ca^{2+} is bound to CGA. Chromogranin A-calcium complexes are important in maintaining the integrity of the secretory granule, since the absence of calcium will cause dissociation of protein complexes and result in osmotic lysis of the vesicle. Therefore, *the intragranular functions of CGA include hormone packaging, stabilization of the granule against osmotic gradients, and excretion of intracellular calcium.*

During the process of secretion, the contents of secretory granules are extruded into the pericapillary spaces. The pH and calcium concentration of the extracellular fluid promote dissociation of CGA complexes and solubilization of its bound calcium and other contents of the granule. Once solubilized, extracellular peptidases cleave CGA into biologically active peptides that act as paracrine or autocrine regulators of secretion. Most of the CGA-derived peptides have been reported to decrease hormone secretion.

Secretory cells in the parathyroids of most animals store relatively small amounts of preformed hormone but are capable of responding to minor fluctuations in calcium ion concentration by rapidly altering the rate of hormonal secretion, and more slowly by altering the rate of hormonal synthesis. In contrast to most endocrine organs that are under complex controls, *the parathyroids have a unique feedback control system based primarily on the concentration of calcium (and to a lesser extent of magnesium) ion in blood.* If the blood calcium is elevated, then circulating levels of parathyroid hormone rapidly and markedly decrease. Conversely, if the blood calcium is lowered, parathyroid hormone levels increase. The concentration of blood phosphorus has no direct regulatory influence on the synthesis and secretion of the hormone; however, certain disease conditions with hyperphosphatemia are associated clinically with secondary hyperparathyroidism. An elevated blood phosphorus level may lead indirectly to parathyroid stimulation by virtue of its ability to lower blood calcium according to the mass-law equation when the serum is saturated with these two ions. Hyperphosphatemia also suppresses the rate of formation of the biologically active, hormonal form of vitamin D_3 (1,25-dihydroxycholecalciferol) in the kidney, which further contributes to the development of hypocalcemia and parathyroid stimulation.

Magnesium ion has an effect on parathyroid secretory rate similar to that of calcium, but its effect is not equipotent to that of calcium. The more potent effects of calcium ion in the control of parathyroid hormone secretion, together with its preponderance over magnesium in the extracellular fluid, suggest a *secondary role* for magnesium in parathyroid control.

Calcium ion controls not only the rate of biosynthesis and secretion of parathyroid hormone, but also other metabolic and intracellular degradative processes within chief cells. Increased calcium ion in extracellular fluids rapidly inhibits the uptake of amino acids by chief cells, synthesis of proparathyroid hormone and conversion to active parathyroid hormone, and secretion of the stored hormone. The shifting of the percentage of flow of proparathyroid hormone from the degradative pathways to the synthetic route represents a key adaptive response of the parathyroid gland to a low-calcium diet. During periods of long-term calcium restriction, the enhanced synthesis and secretion of parathyroid hormone is accomplished by an increased capacity of the entire pathway in individual chief cells and subsequently through hyperplasia of active chief cells. Recently synthesized and processed active parathyroid hormone may be released directly in response to increased demand and bypass the chief cell's storage pool of mature secretory granules in the cytoplasm. *Bypass secretion of parathyroid hormone* can be stimulated only by a low circulating concentration of calcium ion and not by other secretagogues such as cyclic adenosine monophosphate and beta agonists (epinephrine, norepinephrine and isoproterenol) for parathyroid hormone. Degradation of "mature parathyroid hormone" by lysosomal enzymes occurs after prolonged exposure of chief cells to a high calcium environment.

Serum calcium ion (Ca^{2+}) binds to a Ca receptor on the chief cell that permits the serum Ca^{2+} to regulate chief cell function. The receptor is present on the plasma membranes of parathyroid chief cells, renal epithelial cells, and other cells that respond to extracellular Ca^{2+}. Mutations in one or both of the Ca^{2+}-sensing receptor genes in humans result in familial hypocalciuric hypercalcemia or neonatal severe hypercalcemia, respectively. Interaction of serum Ca^{2+} with its receptor on chief cells results in the formation of an inverse sigmoidal relationship between serum Ca^{2+} and PTH concentrations. The serum $[Ca^{2+}]$ that results in half maximal PTH secretion is defined as the serum calcium "set-point" and is stable for an individual animal. The sigmoidal relationship between serum [Ca^{2+}] and PTH secretion permits the chief cells to respond rapidly to a reduction in serum Ca^{2+}. *The major inhibitors of PTH synthesis and secretion are increased serum [Ca^{2+}] and 1,25-dihydroxyvitamin D_3.* Inhibition of PTH synthesis by 1,25-dihydroxyvitamin D_3 completes an important endocrine feedback loop between the parathyroid chief cells and the renal epithelial cells, since PTH stimulates renal production of 1,25-dihydroxyvitamin D_3.

Biologic action of parathyroid hormone

Parathyroid hormone is the principal hormone involved in the minute-to-minute, fine regulation of blood calcium. It exerts its biologic actions by directly influencing the function of target cells primarily in bone and kidney, and indirectly in the intestine.

The action of PTH on bone is to mobilize calcium from skeletal reserves into extracellular fluids. The administration of parathyroid hormone causes an initial decline followed by a sustained increase in circulating levels of calcium. The transitory decrease in blood calcium probably results from a sequestration of calcium phosphate in bone and soft tissues. The subsequent increase in blood calcium results from an interaction of parathyroid hormone with osteocytes and (indirectly) osteoclasts in bone. The initial binding of parathyroid hormone to osteoblasts lining bone surfaces causes the cells to contract, thereby exposing the underlying osteoid-covered bone matrix. Osteoblasts secrete latent collagenase and neutral proteases that result in degradation of the osteoid and expose the underlying bone mineral, which attracts osteoclasts.

The response of bone to parathyroid hormone is *biphasic*. The immediate effects are the result of increasing the activity of existing osteoclasts and osteocytes present in bone. This results in an increased flow of calcium from deep in bone-to-bone surfaces through the coordinated action of osteocytes and endosteal lining cells (inactive osteoblasts). Osteoclasts are primarily responsible for the long-term action of parathyroid hormone on increasing bone resorption and overall bone remodeling. If the increase in parathyroid hormone is sustained, the active osteoclast pool in bone is increased and the mineral and organic components (e.g., hydroxyproline) released from bone are released into the extracellular fluid compartment. A long-term increase in parathyroid hormone secretion, such as occurs with certain disease conditions, may also result in the formation of greater numbers of osteoblasts with a resultant increase in bone formation as well as resorption. However, bone resorption usually is greater than bone formation, leading to a net negative skeletal balance.

Osteoclasts are primarily responsible for the catabolic action of PTH on bone by increasing resorption. PTH not only stimulates increased activity of preformed osteoclasts, but increases their differentiation from precursor cells of the osteoclast lineage. However, receptors for PTH are present on osteoblasts, not on osteoclasts. Isolated osteoclasts respond to PTH only in the presence of osteoblasts. The mechanism by which binding of PTH to osteoblasts results in stimulation of osteoclasts appears to include direct effects on the osteoblast as well as the local release of factors by osteoblasts that are capable of stimulating osteoclastic bone resorption (Fig. 3.27).

Bone resorption is a complex, multistep, process that involves the activation of multiple genes and the action of multiple hormones. Most hormones and cytokines that are involved in the regulation of bone resorption (e.g., parathyroid hormone, calcitriol, interleukin-1β, tumor necrosis factor (TNF), interleukin-6, prostaglandin E_2) act via receptors on osteoblasts. Three new family members of the TNF ligand and receptor signaling system that have been identified and cloned recently play a critical role in the regulation of bone resorption. In the presence of permissive concentrations of macrophage colony-stimulating factor (M-CSF), these three new TNF superfamily molecules constitute the common pathway for regulation of osteoclast formation and function by cells of the osteoblast lineage, thereby mediating the biologic effects of many upstream hormones and cytokines.

The **receptor ligand (RANK ligand** or **RANKL)** is a membrane-bound protein on osteoblasts that serves as a common mediator for osteoclastic bone resorption. This ligand (initially termed **osteoclast differentiation factor (ODF)** and **osteoprotegrin ligand (OPGL)**) is produced by osteoblast lineage cells and *stimulates differentiation of cells of the osteoclast lineage, enhances the functional activity of mature osteoclasts, and prolongs osteoclast life by inhibiting apoptosis.* Targeted deletion of the receptor ligand in mice leads to osteopetrosis, shortened bones, impaired tooth eruption, and immunologic abnormalities. Expression of RANKL on RNA in osteoblasts/stromal cells is up-regulated by osteotrophic factors such as calcitriol, PTH, and interleukin-11. This molecule is identical to TNF-related activation-induced cytokine (TRANCE) or receptor activator of NF-kappa B ligand (RANKL) reported to stimulate T-cell growth and dendritic cell function in the immunology literature.

The **membrane receptor (RANK)** for the ligand (RANKL) on cells of the osteoclast lineage is identical with a receptor of similar name identified previously on immune cells. The receptor also has been referred to in the literature as **osteoclast differentiation and activation receptor (ODAR)**. *Binding of the ligand to this receptor activates signaling pathways in osteoclasts that lead to increased functional activity.* Osteoclast precursors express RANK, recognize RANKL through cell-to-cell interaction with osteoblasts/stromal cells, and differentiate into prefusion osteoclasts in the presence of M-CSF. Mice made deficient in RANK by targeted deletion of the gene develop severe osteopetrosis due to decreased osteoclast function and fail to develop peripheral lymph nodes.

Osteoprotegrin (OPG) ("decoy receptor") is a novel member of the TNF receptor superfamily produced by cells of the osteoblast lineage/stromal cells and a negative regulator of bone resorption. *When this soluble decoy receptor binds to the ligand (RANKL), it prevents the ligand from binding to its biological membrane receptor (RANK) thereby resulting in its inactivation.* Overexpression of this decoy receptor in transgenic mice leads to osteopetrosis associated with decreased osteoclast formation and function. In contrast, targeted gene ablation in mice results in severe osteoporosis and arterial mineralization.

These findings clearly indicate that *the microenvironment in bone marrow provided by osteoblast lineage/stromal cells regulates osteoclast differentiation and function.* Osteoclast formation appears to be determined by the ratio of RANKL:OPG, and alterations in this ratio may be a major cause of bone loss in certain metabolic disorders such as estrogen deficiency and glucocorticoid excess.

Binding of PTH to specific receptors on bone cells results in the activation of adenylate cyclase in the plasma membrane. Adenylate cyclase catalyzes the conversion of ATP to cAMP in target cells. Accumulation of cAMP in target cells functions as an intracellular

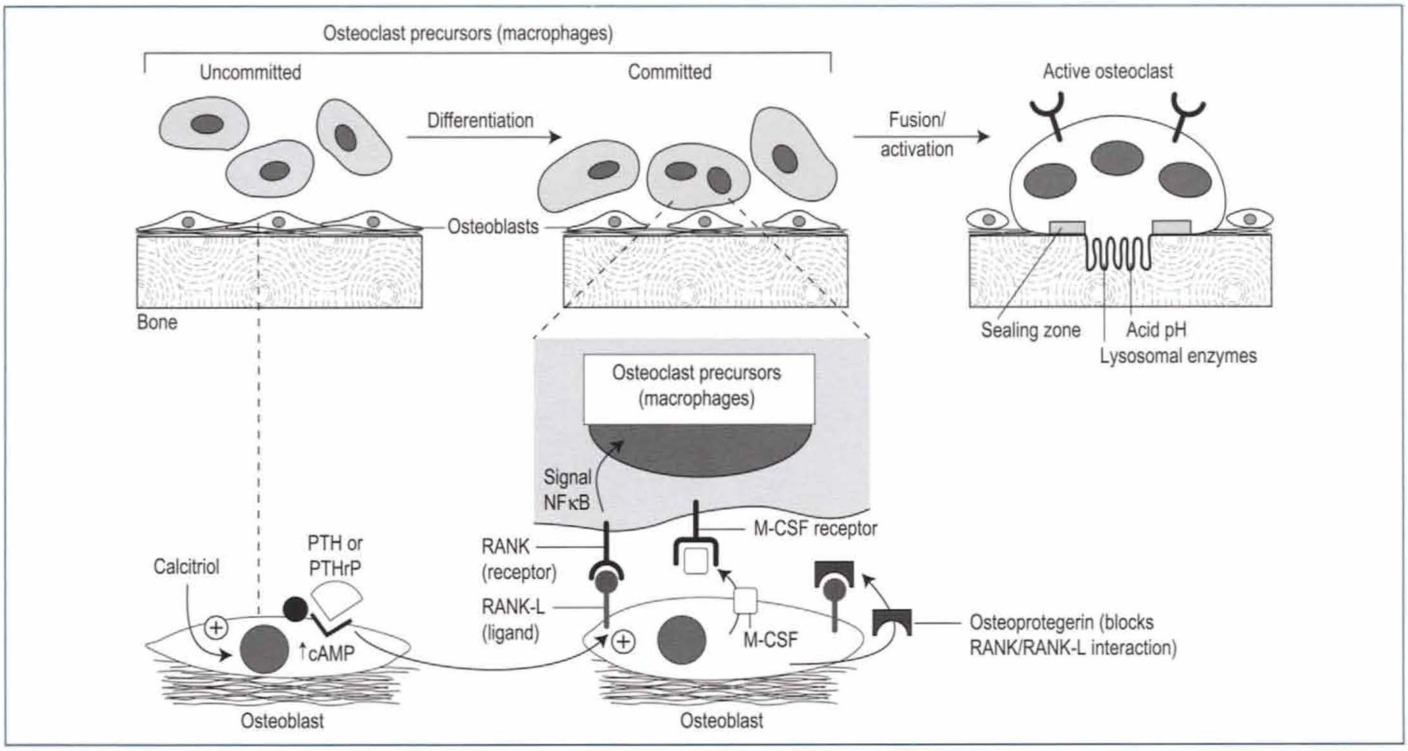

Figure 3.27 Cellular control of bone resorption. Specific receptors for parathyroid hormone (PTH) are present on osteoblasts but not on osteoclasts. RANK-L, or osteoclast differentiation factor, is produced by cells of the osteoblast lineage, serves as a common mediator for osteoclastic bone resorption, and its expression is up-regulated by osteotrophic factors such as PTH, PTHrP and calcitriol. M-CSF = macrophage colony stimulating factor; R = receptor for either PTH or PTHrP; RANK-L = receptor activator NF-kappa B ligand.

messenger of PTH action in osteoblasts. Parathyroid hormone also induces an increase in cytoplasmic calcium and stimulates phosphatidylinositol turnover in osteoblasts. The increase in cytosolic calcium is partially dependent on cAMP accumulation. Calcium concentration in the osteoblast may also be increased by the activation of protein kinase C, resulting in the production of inositol triphosphate and subsequent release of calcium from the endoplasmic reticulum. PTH also appears to use a second intracellular messenger in target cells by stimulating inositol triphosphate and diacylglycerol production.

Parathyroid hormone has a rapid (5–10 min) and direct effect on renal tubular function leading to decreased reabsorption of phosphorus and phosphaturia. The site where PTH blocks tubular reabsorption of phosphorus has been localized by micropuncture methods to the proximal tubule of the nephron. PTH binds to a receptor on the basolateral aspect of renal epithelial cells. The hormone stimulates adenylate cyclase, increases intracellular cAMP, and inhibits phosphorus reabsorption across the brush border through the actions of protein kinases. The parathyroid hormone receptor has been cloned and sequenced from cDNA isolated from kidney cells. The PTH receptor has a striking degree of sequence homology (~56%) with the calcitonin receptor, but lacks similarity with other G protein-linked receptors. The receptors for these calcium-regulating hormones belong to a family of G protein-linked receptors with seven transmembrane spanning domains that activate adenylate cyclase.

Although the effects of PTH on the tubular reabsorption of phosphorus have been considered to be of major importance, there is substantial evidence that the ability of PTH to enhance the reabsorption of calcium contributes in a significant manner to the maintenance of calcium homeostasis. *This effect of PTH upon tubular reabsorption of calcium appears to be due to a direct action on the distal convoluted tubule.* The biochemical mechanism by which PTH enhances calcium reabsorption also is coupled to increases in intracellular cAMP.

The other important effect of parathyroid hormone is the regulation of the conversion of inactive 25-hydroxycholecalciferol to biologically active (1,25-dihydroxycholecalciferol) and other metabolites of vitamin D_3. Under normal conditions parathyroid hormone is secreted continuously from chief cells. In the liver, kidney, peripheral circulation, and at target cells, PTH is cleaved into a biologically active (N-terminal) and a biologically inactive C-terminal portion.

Age-related changes in the parathyroid gland

Parathyroid structure has been evaluated by light and electron microscopy in neonatal (2–6 days of age), growing (2–5 months), and adult (2–3 years) dogs. **Dark (active) chief cells** with an electron-dense cytoplasm, prominent rough endoplasmic reticulum and Golgi apparatuses, numerous membrane-limited secretory granules, and frequent interdigitations of the plasma membrane predominated in the parathyroid glands of growing and adult dogs. Parathyroid glands of neonatal dogs were different, with more numerous **light (inactive) chief cells** that were interpreted to be cells in transitional stages with slightly distended cisternae of rough endoplasmic reticulum, inconspicuous Golgi apparatuses, and few secretory granules. Ultrastructural morphometric analysis has established that the volume of the predominant parathyroid cell in neonatal dogs is significantly less than that of chief cells of growing dogs, but the cell surface was not significantly different between groups. The volume of chief cells occupied by mitochondria, rough endoplasmic reticulum, and lysosomes in growing dogs is greater than in neonatal dogs, but the surface of the Golgi apparatus and rough endoplasmic reticulum did not differ between groups. These findings suggest that the secretory activity is greater in parathyroid glands of neonatal dogs than in those of growing dogs. *The storage capacity for PTH is low in the canine parathyroid gland (similar to other species), and the biosynthesis of PTH by chief cells can be stimulated or inhibited within minutes by changes in the circulating concentration of calcium ion.*

Thyroid C cells and calcitonin

Development and structure of thyroid C cells

A second calcium-regulating hormone, **calcitonin**, secreted by the **thyroid C cells** in response to hypercalcemia, lowers plasma calcium. C cells are distinct from follicular cells, which secrete thyroxine and triiodothyronine. They are situated either within the follicular wall between follicular cells or as small groups between follicles. They do not border the follicular colloid directly, and their secretory polarity is oriented toward the interfollicular capillaries.

The **ultimobranchial body** (last, usually fifth pharyngeal pouch), which delivers the neural crest-derived C cells to the postnatal thyroid gland, fuses with each thyroid lobe at the hilus and distributes C cells throughout each lobe to various degrees in different species. In the dog, nodular aggregates of C cells frequently persist along the course of the major vessels to the thyroid. There are occasional ultimobranchial-derived, colloid-containing follicles within the focal accumulations of C cells along the course of vessels within the thyroid lobe or in the connective tissues of the thyroid hilus in dogs. Islands of lightly stained cells, termed **C-cell complexes**, are present in the thyroid glands (especially prominent in dogs) often near the internal parathyroid gland. They are remnants of the ultimobranchial body that can give rise to thyroid follicles and C cells, and should not be misinterpreted as areas of C-cell hyperplasia. *C-cell complexes in the thyroid gland contain four cell types*:

1. *follicular cells* that stain positive for thyroglobulin,
2. *C cells* staining positive for calcitonin, calcitonin gene-related peptide, and neuron-specific enolase,
3. *stellate and cuboidal cells* forming follicle-like structures that stain positive for somatostatin, and
4. *undifferentiated cells* staining negative for all antigens.

The C-cell complex may be the origin of the unique **mixed thyroid carcinoma** (differentiated thyroid carcinoma, intermediate type) in human patients or **ultimobranchial thyroid neoplasms** in bulls that are composed of cells that have a positive immunoreactivity for both thyroglobulin and calcitonin.

Cysts derived from remnants of the ultimobranchial body are observed frequently in the postnatal thyroid of rats lined by squamous epithelium and containing keratin debris. Occasional follicles derived from ultimobranchial primordia contain heterogeneous material in the lumen and scattered ciliated epithelial cells in the follicular wall. In rats, CT-immunoreactive cells have been demonstrated in the wall of the ultimobranchial tubule as well as thyroglobulin-positive staining in adjacent follicles and solid clusters. These findings, plus the presence of numerous mitoses and PAS-positive microfollicles, support the hypothesis that the ultimobranchial body contributes to the formation of follicles in certain areas of the thyroid lobes.

In submammalian species, C cells and calcitonin activity remain segregated in the **ultimobranchial gland**, which is anatomically distinct from both the thyroid and the parathyroid glands. In the avian ultimobranchial gland, a network of stellate cells with long cytoplasmic processes supports the C cells.

The concentration of calcium ion in plasma and extracellular fluids is the principal physiologic stimulus for the secretion of calcitonin by C cells. Calcitonin is secreted continuously under conditions of normocalcemia, but the rate of secretion is increased greatly in response to elevations in blood calcium. Magnesium ion has an effect on calcitonin secretion similar to that of calcium, but this effect is observed only under experimental conditions with nonphysiologic levels.

Biosynthesis and secretion of calcitonin

The complete amino acid sequence of porcine, bovine, ovine, canine, salmon, and other animal species, as well as human calcitonin has been determined. Synthetic human calcitonin has been prepared and shown to be biologically active. The structure of calcitonin differs considerably between species. The molecules in 8 selected species share only 9 of the 32 amino acid residues. However, the amino terminal of the calcitonin molecule is similar in all species. It consists of a seven-membered ring enclosed by an intrachain disulfide bridge. The complete sequence of 32 amino acids and the disulfide bond are essential for full biologic activity. Salmon calcitonin is more potent in lowering blood calcium on a weight basis than any of the other calcitonins when administered to mammals, including humans. The reason for the greater biologic potency of salmon calcitonin in mammals is uncertain but probably is related to an increased resistance to metabolic degradation or a greater affinity for receptor sites in bone and other target tissues.

Hyperplasia of C cells occurs in response to long-term hypercalcemia. When the blood calcium is lowered, the stimulus for calcitonin secretion is diminished and numerous secretory granules accumulate in the cytoplasm of C cells. The storage of large amounts of preformed hormone in C cells and rapid release in response to moderate elevations in blood calcium probably reflect the *physiologic role of calcitonin as an "emergency" hormone to protect against the development of hypercalcemia.*

Calcitonin secretion is increased in response to a high-calcium meal, often before a significant rise in plasma calcium can be detected. The cause of this increase in calcitonin secretion could be either a small undetectable rise in plasma ionized calcium or direct stimulation by the oral calcium load of certain gastrointestinal hormones, which in turn act as secretagogues for calcitonin release from the thyroid gland. Gastrin, pancreozymin, and glucagon all stimulate calcitonin release under experimental conditions. Thus **gastrointestinal hormones** may be important in triggering the early release of calcitonin to prevent the development of hypercalcemia following ingestion of a high-calcium meal.

Biologic action of calcitonin

Calcitonin exerts its function by interacting with target cells primarily in bone and kidney. *The actions of parathyroid hormone and calcitonin are antagonistic on bone resorption but synergistic on decreasing the renal* *tubular reabsorption of phosphorus*. The hypocalcemic effects of calcitonin are primarily the result of decreased entry of calcium from the skeleton into plasma due to transient inhibition of parathyroid hormone-stimulated bone resorption. The hypophosphatemia develops from a direct action of calcitonin increasing the rate of movement of phosphate out of plasma into soft tissue and bone, as well as from the inhibition of bone resorption. The action of calcitonin is not dependent on vitamin D, since it acts both in vitamin D-deficient animals and following the administration of large doses of vitamin D.

The action of calcitonin on inhibiting bone resorption stimulated by parathyroid hormone and other factors results from blockage of osteoclastic bone resorption. Calcitonin produces specific structural alterations osteoclasts, which have specific receptors for the hormone on their surfaces. Osteoclasts withdraw from resorptive surfaces and the brush border and transitional zone become atrophic. In addition, there are fewer osteoclasts in bone. Although calcitonin can block bone resorption completely, the inhibition is a transient effect. Eventually the effects of parathyroid hormone on increasing bone resorption become manifest in the presence of calcitonin.

Both calcitonin and parathyroid hormone decrease renal tubular reabsorption of phosphate, leading to phosphaturia; however, the adenylate cyclase-linked receptors for calcitonin are found in the ascending limb of the loop of Henle and the distal convoluted tubule. In addition, calcitonin results in diuresis of sodium, chloride, and calcium, whereas parathyroid hormone causes renal retention of calcium and hydrogen ions.

Serum calcitonin is best measured by radioimmunoassay. Due to the low degree of homology of calcitonin between species, there is poor cross-reactivity of radioimmunoassays (RIAs) for calcitonin. In veterinary medicine, the need to measure circulating levels of calcitonin is associated with calcitonin-secreting thyroid neoplasms and other clinical disorders resulting from abnormal blood levels of calcitonin. In humans, calcitonin RIA is useful to identify functional C-cell (medullary) tumors of the thyroid gland. RIAs for calcitonin are necessary also to experimentally investigate regulation of C cells in vivo or in vitro. Since the sequencing of canine calcitonin, a canine-specific RIA has been developed and has been used to measure serum calcitonin in dogs.

Calcitonin and parathyroid hormone, acting in concert, provide a dual negative feedback control mechanism to maintain the concentration of calcium in extracellular fluids within narrow limits. Parathyroid hormone is the major factor involved in the minute-to-minute regulation of blood calcium under normal conditions. In most higher mammals that live in a relatively low-calcium high-phosphorus environment, protection against the development of hypocalcemia by parathyroid hormone is a life-sustaining function. *Calcitonin appears to function more as an "emergency" hormone* to prevent the development of hypercalcemia during the rapid postprandial absorption of calcium and to protect against excessive loss of calcium and phosphorus from the maternal skeleton during pregnancy.

Cholecalciferol (vitamin D_3)

Biosynthesis of vitamin D_3 and metabolites

The third major hormone involved in the regulation of calcium metabolism and skeletal remodeling is **cholecalciferol** or **vitamin D_3**. *Although this compound has been designated a vitamin for a long time, it can equally be considered a hormone.* Cholecalciferol is ingested in small amounts in the diet and can be synthesized in the epidermis from precursor molecules (e.g., 7-dehydrocholesterol) through a previtamin D_3 intermediate form. This reaction is catalyzed by ultraviolet irradiation (wave length 2900–3200 Å) from the sun. A high-affinity vitamin D-binding protein transports cholecalciferol in the blood.

Vitamin D must be metabolically activated before it can produce its known physiologic functions. Vitamin D_3 from dietary sources is absorbed by facilitated diffusion and bound to an α-2 globulin in the blood for transport. Endogenous cholecalciferol synthesized in the skin from 7-dehydrocholesterol also is protein-bound for transport to the liver. In the liver, cholecalciferol is converted to 25-hydroxycholecalciferol ($25(OH)D_3$) by a hepatic microsomal enzyme, **calciferol-25-hydroxylase**, which is associated with the endoplasmic reticulum in hepatocytes.

This first (inactive) metabolite, 25-hydroxycholecalciferol ($25(OH)D_3$), is transported to the kidney and undergoes further transformation to a more polar active metabolite, 1,25-dihydroxycholecalciferol ($1,25(OH)_2D_3$). Other metabolites are formed, such as 24,25-dihydroxycholecalciferol ($24,25(OH)_2D_3$). The formation of $1,25(OH)_2D_3$ is catalyzed by **25-hydroxycholecalciferol-1-α-hydroxylase** (1-α-hydroxylase) in mitochondria, primarily in cells of the proximal convoluted tubule. *The conversion of $25(OH)D_3$ to $1,25(OH)_2D_3$ is the rate-limiting step in vitamin D metabolism* and is the primary reason for the delay between vitamin D administration and expression of its biologic effects.

The control of this final step in the metabolic activation is complex and is regulated in part by the plasma calcium concentration and its influence on the rate of secretion of parathyroid hormone. Parathyroid hormone and conditions that stimulate its secretion increase the transformation of $25(OH)D_3$ to $1,25(OH)_2D_3$. Low blood phosphorus increases the formation of $1,25(OH)_2D_3$, whereas high blood phosphorus suppresses the activity of the 1-α-hydroxylase (Fig. 3.28).

The rates of synthesis of $24,25(OH)_2D_3$ and $1,25(OH)_2D_3$ appear to be reciprocally related and controlled by similar factors. When $1,25(OH)_2D_3$ synthesis increases, the synthesis of $24,25(OH)_2D_3$ declines, and vice versa. $24,25(OH)_2D_3$ may play a role in bone formation and egg hatchability in certain animals, and with $1,25(OH)_2D_3$ may exert negative feedback control on the parathyroid gland.

Other hormones also may increase the activity of renal 1-α-hydroxylase and the formation of $1,25(OH)_2D_3$ under certain conditions. Prolactin, estradiol, placental lactogen, and somatotropin all enhance 1-α-hydroxylase activity. Increased secretion of these hormones, either alone or in combination, appears to be important in the efficient adaptation to major calcium demands, such as pregnancy, lactation, and growth.

Biologic action of hormonal form of vitamin D

The active metabolites of vitamin D increase the absorption of calcium and phosphorus from the intestine. From a functional point of view, *vitamin D can be thought to bring about the retention of sufficient mineral ions to ensure mineralization of bone matrix*, whereas *parathyroid hormone maintains the proper ratio of calcium to phosphate in extracellular fluids*.

The major target tissue for $1,25(OH)_2D_3$ is the mucosa of the small intestine, where it increases the active transcellular transport

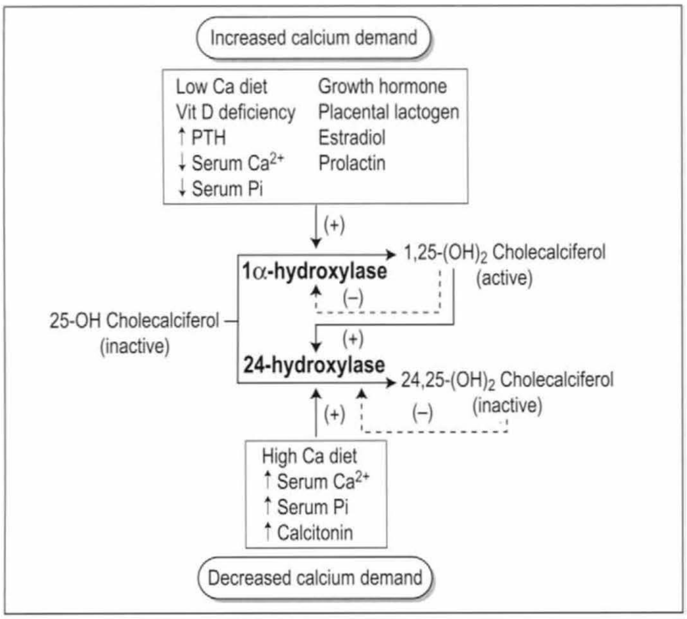

Figure 3.28 Multifactorial control of the final step of metabolic activation of vitamin D in the kidney. Conditions associated with increased calcium demand result in the stimulation of the production of 1,25-$(OH)_2$ cholecalciferol from 25-OH cholecalciferol by increasing the activity of 1α-hydroxylase in the mitochondria of renal tubular cells. Under conditions of decreased calcium demand, the production of 1,25-$(OH)_2$-cholecalciferol is diminished and 24,25-$(OH)_2$-cholecalciferol (an inactive metabolite) is formed by the enzymatic action of a 24-hydroxylase.

of calcium (proximal part) and phosphorus (distal part). Following synthesis in the kidney, 1,25$(OH)_2D_3$ is transported in a protein-bound form to specific target cells in the intestine and bone. Free 1,25$(OH)_2D_3$ penetrates the plasma membrane of target cells and initially may bind to a cytoplasmic receptor in cells of the intestine. However, the hormone–receptor complex is rapidly transferred to the nucleus, and 1,25$(OH)_2D_3$ binds to specific receptors in the nuclear chromatin. In the nucleus, it stimulates gene expression with increased messenger RNA formation, which directs the synthesis of vitamin D-dependent proteins.

Intestinal absorptive cells are concerned with the transport of calcium from the lumen to the blood stream and in response to 1,25$(OH)_2D_3$ they synthesize a specific **calcium-binding protein** (CaBP, calbindin). The highest concentration of CaBP is at the luminal aspect of intestinal absorptive cells, where it complexes with calcium ions for transport to the basolateral aspect of the cell. Calcium-binding protein has also been isolated from kidney, parathyroid gland, and the shell gland of laying hens, and a vitamin D-dependent calcium binding protein is present in bone, particularly in the spongiosa and cartilaginous growth plate.

The absorptive capacity of the intestine for calcium is a direct function of the amount of CaBP present. Vitamin D or low-calcium diets stimulate the synthesis of CaBP. The physiologic function of CaBP may be to protect absorptive cells against high cytosolic concentrations of calcium ion during the transcellular transport of calcium from the luminal border to the laterobasilar border of intestinal cells. At the basilar aspect of intestinal absorptive cells, calcium is exchanged for sodium and enters the extracellular fluids.

The active metabolites of cholecalciferol also act on bone. Rickets and osteomalacia develop in young and mature animals respectively, when it is deficient (see Vol. 1, Bones and joints). Vitamin D also is necessary for osteoclastic resorption and calcium mobilization from bone in adults. Small amounts of active vitamin D metabolite are necessary to permit osteolytic cells to respond to parathyroid hormone ("permissive effect") under physiologic conditions. Both 25$(OH)D_3$ and 1,25$(OH)_2D_3$, and vitamin D_3 in pharmacologic doses, stimulate osteoclastic proliferation and the resorption of bone.

Less is known regarding the action of cholecalciferol and its active metabolite on the kidney. *The active metabolite(s) of vitamin D appear to stimulate the retention of calcium by increasing renal tubular reabsorption, probably in the distal part of the nephron.* The active metabolite may have a direct effect on the parathyroid gland, in addition to its well-characterized action on intestine and bone.

Most assays for vitamin D and its metabolites used clinically employ competitive protein or radioreceptor techniques using vitamin-D-binding proteins isolated from tissues and tritium-labeled tracers; however, newer ^{125}I-based radioimmunoassays have been developed. 25$(OH)D_3$ and 1,25$(OH)_2D_3$ are the most frequently measured metabolites in clinical veterinary medicine. Because the structures of the common vitamin D metabolites do not vary between species, the same assays can be used to measure serum metabolites in animals and humans. *1,25$(OH)_2D_3$ is the most potent metabolite in regulating calcium balance; therefore, its measurement is often necessary to understand abnormal calcium regulation.* The circulating concentration of 1,25$(OH)_2D_3$ is approximately 25 pg/mL (65 pmol/L) in adult animals and is greater in younger animals. Measurement of serum 25$(OH)D_3$ is useful to evaluate the potential of dietary vitamin D deficiency or excess since serum levels are much greater and less tightly controlled compared to 1,25$(OH)_2D_3$. Normal serum concentrations of 25$(OH)D_3$ are 10–50 ng/mL (25–125 nmol/L). Animals that have ingested excess vitamin D may have serum 25$(OH)D_3$ concentrations 4- to 20-fold greater than normal.

Disorders of vitamin D metabolism

Deficiency of vitamin D results not only from simple dietary lack or inadequate exposure to sunlight, but also from a deficiency of the hydroxylase enzymes essential for metabolic activation of precursor molecules. **Vitamin D-dependent rickets, type I,** *in both pigs and humans, is a familial disease inherited as an autosomal recessive.* Newborn pigs appear healthy and have normal blood calcium and phosphorus concentrations. At 4–6 weeks of age, blood Ca and P decrease, serum alkaline phosphatase activity increases, and clinically detectable rickets develops during the following 3–4 weeks. The pigs develop deformities of bone in the axial and appendicular skeleton, severe pain, and classic lesions of rickets. Serum 25$(OH)D_3$ levels are markedly increased compared to those of control pigs whereas serum 1,25$(OH)_2D_3$ levels are depressed in rachitic pigs compared with normal pigs. Homozygous, rachitic animals have no renal 25$(OH)D_3$-1-α-hydroxylase in kidney homogenates or mitochondrial preparations, which is responsible for the insufficient renal production of 1,25$(OH)_2D_3$.

Vitamin D-dependent rickets, type II, *is a group of disorders characterized by target organ resistance to 1,25$(OH)_2D_3$.* The disease is characterized by increased serum 1,25$(OH)_2D_3$ levels, hypocalcemia, secondary hyperparathyroidism, and clinically by rickets or osteomalacia. New World primates have a relative end-organ resistance to $1,25(OH)_2D_3$ and require high levels of vitamin D_3 in their diet. The common marmoset has been shown to represent a model of vitamin D-dependent rickets, type II. Marmosets have increased serum $1,25(OH)_2D_3$ concentrations compared to rhesus monkeys, and some marmosets developed osteomalacia even when on high vitamin D_3 diets. The resistance to $1,25(OH)_2D_3$ is likely due to low affinity binding of $1,25(OH)_2D_3$ to its nuclear receptor (see vitamin D-dependent rickets in Vol. 1, Bones and joints).

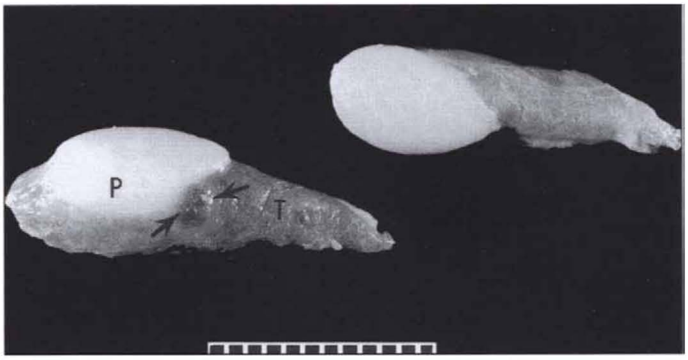

Figure 3.29 Parathyroid cyst adjacent to a hyperplastic parathyroid gland (P), from a dog with chronic renal failure. The cyst (arrows) was formed from the persistence and distention of the embryonic duct that connects parathyroid-thymic primordia in the III and IV pharyngeal pouches (Kürsteiner's cyst). T = thyroid gland. Scale in mm. (From Capen CC. In: Special Veterinary Pathology, 3rd ed., 2001.)

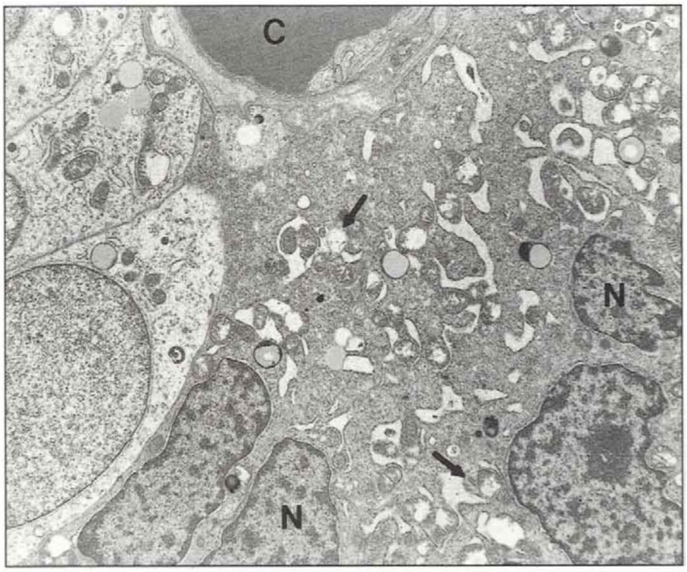

Figure 3.30 Syncytial ("giant") cell (right) and adjacent inactive chief cells (left) in canine parathyroid gland. The large cytoplasmic area of the syncytial cell is formed by the fusion of adjacent chief cells following the disruption of plasma membranes. The multiple nuclei (N) are smaller and more electron-dense than in normal chief cells (left), and they have condensed chromatin. The mitochondria are swollen with disruption of cristae in the syncytial cells, and profiles of endoplasmic reticulum are distended (arrows). C = capillary. (From Capen CC. In: Pathobiology of the Aging Dog, 2001.)

Diseases of the parathyroid gland

Parathyroid and related cysts

Parathyroid (Kürsteiner's) cysts are observed within the parenchyma of the parathyroid or in the immediate vicinity of the gland, frequently in dogs and occasionally in other animal species. Parathyroid cysts usually are small, multiloculated, lined by cuboidal to columnar (often ciliated) epithelium, and contain densely eosinophilic proteinaceous material. Chief cells adjacent to larger cysts may be moderately compressed. *Parathyroid cysts appear to be dilated remnants of the duct of pharyngeal pouches III and IV* that connects the parathyroid and thymic primordia during embryonic development (Figs. 3.25, 3.29). Similar cysts may be present in the cranial mediastinum when remnants of the embryonic duct are displaced with the caudal migration of the thymus. They are lined by pseudostratified columnar epithelium and contain proteinaceous material.

Other cystic structures may occur in the thyroid–parathyroid area:

- Midline cysts derived from remnants of the **thyroglossal duct** are lined by multi-layered thyroidogenic epithelium, which often has colloid-containing follicles, and usually are located on or near the midline, from the base of the tongue caudally into the mediastinum.
- **Ultimobranchial duct cysts** often are present in the parenchyma of the thyroid (near the thyroid hilus in ruminants) and have a keratinizing squamous epithelial lining. Ultimobranchial duct cysts are common in thyroids from laboratory rats. They are derived from remnants of the ultimobranchial body (last, usually fifth, pharyngeal pouch) that fuses with the lateral thyroid lobes during embryonic development, and distributes calcitonin-secreting C cells (derived from neural crest) into each thyroid lobe.
- **Branchial cysts** are located lateral to the parathyroid–thyroid area, often near the base of the ear and angle of mandible, attached deeply to cervical structures, and clinically are referred to as "*lateral neck cysts*." They are lined by pseudostratified columnar or focally squamous, partially ciliated, epithelium that is derived from remnants of the second pharyngeal pouch.
- **Salivary mucoceles** may also be present in the parathyroid–thyroid region. These cysts are lined only with granulation tissue that develops in response to the escape of saliva into the interstitium following disruption of a salivary duct.

Degenerative changes of the parathyroid gland

Parathyroid glands of dogs and rats may develop **multinucleated syncytial giant cells.** They often are more numerous near the periphery of the parathyroid gland, but this variable and considerable numbers can be present in the more central portions of the gland. The number of syncytial cells varies considerably between parathyroid glands in the same animal but may account for up to half of the parenchyma of the gland. They appear to form by the fusion of the cytoplasmic area of adjacent chief cells. The cytoplasm of syncytial cells is densely eosinophilic and homogeneous, and the plasma membranes between adjacent cells are often indistinct (Fig. 3.30). The nuclei are smaller, more hyperchromatic and oval, than those in adjacent chief cells.

The mechanism by which syncytial cells form is uncertain, but it does not appear to be related to improper fixation of the parathyroid, as they have been observed in glands perfused for electron microscopy. They usually do not occur in sufficient numbers to interfere significantly with parathyroid function.

Chemical-induced toxic injury of parathyroids

Ozone. Inhalation of a single dose of ozone for 4–8 hours has been reported to produce light and electron microscopic changes in parathyroid glands. In response to longer exposure to ozone, many chief cells undergo compensatory hypertrophy and hyperplasia with areas of capillary endothelial cell proliferation, interstitial edema, degeneration of vascular endothelium, formation of platelet thrombi, leukocyte infiltration of the walls of larger vessels in the gland, and disruption of basement membranes. Chief cells had prominent Golgi complexes and endoplasmic reticulum, aggregations of free ribosomes, and swollen mitochondria. Inactive chief cells with few secretory granules predominate in the parathyroids in the later stages of exposure to ozone. Plasma membranes of adjacent chief cells were disrupted resulting in coalescence of the cytoplasmic area. *The parathyroid lesions in ozone-exposed animals shared certain features with isoimmune parathyroiditis.* Antibody against parathyroid tissue was localized near the periphery of chief cells by indirect immunofluorescence.

Aluminum. Evidence for a direct effect of aluminum on the parathyroid was suggested from studies of patients with chronic renal failure treated by hemodialysis with aluminum-containing fluids or orally administered drugs containing aluminum. These patients often had normal or minimal elevations of immunoreactive parathyroid hormone (iPTH), little histological evidence of osteitis fibrosa in bone, and a depressed response by the parathyroid gland to acute hypocalcemia. An increase in aluminum concentration in vitro over a range of 0.5–2.0 mM in a low-calcium medium (0.5 mM) progressively inhibits the secretion of PTH. PTH secretion was inhibited by 68% at 2.0 mM aluminum, while high calcium-containing medium (2.0 mM) without aluminum maximally inhibited PTH secretion only 39%. The inhibition of PTH secretion by aluminum does not appear to be related to an irreversible toxic effect, because normal secretion was restored when parathyroid cells were returned to 0.5 mM calcium medium without aluminum. *Aluminum appears to decrease diglyceride synthesis*, which is reflected in a corresponding decrease in synthesis of phosphatidylcholine; however, phosphatidylinositol synthesis was not affected by aluminum.

L-asparaginase. Rabbits administered L-asparaginase develop severe hypocalcemia and tetany characterized by muscle tremors, opisthotonos, carpopedal spasms, paralysis, and coma. This drug was of interest in cancer chemotherapy because of the beneficial effects of guinea pig serum against lymphosarcoma in mice. *Parathyroid chief cells appeared to be selectively destroyed by L-asparaginase.* Chief cells were predominantly inactive and degranulated, with large autophagic vacuoles present in the cytoplasm of degenerating cells. Cytoplasmic organelles concerned with synthesis and packaging of secretory products were poorly developed in chief cells. Rabbits developed hyperphosphatemia, hypomagnesemia, hyperkalemia, and azotemia in addition to acute hypocalcemia. Rabbits with clinical hypocalcemic tetany did not recover spontaneously; however, administration of parathyroid extract prior to or during treatment with L-asparaginase decreased the incidence of hypocalcemic tetany.

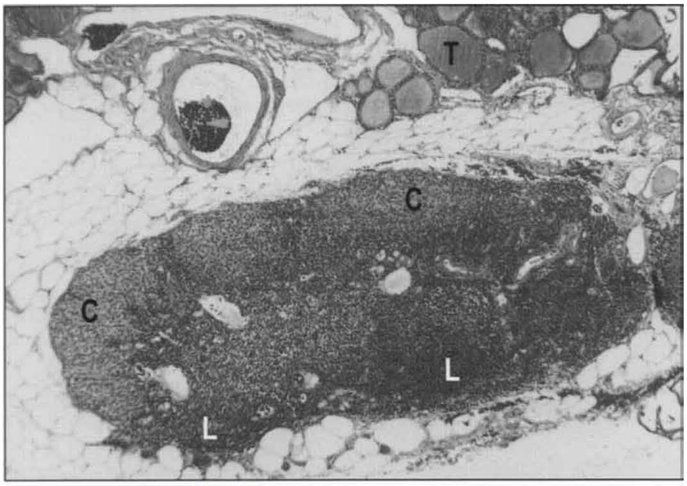

Figure 3.31 Lymphocytic parathyroiditis in a dog with hypocalcemia. There are multifocal areas of lymphocytic (L) infiltration and parenchymal destruction. In this early stage of the disease, there are multiple areas of nodular regenerative hyperplasia of chief cells (C). T = thyroid follicle.

Lymphocytic parathyroiditis and hypoparathyroidism

In hypoparathyroidism, either subnormal amounts of parathyroid hormone are secreted by pathologic parathyroid glands, or the hormone secreted is unable to interact normally with target cells. Hypoparathyroidism has been recognized in dogs, particularly in smaller breeds such as Schnauzers and Terriers, but infrequently in other animal species. *The functional disturbances of hypoparathyroidism primarily are the result of increased neuromuscular excitability and tetany.* Bone resorption is decreased because of a lack of PTH and blood calcium levels diminish progressively.

Several pathogenic mechanisms can result in inadequate secretion of parathyroid hormone. *Idiopathic hypoparathyroidism in adult dogs* is associated usually with diffuse lymphocytic parathyroiditis, resulting in extensive degeneration of chief cells and replacement by fibrous connective tissue. In the early stages, there is infiltration of the gland with lymphocytes and plasma cells, and nodular regenerative hyperplasia of remaining chief cells (Fig. 3.31). Later, the parathyroid gland is completely replaced by lymphocytes, fibroblasts, and neocapillaries, with only an occasional viable chief cell.

Lymphocytic parathyroiditis most likely is an immune-mediated disease. Similar lesions are produced in dogs by injection of parathyroid tissue emulsions and by repeated injections of parathyroid emulsions with Freund's adjuvant.

Other possible causes of hypoparathyroidism include invasion and destruction of parathyroids by primary or metastatic *neoplasms* in the cranial cervical region and trophic atrophy of parathyroids associated with long-term *hypercalcemia*. The parathyroid glands may be damaged or inadvertently removed during the course of *surgery* to remove thyroid tumors or multifocal hyperplasia ("goiter"). If the parathyroid glands or their vascular supply is intact but damaged, there is often regeneration of adequate functional parenchyma and subsequent disappearance of clinical signs. The presence of numerous *canine distemper virus* particles in chief cells of the parathyroid gland may contribute to the low blood calcium in certain dogs with this disease. *Agenesis* of both pairs of parathyroids is a rare cause of congenital hypoparathyroidism in pups.

Parathyroid stimulation associated with acute hypocalcemia near parturition

Parturient paresis *is a complex metabolic disease characterized by the development of severe hypocalcemia and hypophosphatemia near parturition and the initiation of lactation in dairy cattle.* The serum calcium (total and ionized) concentration falls to less than 50% of normal in spite of increased secretion of parathyroid hormone.

The parathyroid glands are capable of responding to the acute hypocalcemia by increased development of cellular organelles for hormonal synthesis and by the secretion of parathyroid hormone. Chief cells in the active stage of synthesis and secretion predominate in the parathyroid glands (Fig. 3.32A); however, decreased numbers of storage granules in chief cells suggest that the increased rate of hormone secretion exceeds the rate of synthesis by the gland. There is a significant increase in plasma parathyroid hormone levels in cows with parturient hypocalcemia as compared to normal parturient cows.

The composition of the prepartum diet is a significant factor in the pathogenesis of parturient hypocalcemia. High-calcium diets increase the incidence of the disease and low-calcium diets, or prepartum diets supplemented with pharmacologic doses of vitamin D, reduce the incidence of the disease.

Cows fed a high-calcium diet have higher blood calcium levels prepartum, but are less able to maintain serum calcium near the critical time of parturition. Plasma parathyroid hormone levels are lower prepartum than in cows fed a balanced diet, and decline further at 48 hours postpartum. Chief cells in the inactive stage of the secretory cycle predominate in cows fed high calcium diets (Fig. 3.32B), whereas actively synthesizing chief cells are most numerous in parathyroids of cows fed balanced prepartal diets. In response to the elevated blood calcium in cows fed high-calcium prepartum diets, thyroid stores of calcitonin are diminished, and C cells are partially degranulated and appear to be actively synthesizing more calcitonin. This stimulation of C cells is accompanied by a decrease in bone turnover near parturition. Trabecular bone surfaces are inactive and few osteoclasts are resorbing bone.

Calcium homeostasis in pregnant cows fed a high-calcium diet appears to be maintained principally by intestinal calcium absorption. This greater reliance on intestinal absorption than on parathyroid hormone stimulated bone resorption probably is a significant factor in the more frequent development of profound hypocalcemia near parturition. Cows fed a high-calcium diet are more susceptible to the decreased calcium available for absorption as a result of the anorexia often associated with the high blood estrogen levels near the time of parturition.

Calcium homeostasis in cows fed balanced or relatively low-calcium diets prepartum appears to be more under the fine control of parathyroid hormone secretion with the approach of parturition. The higher levels of parathyroid hormone secreted during the prepartum period by an expanded population of actively synthesizing chief cells results in a larger pool of active bone-resorbing cells to fulfill the increased needs for calcium mobilization at the critical time near parturition and the initiation of lactation. Cows fed a low-calcium diet are less susceptible to the influence of decreased intestinal calcium absorption and flow into the extracellular calcium pool resulting from the anorexia and intestinal stasis associated with parturition.

Less is known about the development of hypocalcemic syndromes in animal species other than in the cow. In dogs, **puerperal tetany** (eclampsia) is most frequently encountered in the small, hyperexcitable breeds. The clinical course is rapid and the bitch may proceed from premonitory signs of restlessness, panting, and nervousness to ataxia, trembling, muscular tetany, and convulsive seizures in 8–12 hours. There is no evidence to suggest that puerperal tetany in heavily lactating bitches is the result of interference in parathyroid hormone secretion. Severe hypocalcemia and often

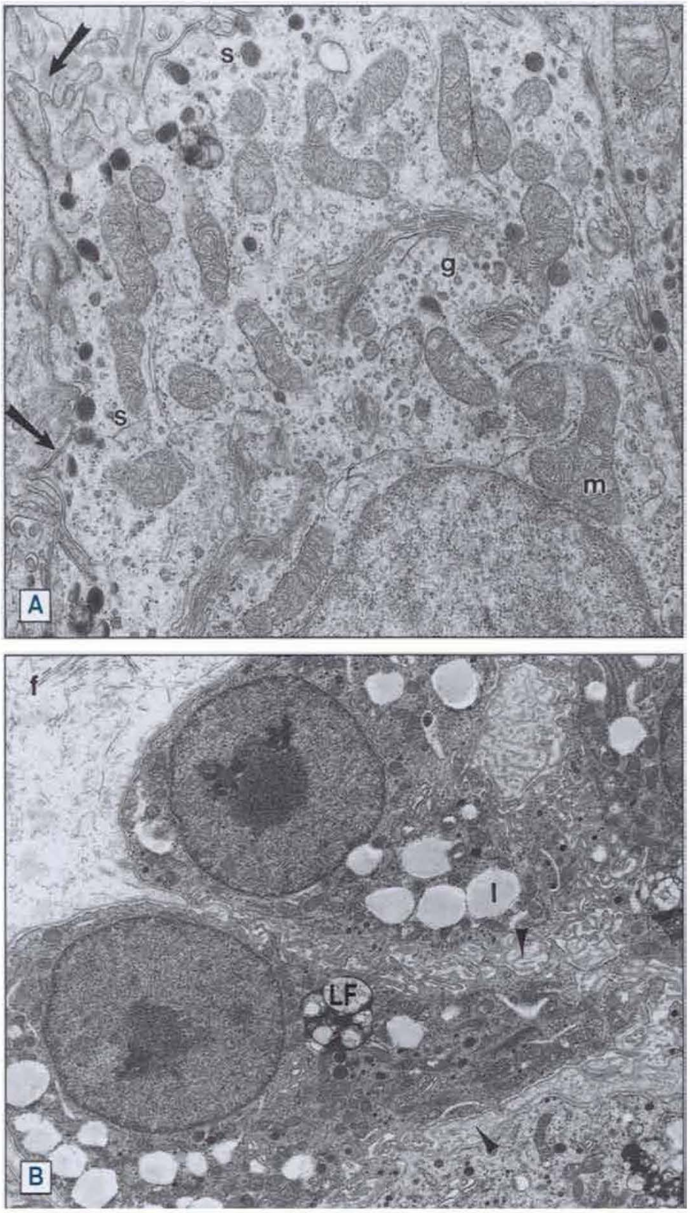

Figure 3.32 A. Acute parathyroid stimulation in response to severe hypocalcemia associated with parturition and initiation of the lactational drain for calcium. Parathyroid hormone-containing secretory granules (s) migrate peripherally and fuse with plasma membrane of actively secreting chief cells (arrow). Golgi apparatus (g) is hypertrophied. Many large mitochondria (m) are present. **B. Chronic parathyroid suppression** in a cow fed a high-calcium diet. Irregularly shaped atrophic chief cells are separated by cytoplasmic processes (arrowheads) in widened intercellular spaces. The electron-dense cytoplasm contains many lipid bodies (l), large lipofuscin bodies (LF), and occasional secretory granules. Cytoplasmic organelles other than mitochondria are poorly developed. Widened perivascular space contains many collagen fibers (f).

hypophosphatemia develop near the time of peak lactation (approximately 1–3 week postpartum), most likely the result of a temporary failure in calcium homeostasis resulting in an imbalance between the rates of inflow to and outflow from the extracellular fluid calcium pool. The administration of intravenous calcium to stop the tetany, combined with temporarily decreasing the lactational drain of calcium by removing the pups, corrects the disruption of calcium homeostasis in the majority of bitches. Supplemental dietary calcium and vitamin D have proven useful in preventing relapses in certain bitches with puerperal tetany.

Functional disturbances associated with hypocalcemia in cows are related to paresis, whereas in the bitch they are primarily the result of neuromuscular tetany. *The occurrence of either tetany or paresis in response to hypocalcemia appears to be the result of basic physiologic differences in the function of the neuromuscular junction of the cow and the bitch.* The release of acetylcholine and transmission of nerve impulses across neuromuscular junctions are blocked by hypocalcemia in cows (but not in the bitch) leading to muscle paresis. The dog appears to have a higher margin of safety in neuromuscular transmission in that the degree to which the endplate potential exceeds the firing threshold is greater than in the cow. Excitation–secretion coupling is maintained at the neuromuscular junction in the bitch with hypocalcemia, and tetany occurs as a result of spontaneous repetitive firing of motor nerve fibers. Due to the loss of stabilizing membrane-bound calcium, nerve membranes become more permeable to ions and require a stimulus of lesser magnitude to depolarize.

Parathyroid hyperplasia

Focal (nodular) hyperplasia. Chief cell hyperplasia may affect the parathyroids in a distinctly focal or multifocal distribution. In focal parathyroid hyperplasia there are single or multiple nodules in one or both glands in which there is an increased number of closely packed chief cells often with an expanded cytoplasmic area. The foci of chief cell hyperplasia are not encapsulated and are poorly demarcated from adjacent parenchyma. Chief cells within the nodules have a relatively uniform composition with a high cytoplasm:nucleus ratio and a slightly more hyperchromatic nucleus than adjacent normal chief cells. There may be slight compression of adjacent chief cells around larger areas of focal hyperplasia. Focal chief cell hyperplasia often is difficult to separate from a chief cell adenoma using only morphologic criteria. *The presence of multiple nodules of various sizes and uniform cellularity in one or both parathyroids with minimal compression and no fibrous encapsulation is more compatible with focal hyperplasia than chief cell adenoma.*

Diffuse hyperplasia. Parathyroid hyperplasia, such as seen with chronic renal failure and long-term dietary imbalances, results in uniform enlargement of all parathyroid glands due to both hypertrophy and hyperplasia of chief cells. There is not a peripheral rim of compressed atrophic parathyroid parenchyma as occurs around a functional adenoma, but rather *a uniform population of hyperplastic chief cells extending to the capsule of the gland.* The chief cells often are packed together with indistinct cell boundaries. The expanded cytoplasmic area of chronically stimulated chief cells is lightly eosinophilic with occasional distinct vacuoles. A more prominent fibrovascular stroma in some diffusely hyperplastic parathyroids may result in a lobulated appearance, and in others chief cells form distinct acinus-like structures.

Hyperparathyroidism secondary to renal disease

Secondary hyperparathyroidism as a complication of chronic renal failure is characterized by excessive production of parathyroid hormone in response to chronic hypocalcemia. When the renal disease reaches the point at which there is a significant reduction in the glomerular filtration rate, phosphorus is retained and progressive hyperphosphatemia develops, which contributes to parathyroid stimulation by virtue of its ability to lower blood calcium.

Impaired intestinal absorption of calcium due to an acquired defect in vitamin D metabolism probably also plays a significant role in the development of hypocalcemia in chronic renal insufficiency and uremia. Chronic renal disease impairs the production of $1,25(OH)_2D_3$ by the kidney and thereby diminishes intestinal calcium transport and increases mobilization of calcium from the skeleton (Fig. 3.33).

Chronic renal insufficiency occurs frequently as a result of several acquired or congenital kidney lesions. All four parathyroid glands undergo marked chief cell hyperplasia (see Fig. 3.37D) and the bones have varying degrees of generalized osteodystrophia fibrosa (see Vol. 1, Bones and joints). Chief cells in the parathyroid glands of dogs with chronic renal disease are primarily in the actively synthesizing stage of the secretory cycle.

The pathogenesis of secondary renal hyperparathyroidism is complex, but it has been recently recognized that $1,25(OH)_2D_3$ (calcitriol) plays an important role in this disease. *Animals with advanced chronic renal failure (CRF) have decreased circulating concentrations of $1,25(OH)_2D_3$* caused by decreased renal synthesis. Initially, the elevated blood phosphorus depresses the activity of the 1-α-hydroxylase in the kidney. In the later stage of chronic renal disease, there are decreased numbers of tubular epithelial cells with 1-α-hydroxylase activity to form the active form of vitamin D. Early stages of CRF are often associated with normal concentrations of circulating $1,25(OH)_2D_3$ (even with the loss of nephrons) due to the correcting effects of increased PTH on renal 1-α-hydroxylase that enhance renal tubular synthesis of $1,25(OH)_2D_3$.

$1,25(OH)_2D_3$ also is an important regulator of parathyroid chief cell function and acts to decrease PTH mRNA expression, increase expression of the vitamin D receptor, and control the set-point of chief cell responsiveness to negative feedback by the serum calcium concentration. The function of $1,25(OH)_2D_3$ serves to complete the endocrine feedback loop with the parathyroid gland to control serum calcium concentration. *Decreased circulating levels of $1,25(OH)_2D_3$ in animals with CRF results in chief cell hyperplasia and increased secretion of intact PTH.*

All four parathyroid glands are enlarged due to organellar hypertrophy initially and cellular hyperplasia later as compensatory mechanisms to increase hormonal synthesis and secretion in response to the hypocalcemic stimulus. Since the parathyroid gland stores comparatively little preformed hormone, the rate of peptide synthesis appears to be rate-limiting for hormonal secretion. Although the parathyroids are not autonomous, the concentration of PTH (especially –COOH terminal fragment) in the peripheral blood in patients with chronic renal failure may exceed that of primary hyperparathyroidism. Therefore, greatly increased numbers of chief cells are required to sustain the increased rates of hormonal secretion in patients with long-standing renal disease.

Hyperparathyroidism secondary to nutritional imbalances

Nutritional secondary hyperparathyroidism occurs commonly in cats, dogs, certain non-human primates, horses, domestic and captive birds, and reptiles. The increased secretion of parathyroid hormone is a compensatory mechanism directed against a disturbance in mineral homeostasis *induced by diets with either low calcium or excessive oxalate content, or high phosphorus with normal or low calcium content.* Inadequate vitamin D_3, besides causing rickets, also causes lesions of secondary hyperparathyroidism in some species. The significant result of these imbalances is hypocalcemia, which results in parathyroid stimulation. In response to the diet-induced hypocalcemia, chief cells undergo hypertrophy and eventually hyperplasia (Fig. 3.34A). The expanded cytoplasmic area is lightly eosinophilic and vacuolated compared with chief cells in normal animals (Fig. 3.34B). Perivascular spaces are narrow and there are few fat cells in the interstitium. The skeletal lesions of nutritional hyperparathyroidism are discussed with Vol. 1, Bones and joints.

Primary parathyroid hyperplasia

Primary parathyroid hyperplasia has been described in *German Shepherd pups* associated with hypercalcemia, hypophosphatemia, increased immunoreactive parathyroid hormone, and increased fractional clearance of inorganic phosphate in the urine. Clinical signs included stunted growth, muscular weakness, polyuria, polydipsia, and diffuse reduction in bone density. Intravenous infusion of calcium failed to suppress the autonomous secretion of parathyroid hormone by the diffuse hyperplasia of chief cells in all parathyroids. Lesions included nodular hyperplasia of thyroid C cells and widespread mineralization of lungs, kidney, and gastric mucosa. The disease is inherited as an autosomal recessive trait.

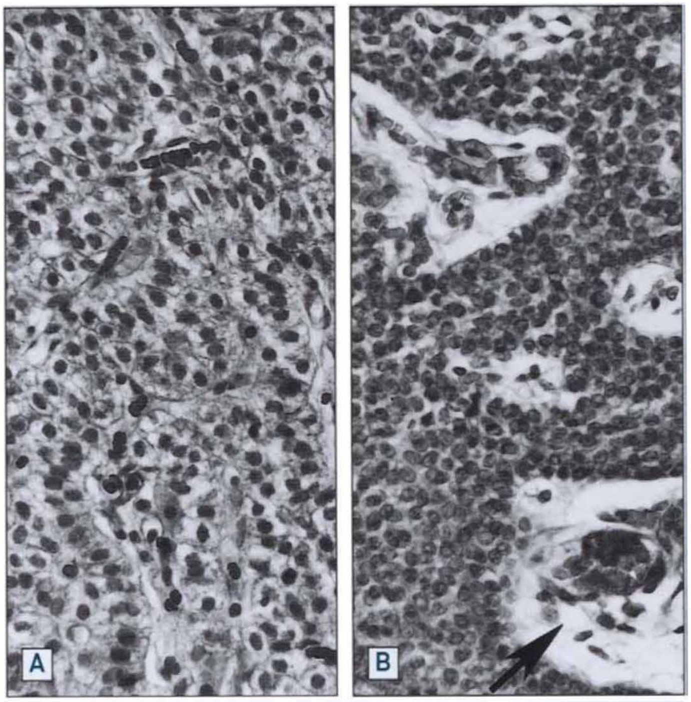

Figure 3.34 **A. Parathyroid chief cell hypertrophy and hyperplasia** in a kitten fed a low-calcium (all-meat) diet. The enlarged chief cells are closely packed, and perivascular spaces are narrow. **B.** Chief cells in parathyroid gland of kitten fed a diet that supplied daily requirements for calcium and phosphorus. Note the more prominent perivascular spaces (arrow).

(day-blooming jessamine) in Florida and elsewhere in the southern United States and *Trisetum flavescens* in the Bavarian and Austrian Alps cause calcinosis in horses, cattle, and sheep. *Solanum malacoxylon* in Argentina and Brazil produces the disease *enteque seco* or *espichamento* in cattle, which is characterized by the development of hypercalcemia, hyperphosphatemia, and severe soft tissue mineralization. Morphologically similar diseases occur in Jamaica (Manchester wasting disease) and Hawaii (*Naalehu* disease). Other plants that contain vitamin D-like activity are *Solanum torvum*, *S. verbascifolium*, *Dactylis glomerata*, and *Medicago sativa*. Sporadic cases of extensive mineralization occur in cattle throughout the world.

The leaves of these calcinogenic plants contain a substance(s) possessing vitamin D-like biologic activity. The dried leaves of *Solanum malacoxylon* contain a steroid–glycoside conjugate in which the steroidal component is identical to $1,25(OH)_2D_3$. The leaves are not palatable when green, but are eaten readily when dry. The calcinogenic plants appear to produce disease only in herbivores after ingestion of leaves. Intoxication produces rapid wasting and marked elevations of the calcium and phosphorus levels in the blood. *The patterns of these elevations of blood electrolytes as well as the soft tissue mineralization are comparable to those produced by intoxication by vitamin D.* The leaves of *S. malacoxylon* are remarkably potent with as little as 2 g being capable of producing elevations of calcium and phosphorus in the blood of adult cattle. The typical wasting syndrome is seen clinically when animals are forced to eat large quantities of the leaves. The animals develop kyphosis with contraction of the tendons and ligaments resulting in an inability to completely straighten their front limbs (Fig. 3.35A). Contraction of the abdominal aponeurosis gives a unique tucked-up line to the abdomen resulting in affected animals having a racehorse-like appearance. Many animals develop severe vascular and pulmonary disease as a result of irregular or occasional exposure to the plant due to mineralization and ossification of interalveolar septa in the lung (Fig. 3.35B).

These diseases associated with the ingestion of calcinogenic plants are not restricted to cattle but also occur also in goats, sheep and horses, although with lesser frequency and severity. Mature animals are most commonly affected, usually producing progressive debility. The earliest signs are those of stiffness and wasting. There is a subtle progression to permanent lameness due to contraction of the tendons. At this stage, affected animals often are excitable, tire easily if made to exercise, and may show signs of acute cardiac insufficiency. If they are removed from affected areas, the stiffness and deformity are not lessened but the wasting is stopped, and the animals gain weight if good pasture is available.

Necropsy reveals widespread mineralization of the tissues, particularly the aorta, heart, and lungs (Fig. 3.36A, B) *often with areas of ossification.* Small mineralized blood vessels are encountered in the subcutis, and mineralized plaques are present on the parietal and visceral pleura. Portions of the lungs fail to collapse and these represent areas of mineralization in which the parenchyma is disrupted and emphysematous. The pulmonary lesions primarily involve the caudal lobes and consist of irregular thickening of alveolar septa due to mineralization and collagen deposition. The opened heart often reveals mineralization of the right atrium but not of the right ventricle. The endocardial mineralization is most severe in the atrium and ventricle (chiefly the basal portion of the latter) also involving the semilunar cusps, the bicuspid valve, and chordae tendineae, and extending into the aorta. The aortic mineralization in early cases is restricted to the zones about the orifices of large branches, but in

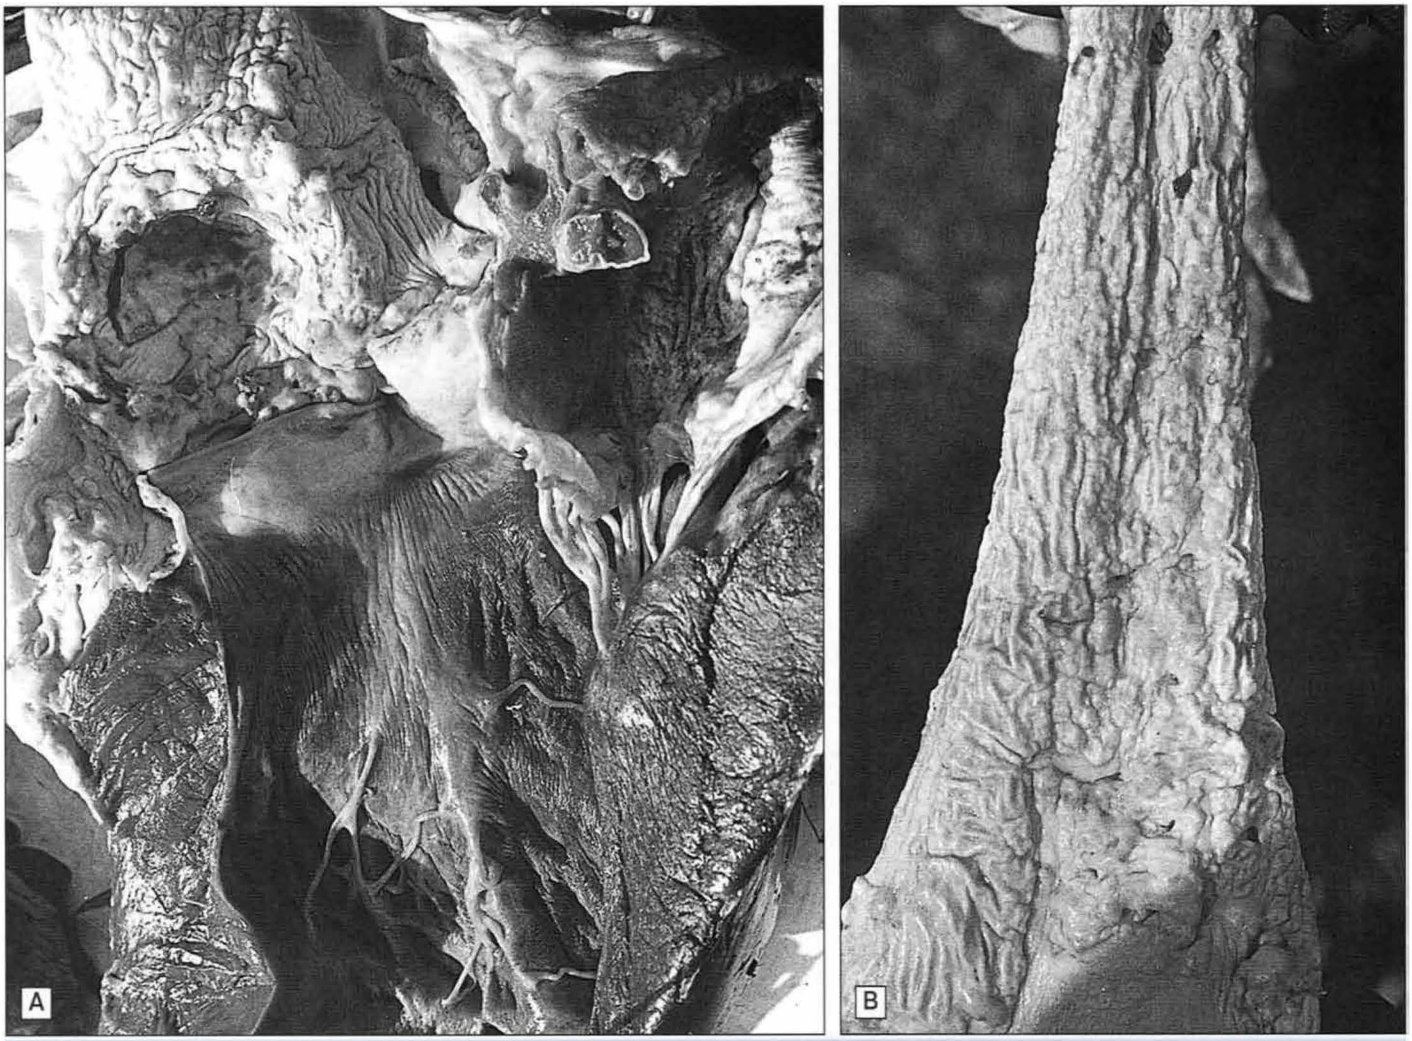

Figure 3.36 Mineralization in poisoning of a cow by *Solanum malacoxylon*. **A.** Heart. **B.** Aorta.

advanced cases it is more diffuse. In advanced cases of intoxification, many small arteries, especially the coronary and mesenteric arteries, are mineralized severely but irregularly. The arterial mineralization begins in the intima and, with continuous accretion, extends to the media disrupting the elastic laminae of the vessels. Areas of mineralization are present microscopically in the mucosa of the abomasal fundus as well as in other fibroelastic tissues. Mineralization of ligaments and of the fibrocartilagenous portions of tendons is responsible for the stiffness along with the degenerative arthropathy that usually is present in affected animals.

In chronic cases, the bones become extremely dense as new trabeculae are formed in the marrow spaces. These trabeculae appear to develop in an atypical basophilic matrix similar to that deposited in vitamin D poisoning (see Vol. 1, Bones and joints,). Parathyroid chief cells appear initially to accumulate secretory granules after feeding *S. malacoxylon* and later to undergo involution and atrophy.

The incidence of hypercalcemia due to vitamin D intoxication in **small animals** *has increased due to use of vitamin D (cholecalciferol) as a pesticide and rodenticide.* The ingested vitamin D is converted to 25-hydroxy vitamin D in the liver and is the major toxic metabolite. 25-hydroxy vitamin D has a much reduced binding affinity for the vitamin D receptor (500- to 1000-fold) than $1,25(OH)_2D_3$ (active form of vitamin D), but is present at such high concentrations that it stimulates hypercalcemia by increasing intestinal absorption of calcium. Only small amounts of the 25-hydroxy vitamin D are converted to the active form of vitamin D, $1,25(OH)_2D_3$, which often is present in the circulation at normal to subnormal levels. This is due to inhibition of renal 1-α-hydroxylase by low serum PTH levels, hypercalcemia, hyperphosphatemia, and negative feedback from $25(OH)D_3$ that binds to the vitamin D receptor. The hypercalcemia of hypervitaminosis D is usually accompanied by hyperphosphatemia (since vitamin D also increases intestinal absorption of phosphorus in addition to calcium) and normal serum alkaline phosphatase activity. Skeletal disease is not a consistent feature, since the increased concentrations of blood calcium and phosphorus are derived principally from augmented intestinal absorption; however, widespread mineralization of soft tissue occurs similar to animals ingesting calcinogenic plants.

Neoplasms of the parathyroid glands

Functional adenomas and carcinomas of *parathyroid glands secrete parathyroid hormone in excess of normal, causing a syndrome of* **primary hyperparathyroidism** (Fig. 3.37). The normal control mechanism

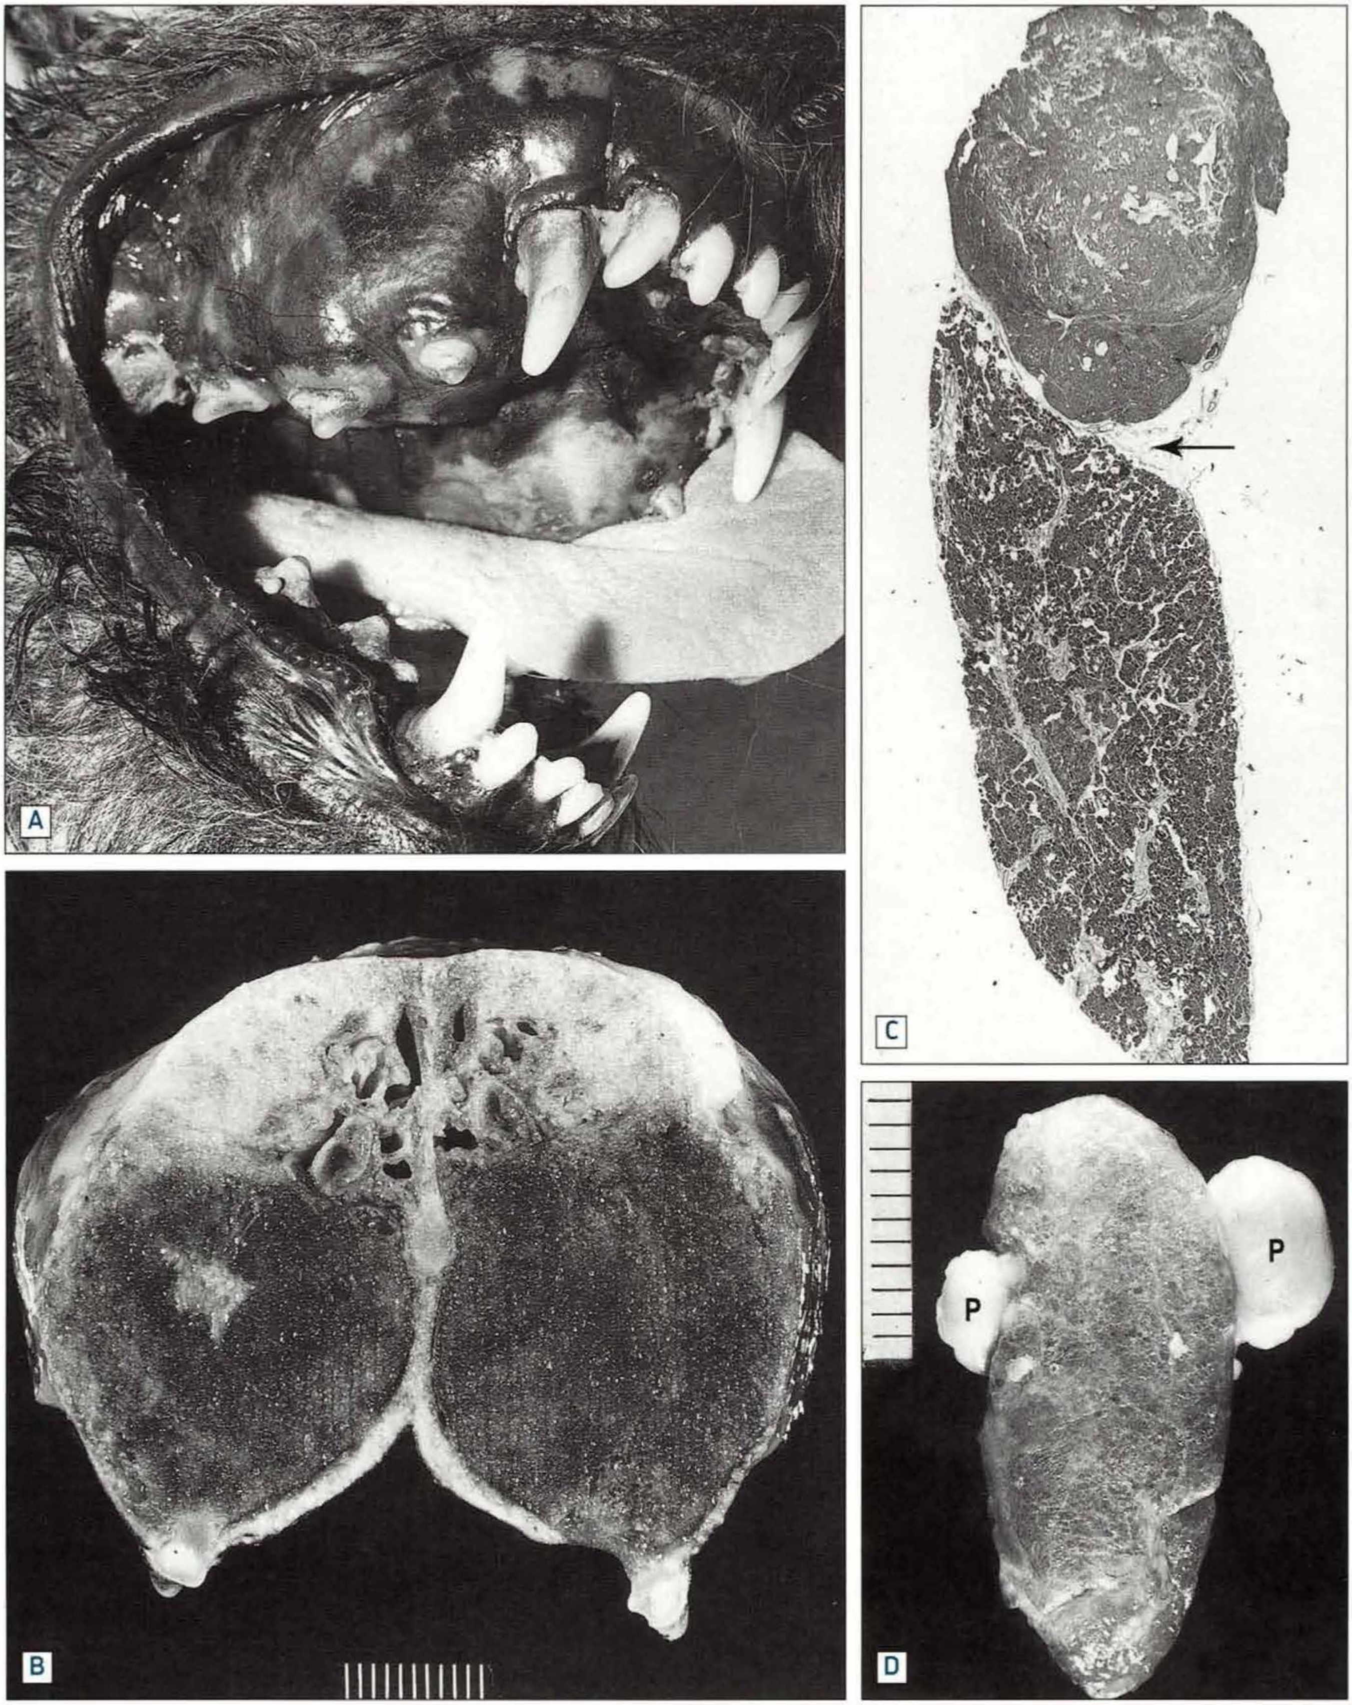

Figure 3.37 Hyperostotic fibrous osteodystrophy in the maxilla of a dog with primary hyperparathyroidism. **A.** Bony enlargement of maxilla. **B.** Cross section showing encroachment on the nasal cavity by extensive proliferation of woven bone. **C. Chief cell hyperplasia** resulting in enlargement of internal and external parathyroids (P) in a dog with chronic renal failure.

for parathyroid hormone is lost and hormone secretion is excessive in spite of an increased level of blood calcium. Cells of the renal tubules are sensitive to alterations in the amount of circulating parathyroid hormone. The excretion of phosphorus and retention of calcium initially are enhanced. A prolonged increased secretion of parathyroid hormone accelerates osteoclastic bone resorption and results in generalized fibrous osteodystrophy.

Adenomas of parathyroid glands are encountered in older animals, particularly dogs and occasionally cats. The number of cases studied in dogs is inadequate to determine any breed or sex predisposition. Tumors of parathyroid chief cells in animals do not appear to be sequelae of long-standing secondary hyperparathyroidism of renal or nutritional origin.

Chief cell adenomas usually result in considerable enlargement of a single parathyroid gland. They are light brown to red and are located either in the cervical region by the thyroids or infrequently within the thoracic cavity near the base of the heart. Parathyroid neoplasms in the precardiac mediastinum are derived from ectopic parathyroid tissue, displaced into the thorax with the expanding thymus during embryonic development. Parathyroid adenomas are sharply demarcated and encapsulated from the adjacent thyroid gland (Fig. 3.37C). Multiple white foci may be seen in the thyroids of dogs with functional parathyroid tumors. These represent areas of C-cell hyperplasia in response to the long-term hypercalcemia (Fig. 3.38). In secondary hyperparathyroidism, all four parathyroids are enlarged 2–5 times normal size (Fig. 3.37D). In comparison, a parathyroid adenoma will enlarge a single gland to a much greater degree; however, the remaining parathyroids will be atrophic. *Histologic demonstration of a compressed rim of parathyroid parenchyma and a partial-to-complete fibrous capsule in an enlarged gland points to the diagnosis of adenoma rather than chief cell hyperplasia* (Fig. 3.39).

Parathyroid adenomas are composed of closely packed chief cells subdivided into small groups by fine connective tissue septa with many capillaries. The chief cells are cuboidal or polyhedral, and the cytoplasm stains lightly eosinophilic. Occasional oxyphil cells, water-clear cells, and transitional forms may be distributed throughout the adenoma. The transitional oxyphil cells contain organelles concerned with hormonal synthesis and packaging, as well as occasional secretory granules. This is in contrast to the oxyphil cell of normal parathyroid glands, which has a cytoplasm filled with tightly packed mitochondria, but a poorly developed endoplasmic reticulum and Golgi apparatus. Fat cells and mast cells often are present in the stroma of adenomas.

Adenomas are surrounded by a fine, partial to complete, connective tissue capsule, and may compress the adjacent thyroid gland. A rim of compressed and atrophic parathyroid parenchyma usually is present outside the capsule of a small adenoma (Fig. 3.39). The parathyroid tissue in the rim, and in other parathyroids, of an animal with a functional parathyroid adenoma is chronically suppressed by the elevated serum calcium (Fig. 3.40). The suppressed chief cells have numerous droplets of lipofuscin and lipid. These atrophic chief cells are small, irregular in shape, and have a small amount of densely eosinophilic cytoplasm and densely basophilic nuclei.

Parathyroid adenomas usually are slow growing and compress the adjacent thyroid to various degrees. They are well encapsulated and can be surgically excised without difficulty. Successful removal of a functional parathyroid adenoma results in a rapid decrease in circulating parathyroid hormone levels, since the half-life of parathyroid hormone in plasma is short (~5 min). *Plasma calcium levels in animals with overt bone disease may decrease rapidly following surgical removal of the parathyroid adenoma* due to mineralization of osteoid matrix and reach subnormal levels within 12–24 hours, resulting in life-threatening hypocalcemic tetany (Fig. 3.41). Postoperative hypocalcemia is the result of depressed secretory activity in the remaining parathyroid tissue due to long-term suppression by chronic hypercalcemia, decreased bone resorption, and accelerated mineralization or organic matrix formed by the hyperplastic osteoblasts along bone surfaces. Infusion of calcium gluconate, feeding a high-calcium diet, and supplemental vitamin D therapy will correct this postoperative complication.

Chief cells comprising functional parathyroid adenomas are in the actively synthesizing stage of the secretory cycle by electron microscopy. Multiple large lamellar arrays of rough endoplasmic reticulum and clusters of free ribosomes are present in the cytoplasm. However, few mature secretory ("storage") granules are present in the cytoplasm suggesting that parathyroid hormone is secreted at a faster rate than synthesis and storage in autonomous chief cells. Large mitochondria and prominent Golgi apparatuses are present in neoplastic chief cells. The annulate lamellae that occur frequently in parathyroid adenomas from human patients have not been reported in either normal or neoplastic chief cells of animals. Parathyroid adenomas may contain secretory granules in chief cells as well as in transitional oxyphil cells with well-developed organelles concerned with hormonal synthesis and packaging. Occasional parathyroid adenomas in both dogs and human beings may be composed predominantly of large eosinophilic oxyphil cells.

Parathyroid carcinomas *are larger than adenomas, invade the capsule and adjacent structures (e.g., thyroid glands and cervical muscles), and may metastasize to regional lymph nodes and lung.* They are uncommon in animals but have been observed in dogs and cats. Parathyroid carcinomas are composed of chief cells with a highly variable development of cytoplasmic organelles. Alterations of the nuclear morphology have been described in malignant chief cells. There usually is a greater degree of cellular pleomorphism than in chief cell adenomas with more frequent mitotic figures and microscopic evidence of invasion into the adjacent parathyroid, thyroid, or periglandular connective tissues.

Primary hyperparathyroidism. The clinical disturbances observed with functional parathyroid tumors primarily are the result of the persistent hypercalcemia and a weakening of bones by excessive resorption. Hypercalcemia results in anorexia, vomiting, constipation, depression, polyuria, polydipsia, and generalized muscular weakness due to decreased neuromuscular excitability. Cortical bone in longstanding cases is thinned due to increased resorption by osteoclasts stimulated by the autonomous secretion of parathyroid hormone. Lameness due to fractures of long bones may occur after relatively minor physical trauma. Compression fractures of vertebral bodies can exert pressure on the spinal cord and nerves, resulting in motor or sensory dysfunction, or both. Facial hyperostosis due to extensive osteoblastic proliferation and deposition of poorly mineralized osteoid, and loosening or loss of teeth from alveolar sockets, has been observed in dogs with primary hyperparathyroidism (Fig. 3.37A, B). Primary hyperparathyroidism occurs in older animals. They usually have a history of multiple fractures associated with severe generalized skeletal demineralization and normal renal function. Radiographic evaluation reveals

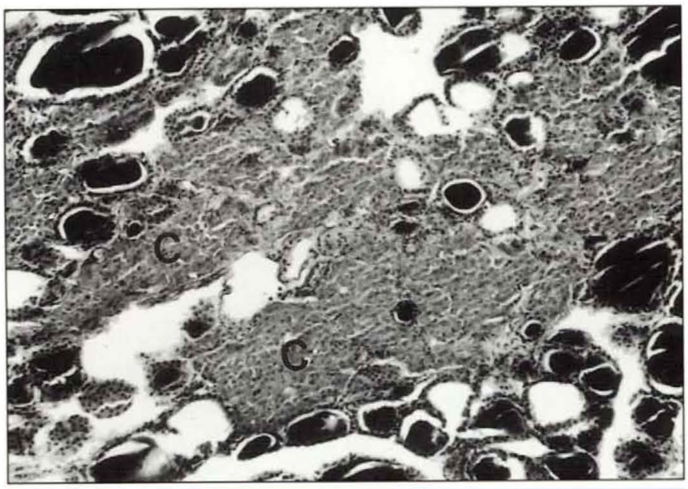

Figure 3.38 Multifocal C-cell hyperplasia (C) in a dog with primary hyperparathyroidism and persistent hypercalcemia. (From Capen CC. Toxicol Pathol 2001:29:8–33.)

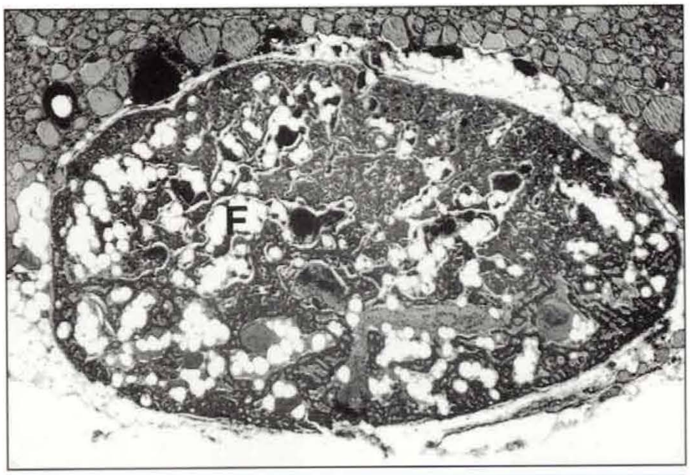

Figure 3.40 Diffuse trophic atrophy of nonneoplastic parathyroid gland in a dog with primary hyperparathyroidism and persistent hypercalcemia. There are prominent fat cells (F) in the interstitium between the groups of atrophic chief cells. (From Capen CC. Toxicol Pathol 2001:29:8–33.)

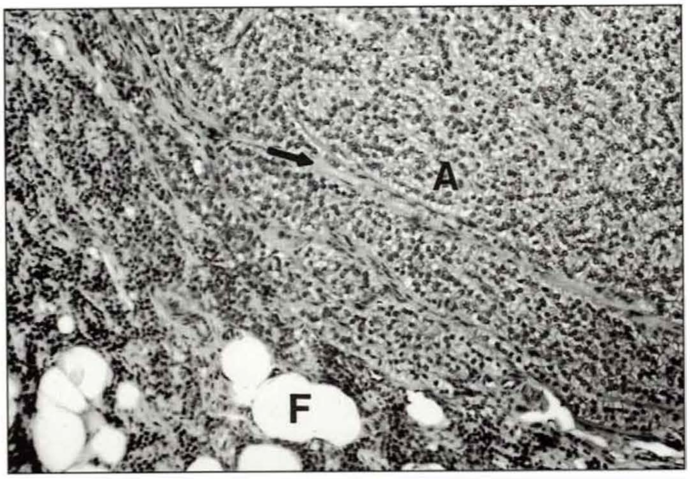

Figure 3.39 Functional chief cell adenoma (A) in the parathyroid gland sharply demarcated and partially encapsulated (arrow) from the rim of adjacent nonneoplastic parathyroid tissue that has undergone severe atrophy in response to persistent hypercalcemia. Prominent fat cells (F) are present in the interstitium between groups of atrophic chief cells in the suppressed parathyroid gland. (From Capen CC. Toxicol Pathol 2001;29:8–33.)

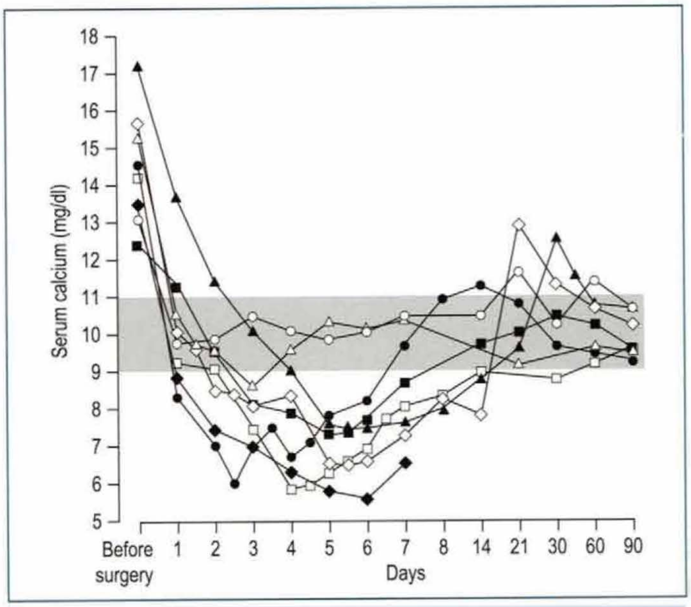

Figure 3.41 Postoperative hypocalcemia in dogs following surgical removal of functional parathyroid adenomas. The remaining atrophic parathyroid glands (as in Fig. 3.40) were unable to maintain the serum calcium because of a subnormal rate of PTH secretion. Supplemental vitamin D and calcium carbonate slowly returned the blood calcium to the reference range (shaded area). (From Berger B. Feldman EC. J Am Vet Med Assoc 1987:191:350–356.)

areas of subperiosteal cortical resorption, loss of lamina dura around the teeth, soft tissue mineralization, bone cysts, and a generalized decrease in bone density with multiple fractures in advanced cases.

The laboratory tests most useful in establishing the diagnosis of primary hyperfunction of the parathyroid glands is quantitation of total blood calcium and phosphorus, and circulating levels of parathyroid hormone (N-terminal or immunoradiometric assay (IRMA)). Although other laboratory findings may be variable, *persistent hypercalcemia (>12 mg/dL, >3.0 mmol/L) is a consistent finding.* Dogs evaluated with primary hyperparathyroidism often have had a greatly elevated (13–20 mg/dL, 3.25–5.0 mmol/L, or higher) blood calcium level. The blood phosphorus level is low or in the low-to-normal range (<4 mg/dL, <1.3 mmol/L) because of inhibition of renal tubular resorption of phosphorus by excess parathyroid hormone. Serum alkaline phosphatase activity may be increased due to increased osteoblastic activity as a response to mechanical stress of bones weakened by excessive resorption or due to direct (receptor-mediated) stimulation of osteoblasts by the elevated PTH level. The urinary excretion of calcium and phosphorus is increased and may predispose to the development of nephrocalcinosis and urolithiasis. Accelerated bone matrix catabolism is reflected by increased excretion of hydroxyproline in the urine. Repeated palpation of parathyroid gland tumors may result in infarction due to vascular thrombosis with extensive ischemic necrosis of tumor cells and the rapid development of hypocalcemia similar to that seen following surgical removal.

Hypercalcemia associated with neoplasms of nonparathyroid origin

Hypercalcemia is a common disorder that affects animals and has many causes. *The most common cause of hypercalcemia in animals and human beings is cancer-associated hypercalcemia.* There are *three mechanisms* of increased serum calcium induced by neoplasms:

1. humoral hypercalcemia of malignancy (HHM), or pseudohyperparathyroidism,
2. hypercalcemia induced by metastases of solid tumors to bone, and
3. hematologic malignancies.

Hypercalcemia results from an imbalance of calcium released from bones, calcium excretion by the kidney, and/or calcium absorption from the intestinal tract. The functional disturbances of hypercalcemia are similar regardless of underlying cause and depend on the rapidity of onset and magnitude of the increased serum ionized calcium levels. *Animals with serum calcium values in excess of 16.0 mg/dL (4.0 mmol/L) generally have the most severe clinical signs.* Exceptions to this rule occur, and occasionally animals with severe hypercalcemia have mild clinical signs especially if the calcium is primarily protein-bound. Horses and rabbits have normal total serum calcium concentrations greater than other domestic animals, which should be considered before hypercalcemia is diagnosed in these species.

Metabolic acidosis will enhance the severity of clinical signs since it will result in an increase in the ionized fraction of serum calcium. Increased serum ionized calcium will induce clinical signs related to the gastrointestinal, neuromuscular, cardiovascular, and renal systems. Decreased contractility of the gastrointestinal smooth muscle may be associated with anorexia, vomiting or constipation. There may be generalized motor weakness due to decreased neuromuscular excitability. Polyuria and polydipsia are commonly encountered in animals with hypercalcemia. Initially, polyuria and polydipsia are due to impaired renal concentrating ability resulting from an inhibition by the hypercalcemia of the antidiuretic hormone-dependent resorption of NaCl in the diluting segment of the nephron by decreasing adenylate cyclase activity. Hypercalcemia also has a toxic effect on renal tubules either directly or from ischemia induced by vasoconstriction. Tubular epithelial cells undergo degeneration with the collecting system most severely affected.

Humoral hypercalcemia of malignancy (HHM) is one form of cancer-associated hypercalcemia that is induced by the secretion of humoral factors that have effects distant to the site of the neoplasms. Some neoplasms that cause HHM may metastasize to bone (Fig. 3.42A), but the primary mechanism of hypercalcemia involves the distant effects of humoral factors and not the localized effects of bone metastases. *Multiple humoral factors have been associated with HHM including parathyroid hormone, parathyroid hormone-like proteins, cytokines, steroids such as $1,25(OH)_2D_3$, and prostaglandins.* Many of the humoral factors produced by tumor cells that alter calcium metabolism and bone resorption can also be produced by osteogenic cells, such as osteoblasts.

The clinical syndrome of HHM in animals mimics primary hyperparathyroidism, and a term used previously to describe HHM was "*pseudohyperparathyroidism*." However, HHM does not mimic hyperparathyroidism in all aspects, as there are distinct differences in bone remodeling and vitamin D metabolism between patients with HHM and with primary hyperparathyroidism. *The most consistent feature of HHM in animals is increased osteoclastic bone resorption distant to the site of the neoplasm.* Other features include hypercalciuria, decreased fractional excretion of calcium, increased nephrogenous 3′,5′-cyclic adenosine monophosphate (cAMP), hypophosphatemia, and hyperphosphaturia.

The similarities of these clinicopathologic alterations to hyperparathyroidism initially led to the hypothesis that the neoplasms secrete parathyroid hormone (PTH) or PTH-like substances; however, *native PTH is not produced by the vast majority of neoplasms associated with HHM.* Immunoreactive PTH levels are normal or low in patients with HHM, and the tumors do not produce PTH mRNA. There are well-validated reports of ectopic production of PTH by some tumors, but these occurrences are uncommon.

Purification of the PTH-like biologic activity from neoplasms associated with HHM resulted in the discovery of a hormone named **parathyroid hormone-related protein (PTHrP)** (previously referred to as *parathyroid hormone-like peptide* or *hypercalcemia of malignancy factor*). PTHrP plays a central role in the pathogenesis of HHM since it is a consistent feature of HHM and shares most or all of the biologic activities of PTH. PTHrP acts alone in some forms of HHM but may act synergistically or additively with other humoral factors in the pathogenesis of hypercalcemia (Fig. 3.42B).

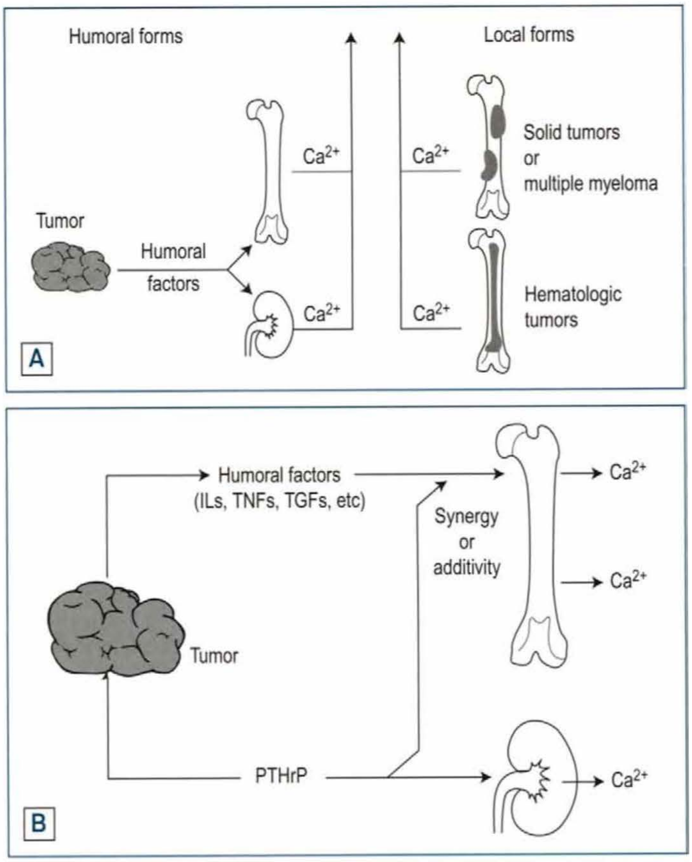

Figure 3.42 A. Humoral and local forms of **cancer-associated hypercalcemia** increase circulating concentrations of calcium by stimulating osteoclastic bone resorption and increasing renal tubular reabsorption of calcium. **B.** Multiple humoral factors can act additively or synergistically to induce hypercalcemia associated with humoral hypercalcemia of malignancy (HHM). (IL = interleukin, TNF = tumor necrosis factor, TGFs = transforming growth factors, PTHrP = parathyroid hormone-related protein. (From Rosol TJ, Capen CC. Lab Invest 1992;67:680–702.)

It is possible that some examples of HHM are not associated with PTHrP production by the neoplasms, but rather are due to recognized or unrecognized humoral factors, cytokines or hormones that are capable of stimulating osteoclastic bone resorption and result in hypercalcemia.

Humoral hypercalcemia of malignancy occurs as a spontaneous disease in domestic and laboratory animals. Malignant neoplasms that are commonly associated with HHM in animals include the *adenocarcinoma derived from apocrine glands of the anal sac in dogs, some T-cell lymphomas of dogs, myelomas, and miscellaneous carcinomas that sporadically induce HHM in various species, such as cats and horses (gastric squamous cell carcinoma)*. The dog is most often affected. HHM occurs in 10–40% of dogs with lymphoma (usually thymic or multicentric forms), and in the majority of dogs with adenocarcinomas derived from apocrine glands of the anal sac. Lymphoma is a relatively common tumor in older, large-breed dogs, whereas the apocrine adenocarcinoma is less common and occurs most often in older female dogs. HHM also occurs sporadically in dogs, usually in association with other carcinomas.

There are three primary mechanisms by which humoral factors can induce hypercalcemia:

1. stimulation of osteoclastic bone resorption,
2. increase in calcium reabsorption from the kidney (Fig. 3.43), and
3. increase in calcium absorption from the intestine.

Increased osteoclastic bone resorption is a fundamental component of the pathogenesis of hypercalcemia and is a consistent feature of HHM. The kidney also plays a central role in the induction of hypercalcemia. Increased osteoclastic bone resorption would increase the flux of calcium into the circulation, but this could be readily excreted by the kidney under normal circumstances. In HHM, fractional excretion of calcium often is reduced, which results in decreased excretion and increased tubular reabsorption of calcium. Therefore, bone and renal mechanisms both appear to be responsible for hypercalcemia in HHM. The role of intestinal absorption of calcium in the pathogenesis of hypercalcemia has not been well evaluated in domestic animals.

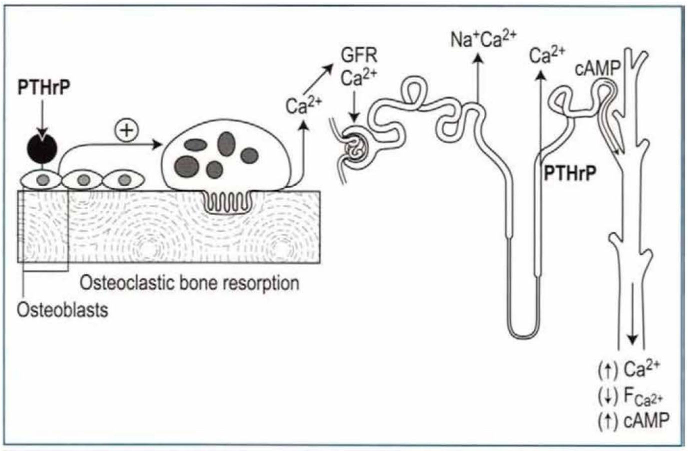

Figure 3.43 Humoral hypercalcemia of malignancy (HHM) develops in animal and human patients when neoplasms constitutively secrete parathyroid hormone-related protein (PTHrP). PTHrP binds to receptors on osteoblasts, which subsequently signal osteoclasts to increase bone resorption, and renal epithelial cells in the distal nephron to enhance calcium reabsorption (decreasing fractional (F) calcium (Ca^{++}) excretion), resulting in persistent hypercalcemia. cAMP = cyclic adenosine monophosphate. (From Capen CC. Toxicol Pathol 2001;29:8–33.)

Most of the humoral factors implicated in the pathogenesis of HHM are capable of stimulating osteoclastic bone resorption in vivo and in vitro. The humoral factors must be secreted by the neoplasms in large enough quantities to increase circulating concentrations and stimulate bone resorption alone or by cooperative interactions with other humoral factors. None of the humoral factors identified stimulates osteoclast formation or activation directly. Most factors, including PTHrP and cytokines, bind to receptors on osteoblasts, which are responsible for coordinating the stimulation of osteoclastic bone resorption.

Parathyroid hormone-related protein (PTHrP) was initially purified from human tumors associated with HHM; subsequently, the cDNA and gene for PTHrP were isolated, sequenced, and characterized. The PTHrP gene is complicated and contains at least 6 exons, two 5′-untranslated regions each with its own promoter, a preprohormone coding region, a main coding region, and 2 additional 3′ regions that have coding and noncoding regions. There is alternate splicing of PTHrP mRNA so that 3 mature peptides can be formed composed of 139, 141 and 173 amino acid residues. The PTHrP gene is located on the short arm of chromosome 12 in humans and is thought to have evolved from the PTH gene on the short arm of chromosome 11 through chromosome duplication. The PTH gene is simpler and has only three exons (5′-untranslated region, preprohormone coding region, and main coding region with a 3′-noncoding region) and encodes for a protein of 84 amino acids.

Parathyroid hormone-related protein binds to the well-defined PTH receptors in bone and kidney with similar affinity to PTH. The first 34 N-terminal amino acids of PTHrP contain the PTH-like biologic activity. This is similar to PTH in which the first 34 N-terminal amino acids (of a total of 84) contain most of the biologic activities. There is 70% sequence homology of the first 13 N-terminal amino acids of PTHrP and PTH, but little homology after amino acid 13. The N-terminus is important in the activation of the PTH receptor. Sequence homology in this region is important for the ability of PTHrP to stimulate PTH receptors. The biologic actions of PTHrP in bone and kidney are similar to PTH. Both PTHrP and PTH induce their cellular actions in osteoblasts and renal cells by stimulating adenylate cyclase, phospholipase C, and pathways leading to increased intracellular calcium concentration. The efficiency of signal transduction by PTHrP in different cells or membranes may be affected by differences in species specificity for PTHrP. N-terminal PTHrP stimulates osteoclastic bone resorption in vivo and in vitro with similar potency to PTH.

Parathyroid hormone-related protein plays a central role in the pathogenesis of HHM. It is produced by most tumors and is present in the circulation at increased concentrations in animals and human patients with HHM. The administration of anti-PTHrP antibodies to animal models of HHM decreases serum calcium levels and bone resorption. Increased circulating concentrations of PTHrP also have been detected in dogs with spontaneous HHM as well as in experimental animal models of HHM. Dogs with adenocarcinomas derived from apocrine glands of the anal sac have markedly elevated concentrations of PTHrP (10–100 pM), suggesting that PTHrP plays a primary role in the pathogenesis of the hypercalcemia associated with these tumors. In contrast, dogs with HHM and lymphoma have PTHrP concentrations which range from undetectable to 17 pM. PTHrP appears not to be the sole humoral factor responsible for the induction of hypercalcemia in dogs with lymphoma, but may interact cooperatively with other humoral factors.

The syndrome of humoral hypercalcemia of malignancy in elderly female dogs most frequently is associated with *perirectal adenocarcinomas derived from apocrine glands of the anal sac.* The dogs have persistent hypercalcemia and hypophosphatemia that return to normal following surgical excision of the neoplasm in its entirety. The hypercalcemia persists following removal of the parathyroid glands. All tumors have histologic features of malignancy and most metastasize to iliac and sublumbar lymph nodes. Apocrine carcinomas are poorly demarcated from adjacent normal tissues. They frequently extend projections of tumor cells along connective tissue planes and early in the course of the disease invade thin-walled lymphatics and veins to form tumor cell emboli (Fig. 3.44). Functional disturbances in dogs with HHM include generalized muscular weakness, anorexia, vomiting, bradycardia, depression, polyuria, and polydipsia. These clinical signs primarily are the result of severe hypercalcemia, and complicate the problems associated with the malignant neoplasm.

Apocrine adenocarcinomas develop as firm masses in the perirectal area, ventral-lateral to the anus, in close association with the anal sac, but are not attached to the overlying skin. The tumor arises in the wall of the anal sac and projects as a mass of variable size into its lumen (Fig. 3.45A). *It forms glandular acini with projections of apical cytoplasm extending into a lumen* (Fig. 3.45B) *and is histologically distinct from the more common perianal (circumanal) gland tumor in this region of dogs.* Most neoplasms are histologically bimorphic with glandular and solid areas (Fig. 3.45C). The solid pattern of arrangement of neoplastic cells is characterized by sheets, microlobules, and packets separated by thin fibrovascular stroma. Pseudorosettes are common in solid areas adjacent to small blood vessels.

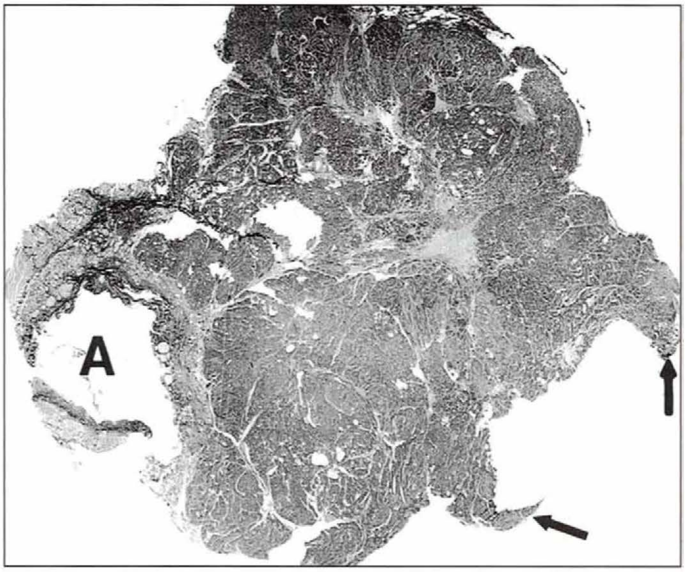

Figure 3.44 Infiltrative carcinoma arising from apocrine glands in the wall of the anal sac (A). extending numerous projections (arrows) into the surrounding perineal connective tissues and into lymphatics in this region. Dog had persistent hypercalcemia and unilateral enlargements of sublumbar lymph nodes due to tumor metastasis. (From Capen CC. In: Tumors of Domestic Animals. 4th ed., 2002.)

The tumor cells in adenocarcinomas derived from apocrine glands of the anal sac contain well-developed rough endoplasmic reticulum, clusters of free ribosomes, large mitochondria, and prominent Golgi apparatuses. Prominent blebs of apical cytoplasm project into the lumens of glandular acini. Small, membrane-limited, secretory granules often are present in the apical cytoplasm of neoplastic cells. These granules are similar in size and electron density to PTH-containing storage granules in chief cells of normal parathyroid glands; however, it has not been determined whether they contain hormonal activity. It appears that the neoplastic cells secrete PTHrP in a constitutive rather than a regulated manner as most tumor cells have few, if any, secretory granules in their cytoplasm.

Skeletal demineralization in dogs with HHM is mild in comparison with other causes of hypercalcemia and usually undetectable by conventional radiographic methods. Neoplastic cells from the perirectal adenocarcinomas rarely metastasize to bone and cause osteolysis. Variable numbers of osteoclasts are present on bone surfaces in dogs with marked hypercalcemia (Fig. 3.45D), possibly reflecting different states in the course of the disease and phases of bone remodeling activity. Osteocytic osteolysis is not detected microscopically and the cement lines are smooth and linear.

Renal mineralization is detected histologically in ~90% of dogs with pseudohyperparathyroidism associated with apocrine adenocarcinomas of the anal sac, particularly when the Ca × P product expressed as mg/100 mL is 50 or greater. Tubular mineralization is most pronounced near the corticomedullary junction but also is present in cortical and deep medullary tubules, Bowman's capsules, and glomerular tufts. Mineralization is present less frequently in the fundic mucosa of the stomach and endocardium.

The parathyroid glands are small and difficult to locate or not visible macroscopically. Microscopically, they are characterized by narrow cords of inactive chief cells with abundant fibrous connective tissue stroma and widened perivascular spaces (Fig. 3.46). This suggests that apocrine adenocarcinomas do not stimulate parathyroid hormone secretion, but rather the parathyroids respond to the persistent hypercalcemia by undergoing trophic atrophy. Thyroid C cells respond to the persistent elevation in blood calcium by undergoing diffuse or nodular hyperplasia. There is an inappropriate serum concentration of 1,25-dihydroxycholecalciferol for the degree of hypercalcemia in tumor-bearing dogs, and the rapid decrease following excision of the tumor suggests that the tumor may secrete a substance(s) that alters the activity of the 1-α-hydroxylase in the kidney.

Physiologic role for parathyroid hormone-related protein. Parathyroid hormone-related protein (PTHrP) is a 139–173 amino acid peptide, originally isolated from human and animal tumors associated with humoral hypercalcemia of malignancy. However, PTHrP is not strictly a calcium-regulating hormone as it appears to have an important physiologic role in may normal tissues. It have been determined that PRTHrP is widely produced in the body and acts as a paracrine factor in the tissues in which it is produced.

In contrast to parathyroid hormone, which is produced only by the parathyroid gland, PTHrP is produced by many normal tissues in adult animals, including stratified squamous epithelium, endocrine glands (adrenal cortex and medulla, fetal and adult parathyroid glands, adenohypophysis, thyroid), skeletal, cardiac and smooth muscle, kidney, bone, lactating mammary gland, lymphocytes, lung, skin, bone, brain, pancreas, testis, prostate, ovary, myometrium, placenta,

There are numerous osteoclasts with excavations (arrows) aligned on trabecular bone surfaces. (From: Meuten DJ, et al. Vet Pathol 1981;18:454–471.)

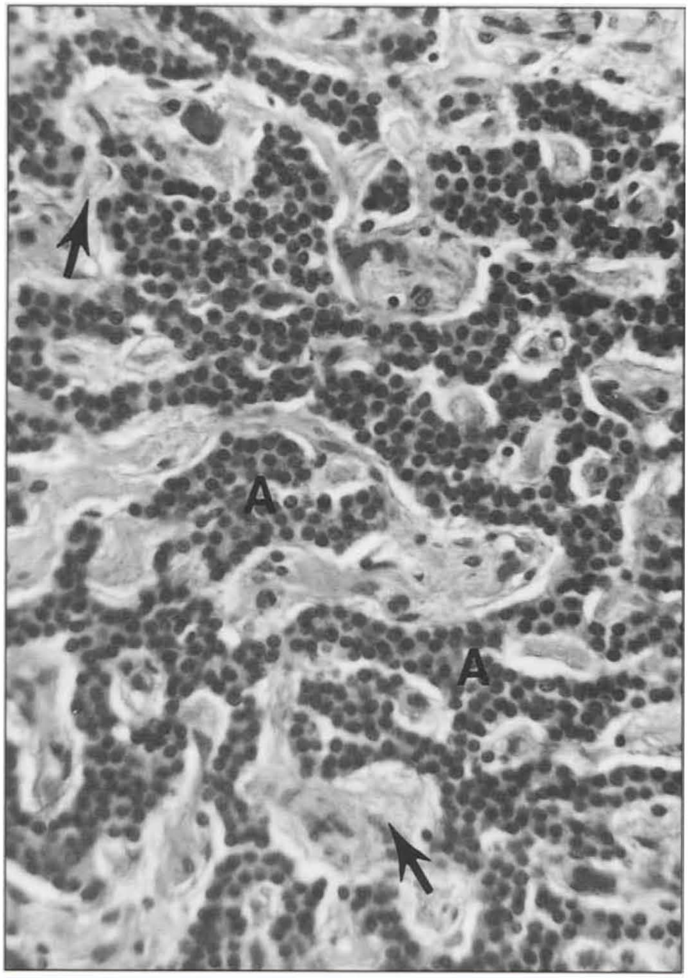

Figure 3.46 Atrophic parathyroid gland from a dog with cancer-associated hypercalcemia. Narrow cords of atrophic chief cells (A) are separated by interstitial spaces with increased connective tissue (arrows).

and avian oviduct. *Present evidence suggests that PTHrP acts as an autocrine or paracrine regulator in these normal tissues,* although its exact function in most normal adult tissues is largely unknown. Circulating concentrations of PTHrP in normal animals and humans are low (<1 pM) and the PTH/PTHrP receptor is often expressed on the same or adjacent cells in tissues that synthesize PTHrP. Epidermal keratinocytes produce PTHrP, which plays a role in their proliferation or differentiation.

The fetus maintains higher concentrations of serum calcium compared to the dam. Because the fetal parathyroid glands produce low levels of PTH, the mechanism of maintaining increased serum concentrations of calcium was unknown until the finding that *PTHrP maintains calcium balance in the fetus and is the major hormone secreted by the chief cells of the fetal parathyroid glands.* The PTHrP produced by the placenta also stimulates the uptake of calcium by the fetus. Parathyroid hormone-related peptide plays a role in the differentiation of many tissues during gestation and is especially important in the growth and development of bone. Growth of cartilage at the epiphyseal plate is regulated by PTHrP, which stimulates chondrocyte proliferation, inhibits apoptosis, and inhibits the maturation of chondrocytes from the proliferative zone to the hypertrophic zone.

The greatest concentration of PTHrP is found in milk (10–100 nmol/L) and is 10 000- to 100 000-fold greater than in the serum. The function of PTHrP in the mammary gland and in milk is poorly understood at present. However, recent studies have reported that over-expression of PTHrP in the mammary gland during glandular development prior to lactation results in glandular hypoplasia due to a reduction in the morphogenesis and branching of the mammary ducts. Biologically active PTHrP produced by alveolar epithelial cells during lactation results in the high concentration of PTHrP in milk and this PTHrP may play a role in stimulating the transport of calcium by alveolar epithelial cells from serum to milk. Synthesis of PTHrP by the mammary gland abruptly ceases when suckling stops and the gland undergoes involution. The PTHrP peptide is enzymatically cleaved in milk, but the N-terminal PTHrP fragment retains biologic activity. Smooth muscle including blood vessels, uterus, urinary bladder, gastrointestinal tract, and the oviduct of the hen produce PTHrP. In general, PTH-rP expression is increased when smooth muscle is stretched and PTHrP induces relaxation of smooth muscle and attenuation of contraction. With progressive distension of the uterus during pregnancy or during descent of the ovum in the hen's oviduct, *PTHrP likely functions as a paracrine regulator of vascular tone causing vasodilation and modulating vasoconstriction by other vasoactive compounds.*

Lymphosarcoma is the most common neoplasm associated with hypercalcemia in dogs and cats. Estimates of the prevalence of hypercalcemia in lymphoma dogs vary from 10 to 40%. Peripheral lymph node enlargement may or may not be detected, but there usually is evidence of cranial mediastinal or visceral involvement. *Most lymphomas associated with HHM in dogs are of the T-cell subset,* whereas lymphomas associated with normal blood calcium are usually of B-cell origin. Most dogs with lymphoma and hypercalcemia have increased circulating concentrations of PTHrP but the concentrations are not as high as those in dogs with HHM and apocrine adenocarcinomas, and PTHrP does not correlate with serum calcium concentration. It is not completely resolved whether the hypercalcemia develops from the production of humoral substances by neoplastic cells or from physical disruption of trabecular bone due to frequent marrow involvement, or from both mechanisms. Dogs with lymphosarcoma cells in bone marrow often have increased numbers of osteoclasts on trabecular bone surfaces opposite a surface lined by osteoid and large columnar osteoblasts (Fig. 3.47A, B).

Hypercalcemia with tumors metastatic to bone. *Solid tumors that metastasize widely to bone can produce hypercalcemia by the induction of local bone resorption associated with tumor growth. This is not common in animals,* but is an important cause of cancer-associated hypercalcemia in human beings. Tumors that often metastasize to bone and induce hypercalcemia in human patients include breast and lung carcinomas. The pathogenesis of enhanced bone resorption is not completely understood, but the *two primary mechanisms* include: (1) secretion of cytokines or factors that stimulate local bone resorption, and (2) indirect stimulation of bone resorption by tumor-induced cytokine secretion from local immune or bone cells. Cytokines or factors that may be secreted by tumor cells and stimulate local bone resorption include PTHrP, transforming growth factor-α and -β, and prostaglandins (especially PGE_2). In some cases, bone-resorbing activity can be inhibited by indomethacin, which suggests that prostaglandins are either directly or indirectly associated with the stimulation of bone resorption. The cytokines most often

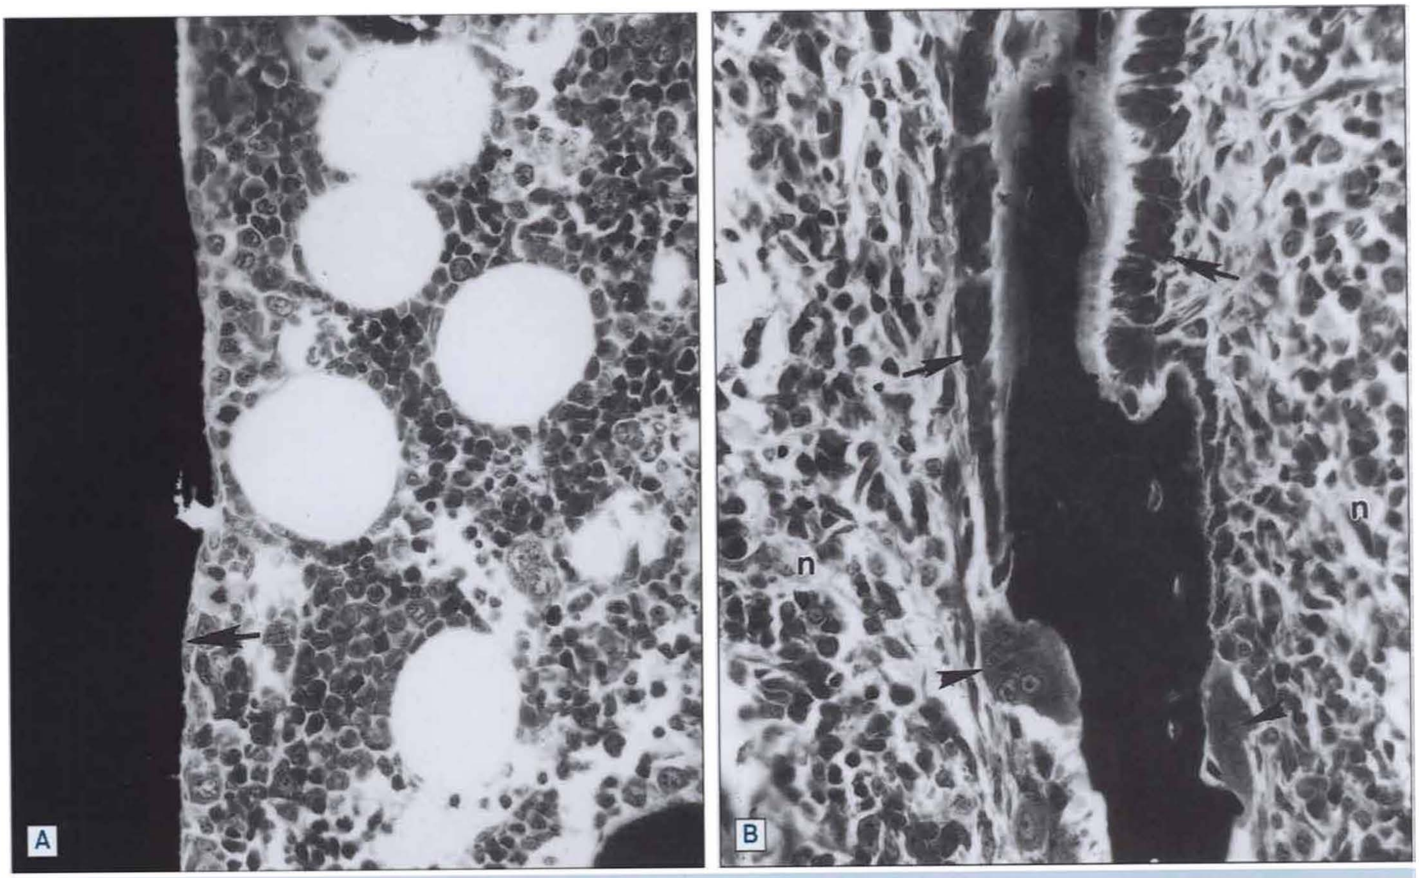

Figure 3.47 Lumbar vertebrae from a dog, von Kossa tetrachrome. **A.** Normocalcemic dog with smooth bone surface and flattened osteoblasts (arrow). **B. Hypercalcemic dog with lymphosarcoma of marrow** (neoplastic cells, n). Several osteoclasts (arrowheads) are present in lacunae. Hyperplastic osteoblasts (arrows) and prominent osteoid seams are present adjacent to resorptive surfaces. (From Meuten DJ, et al. Lab Invest 1983:49:553–562.)

implicated in indirect stimulation of bone resorption by local immune cells include interleukin-1 and tumor necrosis factor.

Differential diagnosis of humoral hypercalcemia of malignancy. *Lymphoma is the most common neoplasm associated with hypercalcemia in dogs and cats.* Peripheral lymph node enlargement may or may not be detected, but evidence usually exists for cranial mediastinal or visceral involvement. Serum immunoreactive PTH levels have been found to be subnormal in hypercalcemic dogs with lymphoma, and plasma immunoreactive PGE_2 levels did not differ from levels in control dogs. Culture media from normal lymphoid tissue and control media had no effect on release of ^{45}Ca from prelabeled fetal mouse forelimb bones; however, media from tumor tissue increased ^{45}Ca release. These findings suggested that the local production of bone-resorbing factors was important in stimulating calcium release from bone in certain dogs with lymphoma and hypercalcemia.

Evaluation of parathyroid function

Parathyroid function may be altered by a wide variety of diseases or by exposure to chemicals that either elevate or lower the blood concentration of calcium (particularly calcium ion). In response to hypocalcemia, chief cells undergo hypertrophy and eventually hyperplasia. On formalin- or Bouin's-fixed sections, the expanded cytoplasmic area is lightly eosinophilic and vacuolated. Perivascular spaces are narrow in a hyperplastic parathyroid and there are few fat cells in the interstitium. In response to hypercalcemia, the cytoplasmic area of chief cells is decreased and more densely eosinophilic often with a widening of intercellular and pericapillary spaces. If the hypercalcemia is prolonged, there is an overall reduction of glandular parenchyma with increased fibrous or adipose connective tissue in the interstitium. Subtle differences between affected and normal animals can be best evaluated by morphometric evaluation. The area ratios of parenchyma:interstitium of the glands and cytoplasm:nucleus of chief cells should be assessed.

Ultrastructural evaluation of chief cells is a sensitive means of morphologically evaluating the parathyroid gland. Perfusion of the thyroid–parathyroid area with glutaraldehyde-based fixatives followed by post-fixation with osmium tetroxide results in the best retention of structural detail in parathyroids of animals. Morphometric studies can be used to quantitate total cytoplasmic area and area occupied by a particular organelle (e.g., secretory granule).

In response to an acute lowering of blood calcium, a larger percentage of chief cells ultrastructurally will be in the active stage of synthesis and secretion than under steady-state conditions. This is indicated by a peripheral migration of secretory granules and alignment along the plasma membrane, aggregation of the endoplasmic reticulum into lamellar arrays, and enlargement of the Golgi apparatus associated with many small dense granules in the process of formation. Conversely, chief cells in response to hypercalcemia are predominantly in the inactive stage of the secretory cycle as evaluated by electron microscopy with dispersed profiles of endoplasmic reticulum, small Golgi complexes with few granules, and often accumulations of either glycogen or lipid (depending upon species) in the cytoplasm. Secretory granules accumulate initially in response to elevated blood calcium, but subsequently decrease due to degradation by lysosomal enzymes by the process of crinophagia. Atrophic chief cells develop in response to sustained and/or more severe hypercalcemia. Their cytoplasm is more electron-dense and irregularly shrunken with widened intercellular spaces. Cytoplasmic organelles are poorly developed and may have early degenerative changes suggested by mitochondrial vacuolation with disruption of cristae and distention of endoplasmic reticulum with loss of ribosomes.

The metabolism of PTH and the formation of multiple circulating forms of PTH have made development of clinically useful immunoassays challenging. The principal circulating forms of PTH include intact PTH (1-84) and C-terminal peptides (PTH 35-84). Parathyroid hormone has two functional domains. N-terminal PTH (1-34) is the region of major biological activity in relation to calcium regulation. N-terminal PTH does not exist in the circulation in a biologically relevant concentration, but administration of exogenous PTH (1-34) will induce the typical actions of PTH on bone and kidney cells. The function of C-terminal PTH-derived peptides is less well understood.

PTH is secreted from chief cells in two forms, *viz.* intact PTH (1-84) and C-terminal peptides. PTH (1-84) is the circulating form of biologically active PTH and is rapidly removed from the circulation by endopeptidases on Kupffer cells or glomerular filtration. Its half-life is less than 5 minutes. Some of the C-terminal peptides are released from the Kupffer cells back into the circulation and are excreted by glomerular filtration. Therefore, C-terminal PTH has a longer serum half-life than PTH (1-84) and is present in the serum at greater concentrations (50–90% of total PTH) than PTH (1-84), especially in states of hyperparathyroidism. End organs (bone and kidney) also are responsible for degradation of a small fraction of serum PTH. This involves internalization of PTH–receptor complexes and intracellular degradation by lysosomal enzymes. Rapid removal of PTH from the circulation allows the in vivo actions of PTH to be controlled by the rate of PTH secretion from the parathyroid chief cells.

Immunoassays for PTH initially were single-site radioimmunoassays (RIA) for C-terminal peptides. These assays were suboptimal, since the biologically active form of PTH was not measured; however, they were clinically useful in states of hyperparathyroidism in patients with normal renal function. Midregion and C-terminal RIAs measure both intact PTH and C-terminal PTH, which make them less clinically relevant. In addition, conditions that reduce glomerular filtration rate, such as renal failure, will result in a large increase in the serum concentration of C-terminal PTH. *Intact serum PTH concentrations are best measured by two-site immunoradiometric assay (IRMA) or N-terminal RIA.* Serum intact PTH can be measured in dogs and cats with assays developed for human PTH due to the cross-reactivity of the antisera used in the assays. Intact PTH has been successfully measured in dogs or cats with either a human N-terminal RIA or two-site IRMA with good correlation between the two assays.

THYROID GLAND

Development, structure, and function

Embryologic development of the thyroid gland

The thyroid gland originates as a thickened plate of epithelium in the floor of the pharynx. It is intimately related to the aortic sac in its development and this association leads to the frequent finding of *accessory thyroid parenchyma* in mediastinal structures, especially in dogs. This accessory thyroid tissue may undergo neoplastic transformation. Branched cell-cords develop from the pharyngeal plate and migrate dorsolaterally but remain attached to the pharyngeal area by the narrow *thyroglossal duct.* The entodermal bud that forms the thyroid gland arises on the midline at the level of the first pharyngeal pouch (see Fig. 3.25). This gives rise to the thyroglossal duct, which migrates caudally. The proliferation of cell cords at the distal end of the thyroglossal duct forms the follicles of each thyroid lobe. The area at the base of the tongue marking the origin on the thyroid gland is referred to as the *foramen cecum linguae* in postnatal life. Calcitonin-secreting C cells of neural crest origin reach the postnatal thyroid gland by migrating into the *ultimobranchial body.* This last pharyngeal pouch moves caudally in mammals to fuse with the primordia of the thyroid gland and distribute C cells into each thyroid lobe.

Folliculogenesis is a complex process in the thyroid that begins by the proliferation of irregularly arranged cell cords derived from the entoderm of the thyroglossal duct on the midline of the developing pharyngeal gut. The solid cell clusters extend caudally into the primitive mesenchyme and develop complex interdigitations of plasma membranes of adjacent cells. Primitive follicles develop either by invagination of the plasma membrane of individual follicular cells to form intracytoplasmic colloid-containing microfollicles that subsequently coalesce to form larger follicles, or by the secretion of colloid in the narrow intercellular spaces limited by zonulae adherens and desmosomes. In rats with a normal 21-day gestation period, thyroid follicles begin to form between days 15 and 18 of gestation. Thyroid stimulating hormone (TSH, thyrotropin) may not be required for the formation of the initial primitive follicles, but follicles formed on day 17 and subsequent days of gestation are responsive to TSH for their final development in rats.

A portion of the thyroglossal duct may persist postnatally and form a cyst. **Thyroglossal duct cysts** are present in the ventral aspect of the cranial cervical region in dogs. Their lining epithelium may undergo neoplastic transformation (see discussion of cervical cysts in parathyroid–thyroid area, above).

Accessory thyroid tissue *is common in the dog,* and may be located anywhere from the larynx to the diaphragm. About 50% of adult dogs have accessory thyroid tissue embedded in the fat on the intrapericardial aorta. These nodules are usually 2–5 mm in dimension and may be multiple (Fig. 3.48). They lack C (parafollicular) cells, which secrete calcitonin, but their follicular structure and function (ability to concentrate iodine and iodinate tyrosyl residues) are the same as that of the main thyroid lobes. Attempts to induce hypothyroidism in the dog by surgical thyroidectomy are not consistently successful because the follicular cells in the accessory thyroids readily respond to the prompt increase in endogenous TSH and undergo hyperplasia sufficient to sustain adequate hormone production.

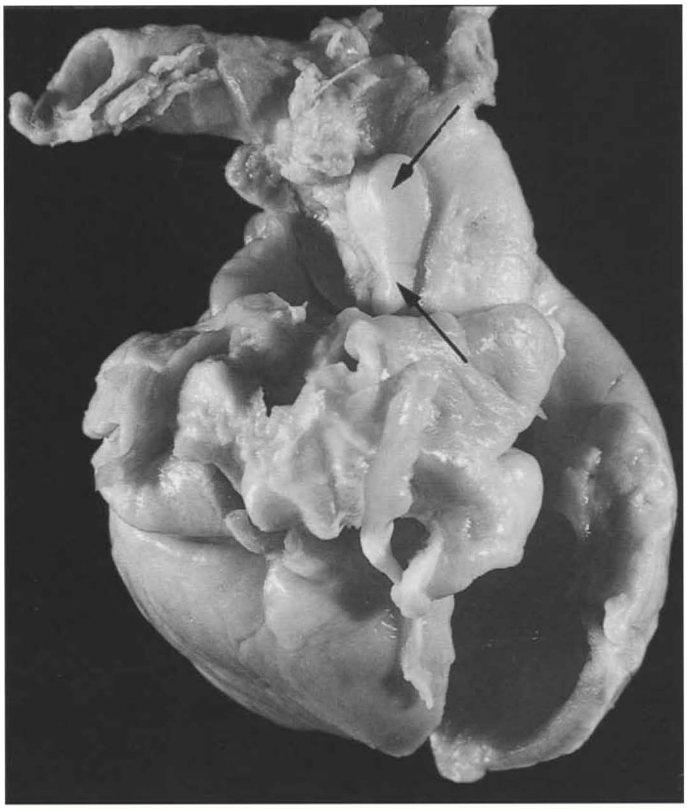

Figure 3.48 Ectopic thyroid tissue (arrows) at the base of the heart from a dog.

Structure of the thyroid gland

The two thyroid lobes in most species are located on the lateral surfaces of the trachea. In pigs, the main lobe of the thyroid is in the midline in the caudal cervical region with dorsolateral projections from each side.

The principal blood supply to each lobe in the dog is from the cranial thyroid artery (a branch of common carotid), and the major venous drainage is via the caudal thyroid vein that enters the internal jugular vein. Lymph drainage from the cranial pole of the thyroid lobes in dogs is to the retropharyngeal lymph nodes. Lymph flow from the caudal aspect of each thyroid lobe is variable, but it often bypasses any lymph nodes before entering the brachiocephalic trunk. Efferent lymphatics usually enter directly into the cervical lymphatic trunk or internal jugular vein. *This explains the frequent occurrence of pulmonary metastases from thyroid carcinoma in dogs prior to development of secondary foci in regional lymph nodes.* Small efferent lymphatics may pass through the caudal cervical lymph nodes along the ventral surface of the trachea before entering the cranial mediastinum. These vascular arrangements are significant for the spread of thyroid carcinomas.

The thyroid gland is the largest of the endocrine organs that functions exclusively as an endocrine gland. The basic histologic structure of the thyroid is unique for endocrine glands, consisting of follicles of various sizes (20–250 μm) that contain colloid produced by the **follicular cells (thyrocytes)**. The follicular cells are cuboidal to low columnar (under conditions of normal iodine intake), and their secretory polarity is directed toward the lumen of the follicles. An extensive network of interfollicular capillaries provides the follicular cells with an abundant blood supply. Follicular cells have extensive

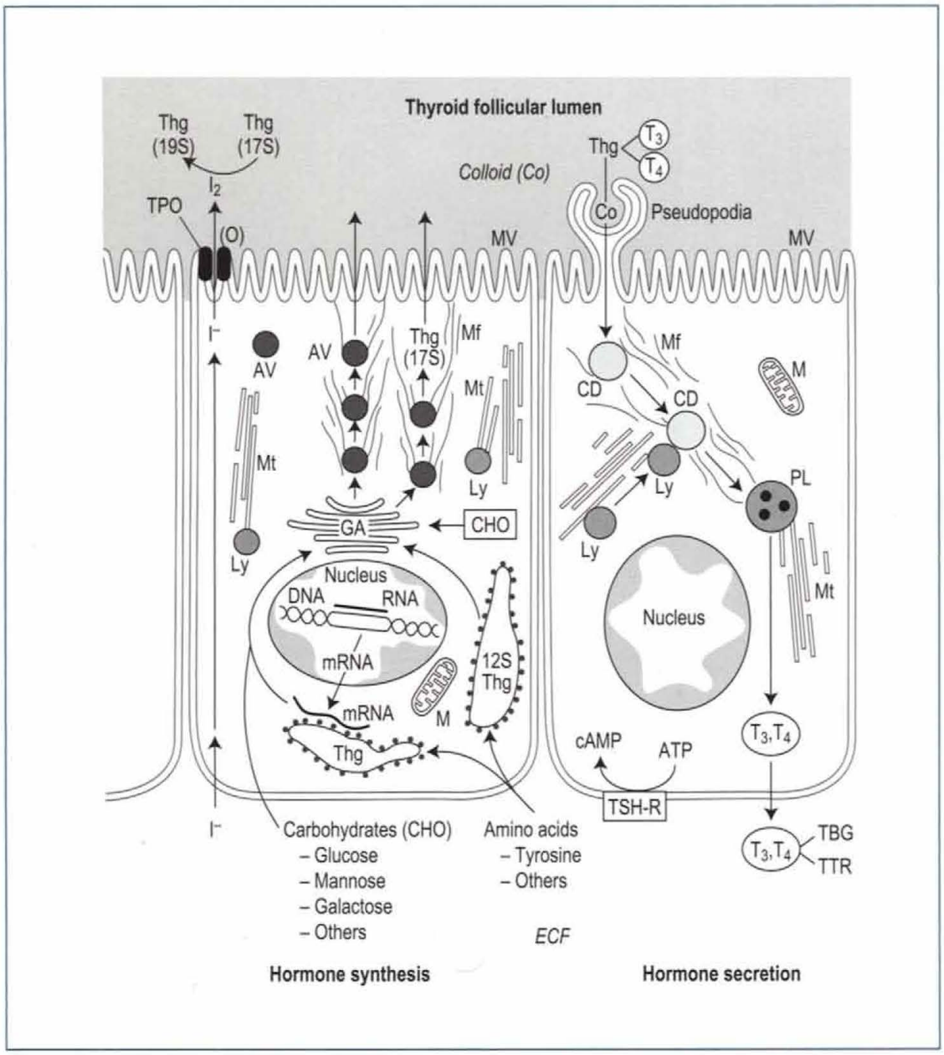

Figure 3.49 Thyroid follicular cells illustrating two-way traffic of materials from capillaries to follicular lumen. Raw materials, such as iodide ion (I^-), are concentrated and rapidly transported into follicular lumen (left side of drawing). Amino acids (e.g., tyrosine) and sugars are assembled by follicular cells into thyroglobulin (Thg), packaged into apical vesicles (AV), and released into lumen. Iodination of tyrosyl residues occurs within the thyroglobulin molecule to form thyroid hormones (iodothyronines) in the follicular lumen. Elongation of microvilli (MV) and endocytosis of colloid by follicular cells occurs in response to TSH stimulation (right side of drawing). Intracellular colloid droplets (CD) fuse with lysosomal bodies (Ly) and active thyroid hormones (T_4 and T_3) are enzymatically cleaved from thyroglobulin and free T_4 and T_3 are released into circulation. (Modified and redrawn from Bastenie PA, et al. In: Molecular Pathology. 1975.)

profiles of rough endoplasmic reticulum and a large Golgi apparatus in their cytoplasm for synthesis and packaging substantial amounts of protein (e.g., thyroglobulin) that is then transported into the follicular lumen. The interface between the luminal side of follicular cells and the colloid is modified by numerous microvillus projections.

Various numbers of lysosomes, histochemically stainable for enzymes such as acid phosphatase, are found in the apical portion of follicular cells. Soon after stimulation of follicular cells by TSH, intracellular droplets of ingested colloid (phagosomes), corresponding to those demonstrated light microscopically by the PAS reaction, are more numerous than in the resting state. Some of these form phagolysosomes in follicular cells by fusion with lysosomes.

Biosynthesis of thyroid hormones

The synthesis of thyroid hormones is unique among endocrine glands because the final assembly of hormone occurs extracellularly within the follicular lumen. Essential raw materials, such as **iodide ion (I^-)**, are trapped by follicular cells from plasma, transported rapidly against a concentration gradient to the lumen of the follicle, and oxidized by a peroxidase enzyme in the microvillus membranes to **iodine (I_2)**.

The assembly of thyroid hormones within the follicular lumen is made possible by a unique protein (**thyroglobulin**) synthesized by follicular cells (Fig. 3.49). Thyroglobulin is a high molecular weight glycoprotein synthesized in successive subunits on the ribosomes of the endoplasmic reticulum in follicular cells. The constituent amino acids (tyrosine and others) and carbohydrates (mannose, fructose, galactose) are derived from the circulation. Recently synthesized thyroglobulin leaving the Golgi apparatus is packaged into apical vesicles that are extruded into the follicular lumen.

The amino acid **tyrosine**, an essential component of thyroid hormones, is incorporated within the molecular structure of thyroglobulin. Iodine is bound to the tyrosyl residues in thyroglobulin at the apical surface of follicular cells to form successively **monoiodotyrosine (MIT)** and **diiodotyrosine (DIT)**. These biologically inactive iodothyronines subsequently are coupled together under the influence of thyroperoxidase to form the two **biologically active iodothyronines** (**thyroxine (T4), triiodothyronine (T3)**) secreted by the thyroid gland.

The functionally important **thyroperoxidase** enzyme in the thyroid hormone synthetic pathway is present in the apical plasma membrane and microvilli as well as in other membranous structures of the follicular cells. Thyroperoxidase is a membrane-bound, heme-containing glycoprotein composed of 933 amino acids with a transmembrane domain. This important enzyme oxidizes (in the presence of hydrogen peroxidase) iodide ion (I^-) taken up by follicular cells

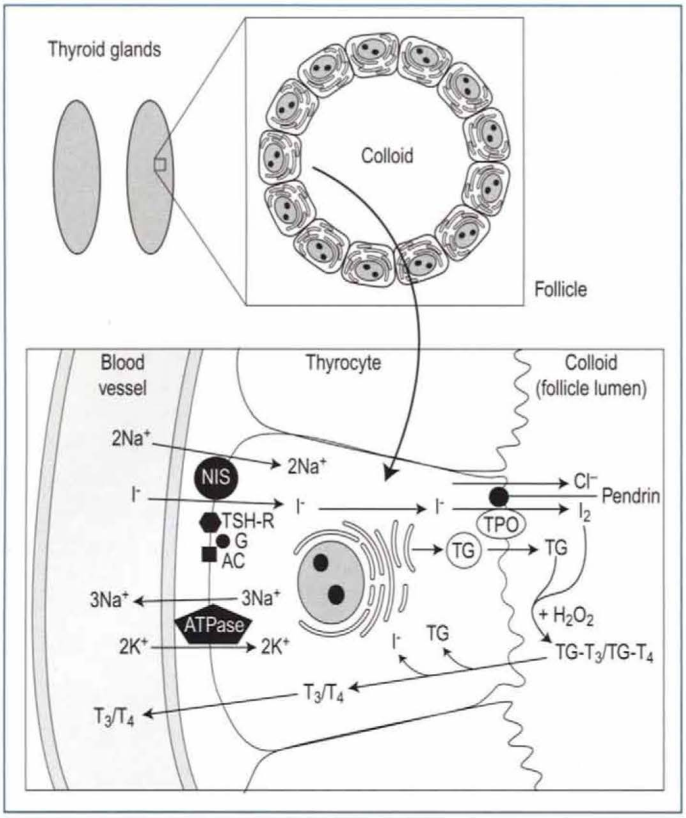

Figure 3.50 Sodium iodide symporter (NIS) and thyroid hormone biosynthesis. The NIS located in the basolateral membrane of thyroid follicular cells is responsible for the rapid uptake and concentration of iodide ion (I^-) from the circulation. The enzyme thyroperoxidase (TPO) in microvilli on the lumenal surface oxidizes I^- in the presence of H_2O_2 to reactive iodine (I_2) that subsequently binds to tyrosyl residues in the thyroglobulin (TG) molecule of the colloid. AC = adenylate cyclase. G = G-protein. T_3 = triiodothyronine. T_4 = thyroxine. TSH-R = thyroid stimulating hormone receptor. (Courtesy of La Perle K. Encyclopedia of Hormones. 2002.)

through the function of the sodium iodide symporter into reactive iodine (I_2), which binds to the tyrosine residues in thyroglobulin. Iodine is incorporated not only into newly synthesized thyroglobulin recently delivered to the follicular lumen, but also into molecules already stored in the lumen. Thyroperoxidase also functions as a coupling enzyme to combine MIT and DIT to form triiodothyronine (T_3), or two DITs to form thyroxine (T_4).

The mechanism of active transport of iodide has been shown to be associated with a **sodium iodide (Na^+–I^-) symporter (NIS)** present in the basolateral membrane of thyroid follicular cells (Fig. 3.50). Transport of iodide ion across the thyroid cell membrane is linked to the transport of Na^+. The ion gradient generated by the Na^+–K^+ ATPase appears to be the driving force for the active co-transport of iodide. The transporter protein is present in the basolateral membrane of thyroid follicular cells and is a large protein containing 643 amino acids with 13 transmembrane domains.

Other tissues, such as salivary gland, gastric mucosa, choroid plexus, ciliary body of the eye, and lactating mammary gland, also have the capacity to actively transport iodide, albeit at a much lower level than the thyroid. In the salivary glands, NIS protein has been detected in ductal cells but not in acinar cells. Only the thyroid follicular cells accumulate iodide in a TSH-dependent manner. The NIS gene is complex (15 exons, 14 introns) and its expression in the thyroid is up-regulated by TSH. *The functionally active iodine transport system in the thyroid gland has important clinical applications in the evaluation, diagnosis, and treatment of several thyroid disorders, including cancer.* The NIS and active transport of iodide can be selectively inhibited by competitive anion inhibitors (e.g., perchlorate, thiocyanate); thereby, effectively blocking the ability of the gland to iodinate tyrosine residues in thyroglobulin and synthesize thyroid hormones.

The ability of NIS to concentrate iodide holds clinical relevance, in addition to its physiological importance, by providing the basis for using radioactive iodine in the treatment and management of various thyroid diseases. Radioactive iodine is commonly used to destroy overactive thyrocytes in patients with thyrotoxicosis, to ablate normal and malignant thyroid tissues in patients who have undergone total thyroidectomy for thyroid carcinoma, and to perform whole-body scans for the detection of recurrent and metastatic thyroid cancer.

Once within the thyrocyte, iodide ion is passively transported via **pendrin** into the follicular lumen. Pendrin, an ~86 kDa chloride/iodide transport protein, is located at the apical membrane of thyrocytes, and is responsible for the transport of iodide ion into the follicular lumen. It is the product of the gene responsible for *Pendred syndrome*, a genetic disorder in human patients characterized clinically by sensorineural hearing loss and goiter. Pendrin is characterized by 11 or 12 putative transmembrane domains and is closely related to a family of sulfate transport proteins; however, pendrin does not transport sulfate and unlike NIS does not require sodium for its transport of iodide.

Thyroid hormone secretion

The secretion of thyroid hormones from stores within luminal colloid is initiated by elongation of microvilli on follicular cells and formation of pseudopodia. These elongated cytoplasmic projections are increased by pituitary TSH, extend into the follicular lumen, and indiscriminately phagocytize a portion of adjacent colloid. Colloid droplets within follicular cells subsequently fuse with numerous lysosomal bodies that contain proteolytic enzymes. Triiodothyronine (T_3) and thyroxine (T_4) are released from the thyroglobulin molecule and, because of their hydrophobic nature, diffuse out of follicular cells into the adjacent capillaries. The biologically inactive iodotyrosines (MIT, DIT) simultaneously released from the colloid droplets are deiodinated enzymatically, and the iodide generated is either recycled to the follicular lumen to iodinate new tyrosyl residues or released into the circulation under normal conditions. Thyroxine is rapidly bound in plasma to albumin and several globulin fractions (especially high-affinity **thyroxine-binding globulin (TBG)**), and triiodothyronine is bound to albumin (**transthyretin**) and one globulin fraction in dogs.

Negative feedback control of thyroid hormone secretion is accomplished by the coordinated response of the adenohypophysis and specific hypothalamic nuclei to circulating levels of thyroid hormones (especially T_3). A decrease in thyroid hormone concentration in plasma is sensed by groups of neurosecretory neurones in the hypothalamus that synthesize and secrete a small peptide (3 amino acids), **thyrotropin-releasing hormone (TRH)**, into the hypophyseal portal circulation. Thyroid stimulating hormone (TSH) or thyrotropin (TTH) is conveyed to thyroid follicular cells where it binds to the basilar aspect of the cell, activates adenyl cyclase, and increases the

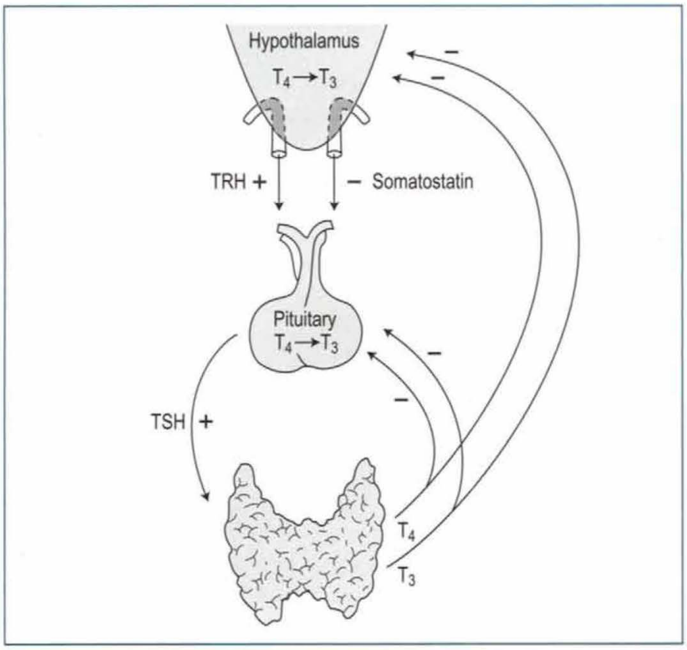

Figure 3.51 Hypothalamic-pituitary-thyroid axis. Thyroid stimulating hormone (TSH) from the pituitary stimulates the secretion of both tetraiodothyronine (T_4) and triiodothyronine (T_3). These act at the pituitary level to control secretion of TSH by a negative feedback mechanism. In addition, T_4 is converted to T_3 within the pituitary by a monodeiodinase. Secretion of TSH is stimulated by thyrotropin-releasing hormone (TRH) from the hypothalamus and inhibited by somatostatin and to a lesser extent by dopamine. Thyroid hormones act at the hypothalamus to stimulate the secretion of somatostatin. T_4 also is deiodinated to T_3 within the hypothalamus and this conversion which plays a role in feedback regulation. (Redrawn from Reichlin S. In: Williams Textbook of Endocrinology, 9th ed., 1998.)

rate of biochemical reactions concerned with the synthesis and secretion of thyroid hormones (Fig. 3.51).

One of the initial responses by follicular cells to TSH is the formation of numerous cytoplasmic pseudopodia, resulting in increased endocytosis of colloid and release of preformed thyroid hormones stored within the follicular lumen. If the secretion of TSH is sustained (hours or days), thyroid follicular cells become more columnar, and follicular lumina become smaller due to increased endocytosis of colloid. Numerous PAS-positive **colloid droplets** are present in the luminal aspect of the hypertrophied follicular cells. The converse of what has been just described occurs in response to an increase in circulating thyroid hormones and a corresponding decrease in circulating pituitary TSH. Thyroid follicles become enlarged and distended with colloid due to decreased TSH-mediated endocytosis of colloid. Follicular cells lining the involuted follicles are cuboidal and there are few endocytotic vacuoles at the interface between the colloid and follicular cells.

There are differences in thyroid morphology and function between canine breeds of European origin and the Basenji, which originated in Africa. At the same level of iodine intake, thyroidal turnover of iodine is 2–3 times faster in the Basenji than in European breeds. The corresponding differences in thyroid morphology in the Basenji include smaller follicles, more widespread and uniform vacuolation of colloid, more columnar follicular epithelium, and ultrastructural features of follicular cells that more closely resemble those of the TSH-stimulated thyroid in European breeds, such as the Beagle.

Action of thyroid hormones

Once released into the circulation, **thyroxine (T_4)** and **triiodothyronine (T_3)** act on many different target cells in the body. The overall functions of the hormones are similar, though much of the biologic activity is the result of monodeiodination by **5′-deiodinase** to 3,5,3′-triiodothyronine (active T_3) prior to interacting with target cells. Under certain conditions (protein starvation, neonatal animals, liver and kidney disease, febrile illness, etc.) or exposure to xenobiotics, thyroxine is preferentially monodeiodinated by 5′-deiodinase to 3,3′,5′-triiodothyronine (**"reverse T3"**) (see Fig. 3.68). Since this form of T_3 is biologically inactive, monodeiodination to form reverse T3 provides a mechanism to attenuate the metabolic effects of thyroid hormones in peripheral tissues.

The subcellular mechanism of action of thyroid hormones resembles that for steroid hormones, in that free hormone enters target cells and binds loosely to cytosol-binding proteins. Free triiodothyronine initially binds to receptors on the inner mitochondrial membrane to activate mitochondrial energy metabolism, and subsequently binds to nuclear receptors and increases transcription of the genetic message (mRNA) to facilitate new protein synthesis (e.g., structural, enzymatic, and binding proteins).

Thyroid hormone functions in target cells are mediated by three nuclear receptors: $T_3R\alpha_1$, $T_3R\beta_1$, and $T_3R\beta_2$ that are encoded by two genes, viz. $T_3R\alpha$ and $T_3R\beta$. Thyroid hormones are essential for numerous postnatal developmental processes including growth and neurogenesis. The $T_3R\alpha$ gene is widely expressed from early development, while the $T_3R\beta$ gene is highly restricted and expressed later in development. Mice with targeted disruption of the $T_3R\alpha$ gene have markedly reduced production of both T_4 and T_3, associated with growth arrest and delayed development of bones and small intestine. By comparison, mice with targeted disruption of the $T_3R\beta$ gene have overproduction of thyroid hormones and impairment of auditory function but no developmental defects.

The *overall physiologic effects of thyroid hormones* are to: increase the basal metabolic rate; make more glucose available to meet the elevated metabolic demands by increasing glycolysis, gluconeogenesis, and glucose absorption from the intestine; stimulate new protein synthesis; increase lipid metabolism and conversion of cholesterol into bile acids and other substances; activate lipoprotein lipase and increase sensitivity of adipose tissue to lipolysis by other hormones; stimulate heart rate, cardiac output, and blood flow; increase neural transmission, cerebration, and neuronal development in young animals.

Diseases of the thyroid gland

Developmental disturbances of the thyroid gland

Aplasia and **hypoplasia** are uncommon and may be bilateral, in species with paired thyroids, or unilateral. Bilateral aplasia or hypoplasia of the thyroid in a young animal may result in dwarfism and other manifestations of early-onset hypothyroidism (i.e., subnormal central nervous system development, failure to grow at a normal rate, etc.).

Congenital hypothyroidism has been reported with primary thyroid hypoplasia in Scottish Deerhound pups. Thyroid glands were smaller than normal and composed of small follicles with little or no colloid (Fig. 3.52A) compared to age-matched normal

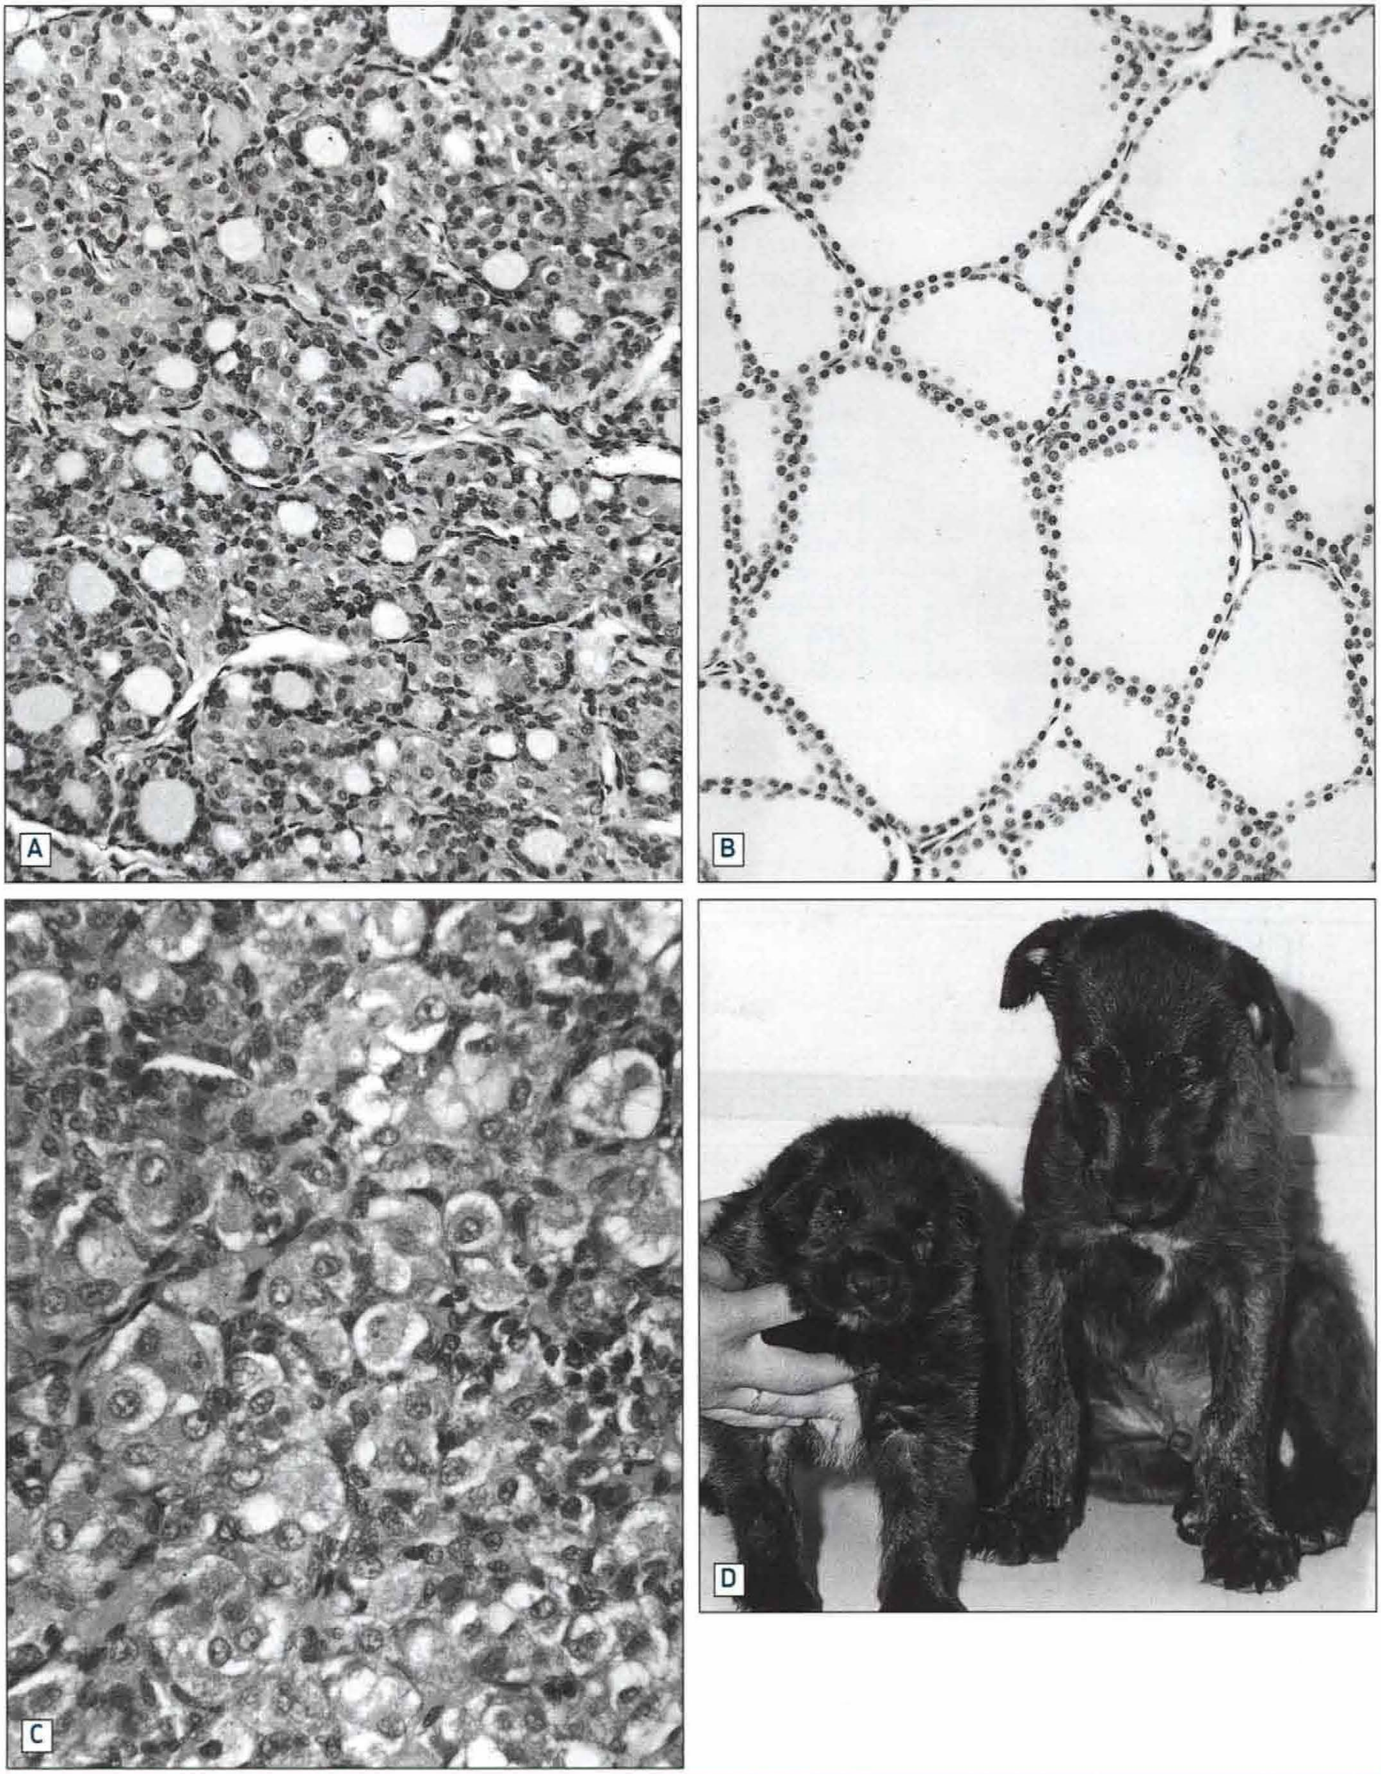

Figure 3.52 Primary thyroid hypoplasia. Scottish Deerhound with nongoitrous congenital hypothyroidism. **A.** Small thyroid follicles with little stored colloid. **B.** Normal thyroid gland from 8-week-old Scottish Deerhound pup with large colloid-filled follicles lined by low cuboidal follicular cells. **C.** Adenohypophysis from pup with thyroid hypoplasia. Numerous vacuolated trophic hormone (TSH)-producing cells are admixed with a few granulated acidophils. **D.** The hypothyroid pup (left) is smaller, has a shortened domed head, and a fine haircoat. (From Robinson WF, et al. Aus Vet J 1988;65:386–389.)

pups (Fig. 3.52B). The pituitary gland was normal macroscopically, but contained few granulated acidophils with a high percentage of markedly vacuolated cells with few cytoplasmic granules, similar to thyroidectomy cells (Fig. 3.52C). Serum thyroxine levels were markedly decreased and did not increase in response to exogenous TSH. The affected puppies had retarded growth, fine hair coat, weakness, difficulty in walking, mental depression and somnolence. Pups with thyroid hypoplasia were smaller than their littermates and had short limbs and a short broad head (Fig. 3.52D). There was an absence of ossification of epiphyses in the axial and appendicular skeleton (see Vol. 1, Bones and joints).

Thyroglossal duct cysts develop most frequently in dogs and pigs and occasionally other animals by persistence of portions of the midline embryologic primordium of the thyroid that migrates caudally from the floor of the primitive pharynx to form the postnatal thyroid lobes. Thyroglossal duct cysts are present in the ventral midline of the cervical region in dogs as fluctuant masses that may rupture and form a fistulous tract to the exterior. Their lining epithelium consists of multiple layers of follicular cells with occasional colloid-containing follicles that may undergo neoplastic transformation and give rise to papillary carcinomas (see Neoplasms of the thyroid gland).

Other cysts that develop in the thyroid region that must be differentiated from thyroglossal duct cysts include parathyroid cysts, branchial ("lateral neck") cysts, ultimobranchial duct cysts, follicular ("colloid") cysts, and salivary mucoceles. These are discussed under Parathyroid and related cysts.

Degenerative changes of the thyroid gland

The formation of densely basophilic spherules or granules in the colloid of thyroid follicles occurs frequently in adult to aged dogs and occasionally in other species. These **corpora amylacea-like bodies** appear to represent the precipitation of mineral on aggregated colloid (possibly with abnormal chemical structure). **Colloid mineralization** develops in animals with normal blood calcium and phosphorus levels, and does not appear to be consistently associated with other diseases. It is distinctly different from the mineralization of interfollicular capillaries associated with chronic renal failure. The mineralization of colloid usually is not associated with any interference with thyroid function, even though it affects many follicles.

The accumulation of **lipofuscin** in follicular cells occurs in many animals and accounts for the progressive darkening (brown-red) of the thyroid with advancing age. The numerous PAS-positive lipofuscin granules accumulate particularly in the luminal aspect of follicular cells, but do not appear significantly to interfere with thyroid function.

The deposition of **amyloid** in the interstitium between thyroid follicles has been observed in dogs, cats (especially certain breeds such as Abyssinian), cattle, and occasionally in other animals. Affected thyroids may be slightly enlarged, pale, and firmer than normal. The interstitial accumulation of amyloid may be extensive and compress adjacent follicles, but usually not to a degree that interferes with thyroid function clinically. Amyloid in the thyroid of dogs and cattle almost always is part of generalized amyloidosis associated with a chronic suppurative process elsewhere in the body.

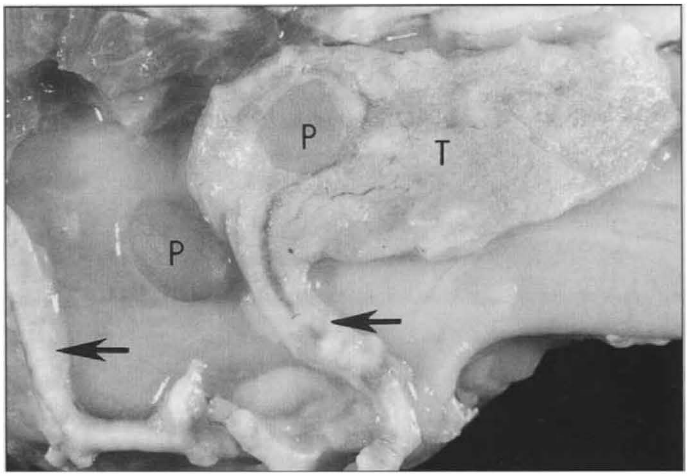

Figure 3.53 Idiopathic follicular atrophy. Thyroid (T) is reduced in size compared to adjacent parathyroids (P) and lighter in color due to increased adipose connective tissue. Thyroid arteries (arrows) are thickened and prominent due to atherosclerosis.

Hypofunction of the thyroid gland

Hypothyroidism of adult onset is a well-recognized clinical disease in dogs, but is encountered only occasionally in other animals. (Congenital hypothyroidism is discussed under Developmental diseases of the thyroid gland.) Although hypothyroidism may occur in many adult purebred and mixed breed dogs, certain breeds (Golden Retrievers, Doberman Pinschers, Dachshunds, Shetland Sheepdogs, Irish Setters, Miniature Schnauzers, Cocker Spaniels, and Airedales) have been reported to be more commonly affected. *Hypothyroidism in dogs usually is the result of* **primary** *lesions in the thyroid gland, particularly lymphocytic thyroiditis and idiopathic follicular collapse.* Less common causes of hypothyroidism in dogs are *bilateral nonfunctional thyroid tumors* or *severe iodine-deficient hyperplastic goiter.* Hypothyroidism associated with long-standing pituitary or hypothalamic lesions that prevent the release of either TSH (**secondary**) or thyrotropin-releasing hormone (TRH) (**tertiary**) is much less common in dogs. The thyroid gland in secondary hypothyroidism is moderately reduced in size and composed of colloid-distended "involuted" follicles lined by flattened follicular cells (see Fig. 3.17).

Idiopathic follicular atrophy ("collapse")

In follicular atrophy, *there is progressive loss of follicular epithelium and replacement by adipose tissue with a minimal inflammatory response.* The gland usually is smaller and lighter in color than normal (Fig. 3.53). The early lesion of follicular atrophy that is seen in dogs with mild clinical signs of hypothyroidism appears to be confined to one part of the thyroid. The affected part of the thyroid gland contains small follicles lined by tall columnar follicular cells, often with little colloid (Fig. 3.54A). Immediately adjacent thyroid follicles are normal. Individual or small groups of degenerate follicular cells with eosinophilic cytoplasm and pyknotic nuclei are present in the follicular wall, colloid, and interstitium (Fig. 3.54B).

A more advanced form of follicular atrophy is seen in dogs with clinical hypothyroidism and low circulating concentrations of thyroid hormones. The thyroid gland is composed predominantly of

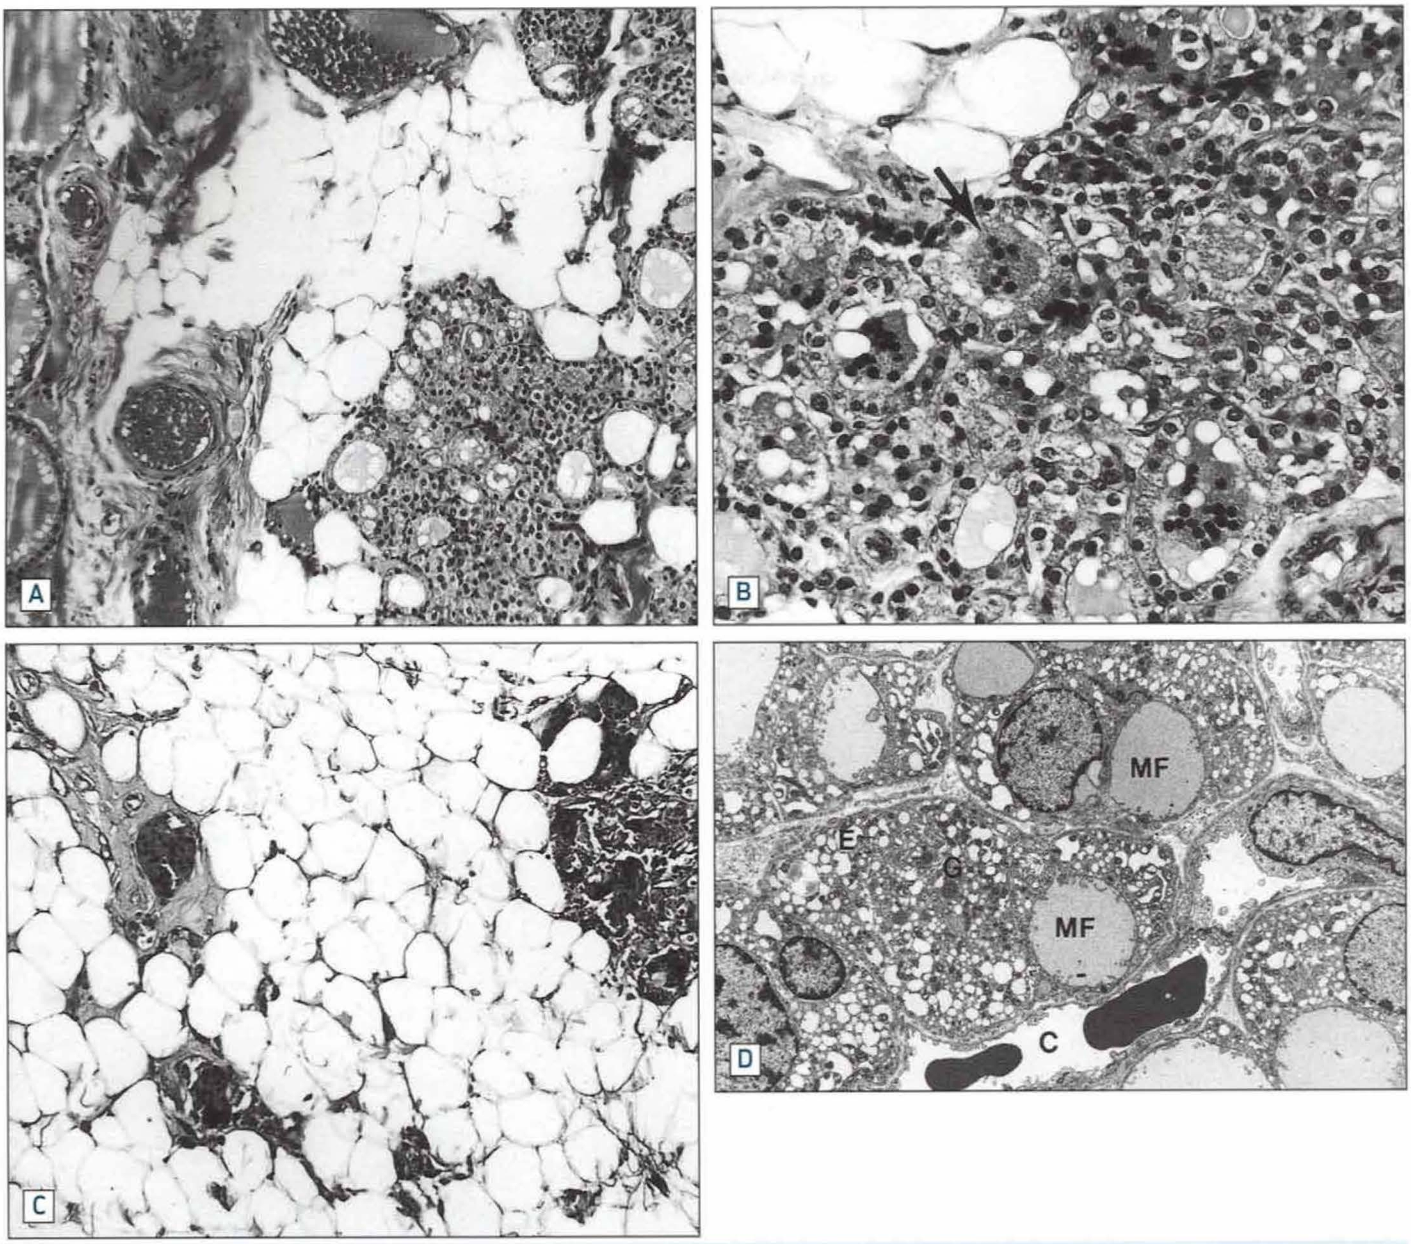

Figure 3.54 Idiopathic follicular atrophy in a dog. **A.** Early stage. **B.** Degenerate follicular cells in follicular wall and colloid (arrow). **C.** Late stage. Thyroid consists mainly of adipose tissue, scattered small follicles and nests of C cells. **D.** Note the lack of normal thyroid follicles and the presence of microfollicles (MF) in the cytoplasm of individual follicular cells. The remaining follicular cells are hypertrophied with dilated endoplasmic reticulum (E) and well-developed Golgi apparatuses (G). C = capillary. (From Gosselin SJ, et al. Vet Pathol 1981;18:299–309.)

adipose tissue with only occasional clusters of small follicles containing vacuolated colloid (Fig. 3.54C). When the thyroid is reduced markedly in size, it consists primarily of small follicles and individual follicular cells with PAS-positive colloid in microfollicles in the cytoplasm (Fig. 3.54D). Small foci of lymphocytes and plasma cells may be associated with disruption of thyroid follicles and release of colloid. The mild increase of connective tissue in the interstitium appears to be the result of condensation of the normal stroma. Focal aggregates of C cells appear relatively more prominent due to progressive loss of follicular cells. Occasionally, thyroid glands with idiopathic follicular atrophy have either an encapsulated microadenoma or a nonencapsulated area of nodular hyperplasia of follicular cells.

The earliest lesion of idiopathic follicular atrophy observed by electron microscopy is degeneration of individual follicular cells lining thyroid follicles. The advanced stage of follicular atrophy is characterized ultrastructurally by a lack of normal thyroid follicles and the presence of microfollicles in the cytoplasm of individual follicular cells. The remaining hypertrophic follicular cells form small nests and are arranged closely along capillaries. The microfollicles appear to form by invagination of the apical surface of the follicular cells. Long microvilli extend into the colloid and membrane-limited colloid droplets are present in the cytoplasm near the microfollicle, suggesting increased endocytotic activity. Degenerate follicular cells with poorly defined plasma membranes, an irregularly shrunken nucleus, markedly dilated profiles of rough endoplasmic reticulum, and swollen mitochondria with disrupted cristae often are scattered in the interstitium. Macrophages with membrane-limited vacuoles containing myelin bodies, other membranous debris, and lysosomes are present near the degenerate follicular cells. The basement membrane may be thickened focally around remaining follicular cells. Small groups of thyroid C cells remain in thyroids with idiopathic follicular atrophy. They appear normal ultrastructurally and have a normal complement of membrane-limited secretory granules in their cytoplasm.

Idiopathic follicular atrophy ("collapse") appears to be a primary degenerative disease of the thyroid and differs distinctly from the trophic atrophy of follicular cells secondary to diminished secretion of TSH. Under the latter conditions, thyroid follicles undergo involution, are lined by a low cuboidal epithelium, and distended by uniformly dense PAS-positive colloid with little evidence of endocytosis. Hypertrophy and hyperplasia of thyrotrophic basophils occurs in the pars distalis of dogs with idiopathic follicular collapse and hypothyroidism.

Lymphocytic thyroiditis

Lymphocytic thyroiditis in dogs, an obese strain of chickens, nonhuman primates, and Buffalo rats closely resembles Hashimoto's disease in humans. Though the exact mechanism in the dog is not well established, evidence suggests a polygenic pattern of inheritance similar to that observed in the human disease. *The immunologic basis for the development of chronic lymphocytic thyroiditis in both humans and dogs appears to be through production of autoantibodies directed against thyroglobulin, thyroperoxidase (a microsomal antigen), or the TSH receptor.* Thyroglobulin autoantibodies have been found in a high percentage of dogs with hypothyroidism, and may be related to the development of the thyroiditis. Laboratory Beagles with spontaneous lymphocytic thyroiditis also have circulating thyroid autoantibodies, but the focal thyroiditis usually is not associated with clinical hypothyroidism. Thyroiditis in laboratory Beagles is similar serologically to human thyroiditis in that antibodies are present against thyroglobulin and thyroperoxidase; however, there is not a positive correlation between the occurrence or height of the thyroglobulin antibody titers and the occurrence or severity of thyroiditis.

Thyroid glands of dogs with lymphocytic thyroiditis may be slightly enlarged and tan-white, normal, or reduced in size. Histologic alterations include *multifocal to diffuse infiltrates of lymphocytes, plasma cells and macrophages.* Lymphoid nodules are present occasionally between follicles. The remaining follicles are small and lined by columnar epithelial cells. Lymphocytes, macrophages, and degenerate follicular cells often are present in the vacuolated colloid (Fig. 3.55A, B). Thyroid C (parafollicular) cells are seen in small nests or nodules between follicles and often are relatively more prominent than in normal dogs.

Lymphocytic thyroiditis is characterized ultrastructurally by lymphocytes, plasma cells, and macrophages in the interstitium, migrating through the follicular wall, and into the lumen where they are mixed with colloid and degenerate follicular cells (Fig. 3.55B). Either the basement membrane around thyroid follicles is thick, or discrete electron-dense deposits are present between the follicular cells and the basement membrane. These electron-dense deposits are similar to those reported to represent immune complexes in humans with Hashimoto's thyroiditis.

The thyroid lesion of lymphocytic thyroiditis progresses to replacement of the thyroid gland by mature fibrous connective tissue with only a few remaining scattered foci of inflammatory cells (Fig. 3.55C). Thyroid follicles are small and widely separated in the "end-stage" of thyroiditis and contain only a small amount of vacuolated colloid. There is a marked increase in collagen fibers surrounding small follicles or groups of follicular cells.

Many of the follicular lesions with lymphocytic thyroiditis are the result of lymphocytes and plasma cells migrating between thyroid follicular cells. This migration causes separation of adjacent follicular cells from the basement membrane, exfoliation of follicular cells, migration of lymphoid cells into the lumen, and eventual destruction of the follicle. To compensate for the progressive destruction of thyroid follicles by inflammatory cells and the decreased production of thyroid hormones, follicular cells in the remaining follicles often undergo hypertrophy, presumably in response to increased secretion of TSH.

Oncocytes with abundant eosinophilic cytoplasm often are seen in thyroids of dogs with long-standing lymphocytic thyroiditis. They contain abundant oxidative enzymes but sparse rough endoplasmic reticulum, suggesting an imbalance between the respiratory and synthesizing activities of the cell. Thyroid hormone synthesis appears to be severely compromised in these modified follicular cells. The occurrence of oncocytes in thyroid glands may be related to ageing or overstimulation.

Extrathyroidal lesions and functional disturbances in hypothyroidism

Many functional disturbances associated with hypothyroidism are due to a reduction in basal metabolic rate. A *gain in body weight* without an associated change in appetite occurs in some hypothyroid dogs. The weight gain varies from slight to striking, and hypothyroid dogs usually are less active than normal.

Lesions in skin and haircoat occur in the majority of hypothyroid dogs. Thyroxine stimulates the anagen or active phase of hair growth, whereas reduced blood levels of thyroid hormones favor the telogen or resting phase. Telogen hairs are more easily dislodged from the hair follicles, resulting in thinning of the haircoat and often a bilaterally symmetrical alopecia. Areas affected initially by hair loss are those receiving frictional wear such as the tail and cervical area. The tail may become almost completely bare in dogs with long-standing hypothyroidism.

Hyperkeratosis is a consistent finding in hypothyroidism and results in increased scaliness of the skin. It may become severe and occur in circular scaling patches resulting in skin lesions suggestive of seborrhea. Microscopic examination consistently reveals marked hyperkeratosis which includes the external root sheath. The excessive keratin formation and accumulation within hair follicles often results in *follicular keratosis* that may cause a grossly observable distention of follicles.

Hyperpigmentation occurs in many dogs with hypothyroidism, especially in localized areas of alopecia such as the dorsal aspect of the nose and distal portion of the tail. Increased numbers of melanocytes are present in the basal layer of the epidermis. Changes in the thickness of the epidermis are variable in dogs with hypothyroidism. Epidermal atrophy is reported in ~50% of hypothyroid dogs, normal thickness in ~20%, and mild-to-moderate epidermal thickening due to a prominent stratum granulosum with an atrophic stratum spinosum in the remaining 30% of dogs.

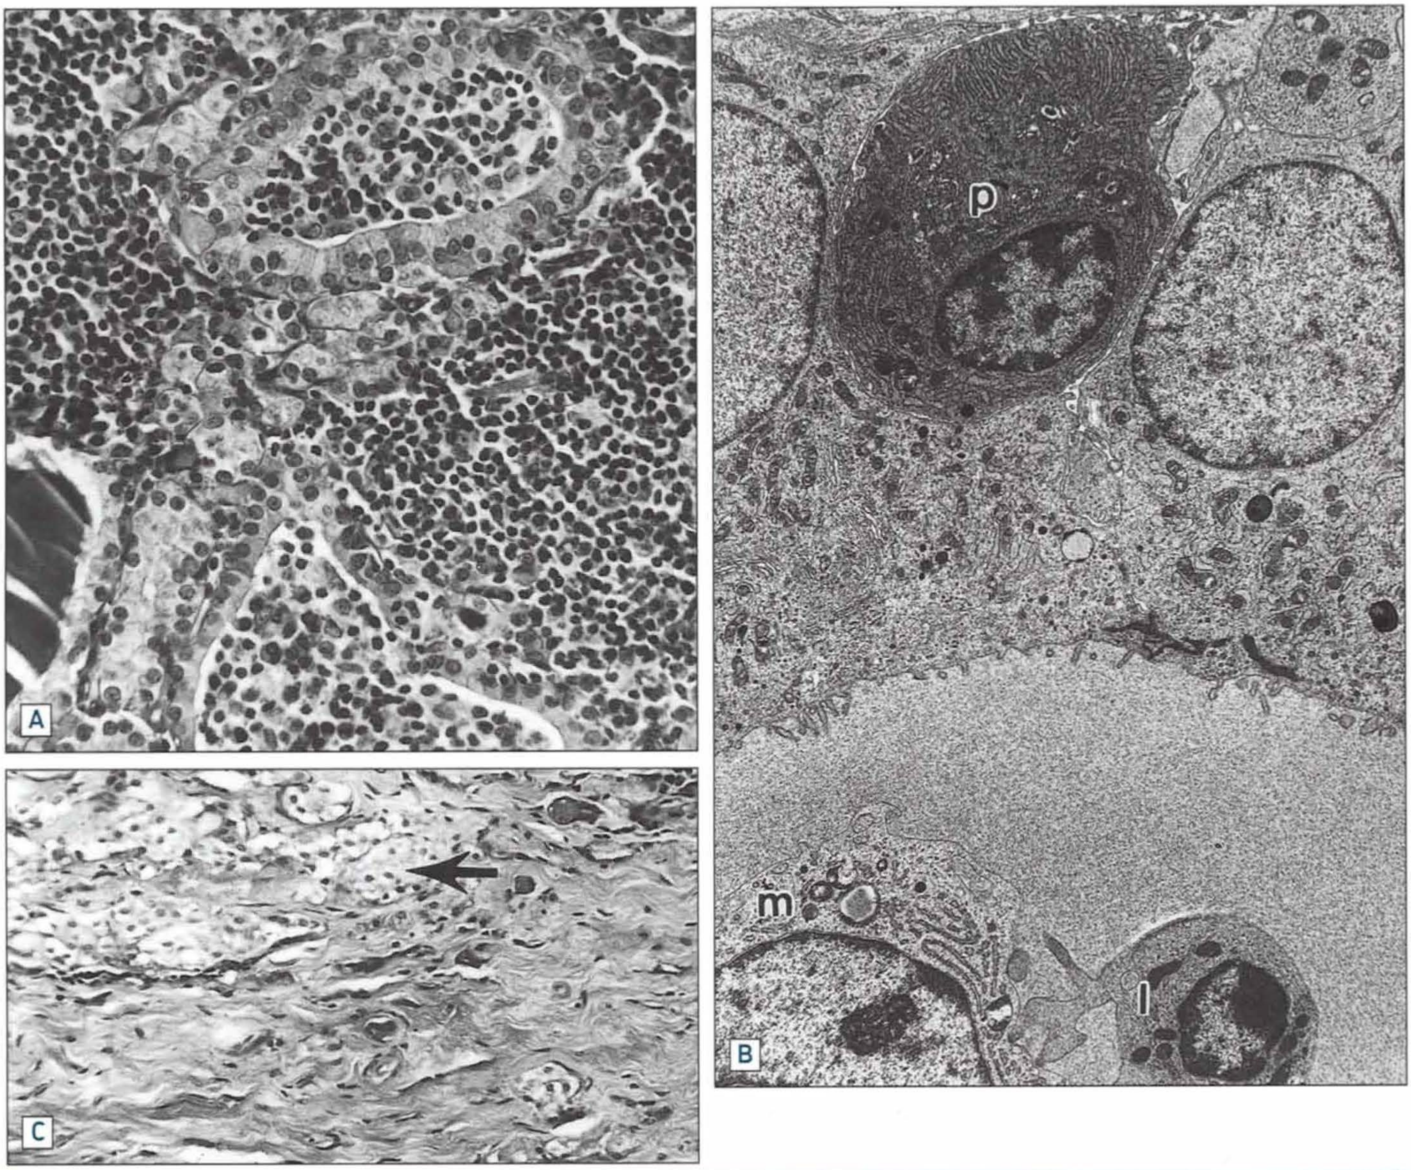

Figure 3.55 Lymphocytic thyroiditis in a dog. **A.** Infiltration of interstitium and follicular lumens with lymphocytes and plasma cells. **B.** Lymphocyte (l) and macrophage (m) are present in colloid of follicle and a plasma cell (p) is infiltrating between follicular cells. (From Gosselin SJ, et al. Am J Pathol 1977;90:285–289.) **C.** End-stage thyroiditis with fibrosis, few follicles, and nests of C cells (arrow).

Myxedema may develop and produce a characteristic clinical appearance in long-standing or severe hypothyroidism. *Mucin (neutral and acid glycosaminoglycans combined with protein) accumulates in the dermis and subcutis.* This material binds considerable amounts of water and produces marked thickening of the skin. This is most obvious around the face and head where accentuation of the normal skin folds causes a "tragic" appearance (Fig. 3.56). The eyelids appear thick and drooping, thus contributing to the sad facial expression. The skin feels thick and doughy but the characteristic pitting observed with other types of edema does not occur with myxedema. Histologically, mucin appears as a blue-purple, granular or fibrillar material that disrupts the normal collagen and elastin fibers on skin sections. Mucin is not well visualized on skin sections stained with hematoxylin and eosin, but disruption of the normal pattern of collagen and elastin fibers is evident in the dermis.

Abnormalities in reproduction are common in hypothyroidism. Lack of libido and reduction in sperm count may occur in males, whereas abnormal or absent estrous cycles with reduced conception rates may result in females. The spermatogenic epithelium in the testis often is markedly atrophic in long-standing cases of hypothyroidism. Impaired joint function with evidence of pain and joint effusion also can result from severe or prolonged hypothyroidism.

Hypothyroidism in dogs is accompanied by reduced circulating concentrations of thyroid hormones, low protein-bound iodine (PBI) levels, and decreased ^{131}I uptake by the thyroid gland. The occurrence of mild, nonresponsive, normocytic, normochromic anemia is consistent with a diagnosis of hypothyroidism.

The marked **hypercholesterolemia** seen with long-standing and severe hypothyroidism results in a variety of *secondary extrathyroidal lesions, including atherosclerosis, hepatomegaly, and renal glomerular and corneal lipidosis.* Hypercholesterolemia results from the decreased rate of lipid metabolism with diminished intestinal excretion of cholesterol and conversion of lipids into bile acids and other compounds.

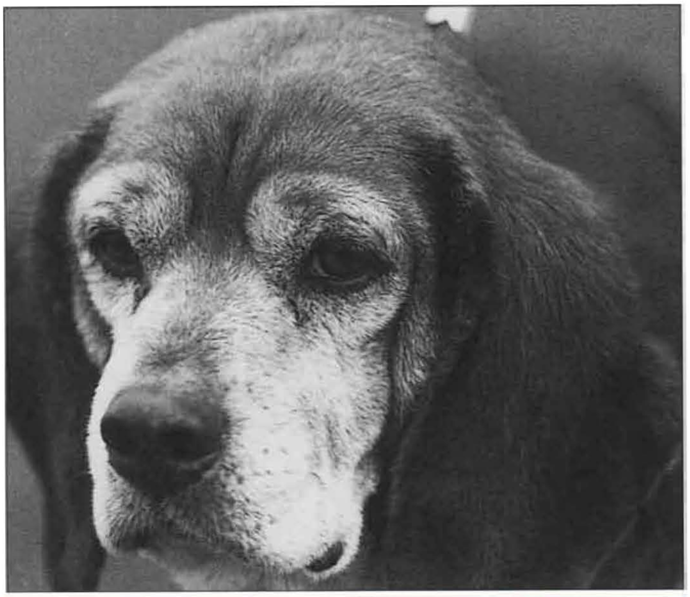

Figure 3.56 Hypothyroidism in a dog. Myxedema with thickened facial skin folds and "tragic" facial expression.

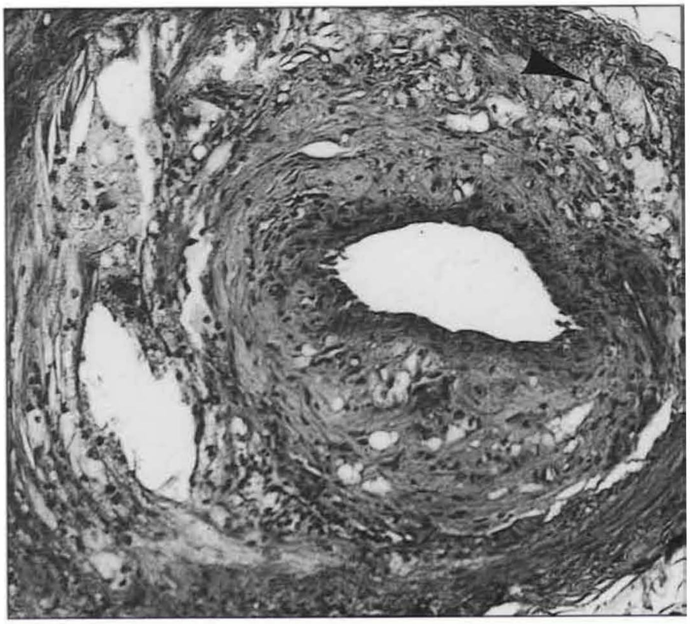

Figure 3.57 Hypothyroidism in a dog. Coronary atherosclerosis with lipid-filled macrophages (arrowhead).

- Atherosclerosis of coronary, cerebral and other vessels may develop in dogs with severe hypothyroidism and long-standing hyperlipidemia (Figs 3.53, 3.57). This occasionally results in hemorrhage and ischemic necrosis of the myocardium due to impingement on the vessel lumina by numerous lipid-laden macrophages in the tunica media and adventitia.
- In dogs with markedly elevated plasma lipids, renal glomeruli may become plugged with lipid, resulting in progressive renal failure. The lipid-filled glomeruli can be seen macroscopically as small yellow-white foci throughout the kidney cortex (Fig. 3.58).

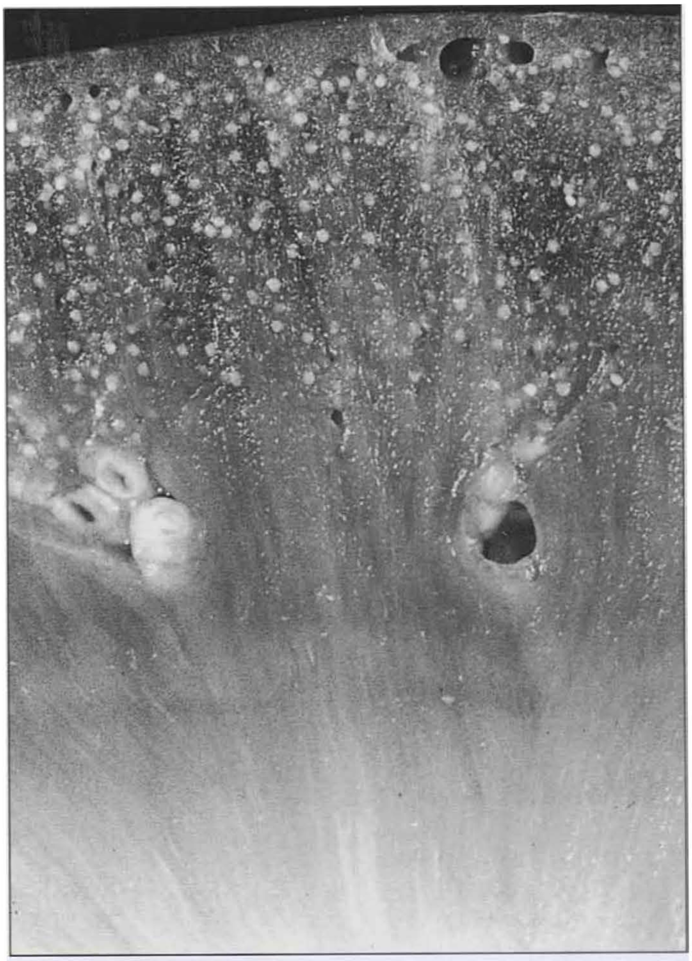

Figure 3.58 Glomerular lipidosis in a dog with severe and long-standing hypothyroidism with marked hypercholesterolemia.

- Accumulation of excessive lipid in the liver often results in various degrees of hepatomegaly with abdominal distention and hepatic failure.
- Corneal lipidosis is observed occasionally in hypothyroid dogs with hypercholesterolemia. This lesion often is unilateral because the lipid is deposited in corneas that have been previously injured and have a network of "ghost" vessels from which the lipid diffuses into the connective tissue stroma.

Evaluation of thyroid function

Serum cholesterol concentration is an indirect and valuable index of the peripheral action of thyroid hormone. Two-thirds of dogs with spontaneous hypothyroidism have fasting serum cholesterol concentration >300 mg/100 mL (>7.75 mmol/L). Hypercholesterolemia is as dependent, however, upon the composition of the dog's diet as upon the severity and duration of hypothyroidism. Cholesterol values tend to be higher in the general population of pet dogs fed table scraps or home diets than in dogs maintained exclusively on commercially manufactured dry dog foods (e.g., under laboratory conditions). Hypercholesterolemia also occurs in some dogs with cortisol excess, a disease that must be considered in the differential diagnosis of hypothyroidism. Therefore, *the measurement of serum cholesterol is not a specific or dependable test of thyroid function, but fasting cholesterol values*

>600 mg/100 mL (>15.5 mmol/L), which are often observed in hypothyroidism, infrequently occur in any other disease of dogs.

Moderate normocytic normochromic anemia often is associated with subnormal function of the thyroid in dogs. This anemia also has been observed in humans and in experimental animals and is of a nonregenerative type. The stained blood smear characteristically has little or no evidence of active erythrogenesis such as anisocytosis, polychromasia, or nucleated red cells. Leptocytosis may be especially prominent. The hemogram is characteristic of anemia associated with a variety of chronic diseases including neoplasia and chronic infection.

The most sensitive and accurate method for evaluation of thyroid function is *measurement of total blood thyroxine (T_4) and triiodothyronine (T_3) levels by radioimmunoassay*. The normal blood level of total T_4 in the dog is 1.5–3.6 μg/dL (13–51 nmol/L) (mean: 2.48 μg/dL, 32 nmol/L) and for total T_3 48–154 ng/dL (0.74–2.37 nmol/L)(mean: 95 ng/dL, 1.46 nmol/L). In dogs with hypothyroidism, the total T_4 level usually is <1.0 μg/dL (<13 nmol/L) and T_3 is <50 ng/dL (<0.77 nmol/L). When levels are borderline, clearer separation of dogs with hypothyroidism from euthyroid dogs can be made by injecting TSH. In euthyroid dogs, the T_4 level will at least double 8 hours after IV or IM administration of TSH. In dogs with hypothyroidism, T_4 and T_3 levels do not change significantly after injection of TSH. Plasma T_4 levels are no more than 0.2 μg/dL (2.6 nmol/L) above control values at 8 hours post-TSH, and plasma T_3 is increased by no more than 10 ng/dL (0.15 nmol/L) after TSH. The increase in serum T_3 after TSH is more variable in normal dogs than for T_4, but in dogs with primary hypothyroidism there usually is little (10 ng/dL, 0.15 nmol/L; or less) change in serum T_3 at 8 hours after TSH administration.

Free thyroxine can be measured by equilibrium dialysis with tracer. Other methods of measuring free T_4 are technically less difficult but are much less accurate. The serum free T_4 in normal dogs ranges from 0.5–2.7 ng/dL (6.7–34.7 pmol/L). The *advantages of measuring free T_4 over total T_4* include: (1) higher correlation with thyroid secretory function, (2) less overlap of hypothyroid and euthyroid levels, and (3) slower decrease with nonthyroidal illness.

Histologic examination of a thyroid biopsy is a useful and reliable aid in the diagnosis of thyroid disease when either the results of serum assays for T_4 and T_3 are equivocal or a nodule is palpated in the thyroid area. The removal of the caudal one-fourth of either lobe of the thyroid for histologic examination is a relatively simple surgical procedure without significant risk, even when the dog is hypothyroid. In most cases of hypothyroidism, there is either marked loss of thyroid follicles with replacement by adipose connective tissue or multifocal lymphocytic thyroiditis and interstitial fibrosis that develops on an immunologic basis.

In the evaluation of clinically important thyroid disease problems and potential thyroid toxicity of various xenobiotics, an accurate quantitation of circulating levels of thyroid stimulating hormone (TSH or thyrotropin) is important in the critical assessment of thyroid hormone economy. Thyrotropin is the major regulator of the synthetic and secretory processes of thyroid follicular cells. However, the immunoassay for TSH is highly species-specific, with considerable interanimal and interassay variations. Thyrotropin is a glycoprotein synthesized by thyrotrophic basophils in the adenohypophysis and is composed of α and β subunits. The α subunit is similar to that of several pituitary hormones of the same family, but the β subunit is specific for TSH. The hormone circulates primarily in the free (unbound) form and has a short (approximately 15 min) plasma half-life. Serum plasma samples for TSH assay should be collected in the morning before noon to minimize the effects of diurnal variation on hormone levels. A serum TSH procedure has been recently introduced to measure canine TSH and is available either as an immunoradiometric, luminescence assay, or ELISA. The β-subunit of canine TSH has an 89% homology with the human subunit, and circulating TSH levels in dogs are 10- to 20-fold lower than those in humans. Although the first generation canine TSH assay is considerably less sensitive than the rat and human TSH assays, an increased TSH level has been demonstrated in dogs with primary hypothyroidism that returned to normal 24 hours after once daily T_4 therapy. A peak increase in serum TSH occurred at 30 min postinjection of thyrotropin-releasing hormone (TRH) that subsequently rapidly returned to baseline values.

Hyperplasia of the thyroid gland

Non-neoplastic and noninflammatory clinical enlargements (**"goiter"**) *of the thyroid* develop in all domestic mammals, birds, and submammalian vertebrates. The major pathogenetic mechanisms responsible for the development of thyroid hyperplasia include *iodine-deficient diets, goitrogenic compounds that interfere with thyroid hormone synthesis, dietary iodide excess, and genetic enzyme defects in the biosynthesis of thyroid hormones* (Fig. 3.59). All of these factors result in inadequate thyroid hormone synthesis and decreased blood levels of T_4 and T_3. The low blood levels are detected by the hypothalamus and pituitary to increase the secretion of TSH, which results in hypertrophy and hyperplasia of follicular cells.

Diffuse hyperplastic and colloid goiter

Iodine deficiency that resulted in diffuse thyroid hyperplasia was common in many goitrogenic areas throughout the world before the widespread addition of iodized salt to animal diets. Although iodine-deficient goiter still occurs in large areas of the world in domestic animals, the outbreaks are sporadic and fewer animals are affected. Marginal iodine-deficient diets containing certain *goitrogenic compounds* may result in severe thyroid hyperplasia and clinical evidence of goiter. These substances include thiouracil, sulfonamides, anions of the Hofmeister series, and a number of plants from the family Brassicaceae (see Thyrotoxic effects of drugs and chemicals, below). Young animals born to females on iodine-deficient diets are more likely to develop severe thyroid hyperplasia and have clinical signs of hypothyroidism (Fig. 3.60).

Although seemingly paradoxical, *excess iodide in the diet also can result in thyroid hyperplasia in animal and human beings*. Foals of mares fed dry seaweed containing excessive iodide may develop thyroid hyperplasia and clinically evident goiter. The thyroid glands of the young are exposed to higher blood iodide levels than the dam because of concentration of iodide, first by the placenta, and second by the mammary gland. High blood iodide interferes with one or more steps of thyroid hormone synthesis and secretion, leading to lowered blood T_4 and T_3 levels, and a compensatory increase in pituitary TSH secretion. Excess iodine appears to primarily block the release of thyroid hormones by interfering with the fusion of colloid droplets and lysosomal bodies thereby disrupting the proteolysis of colloid and release of T_4 and T_3.

Clinical Status

Figure 3.59 Mechanisms of goitrogenesis. Multiple pathogenic factors (goitrogenic compounds, deficient and excessive dietary iodine intake, and genetic defects) result in inadequate thyroxine (T_4)/triiodothyronine (T_3) synthesis and lead to long-term stimulation of thyroid follicular cells (hypertrophy and hyperplasia) by increased secretion of pituitary thyroid stimulating hormone (TSH). B = bovine, C = caprine, O = ovine, H = human, $KCLO_4$ = potassium perchlorate, KSCN = potassium thiocyanate, LATS = long acting thyroid stimulator, an autoantibody that binds to the TSH receptor and stimulates the synthetic and secretory activity of follicular cells. NIS = sodium iodide symporter, PTU = propylthiouracil, TcO_4^- = pertechnetate, TPO = thyroperoxidase, TRH = thyrotropin releasing hormone. (From Capen CC. In: Tumors of Domestic Animals, 4th ed., 2002.)

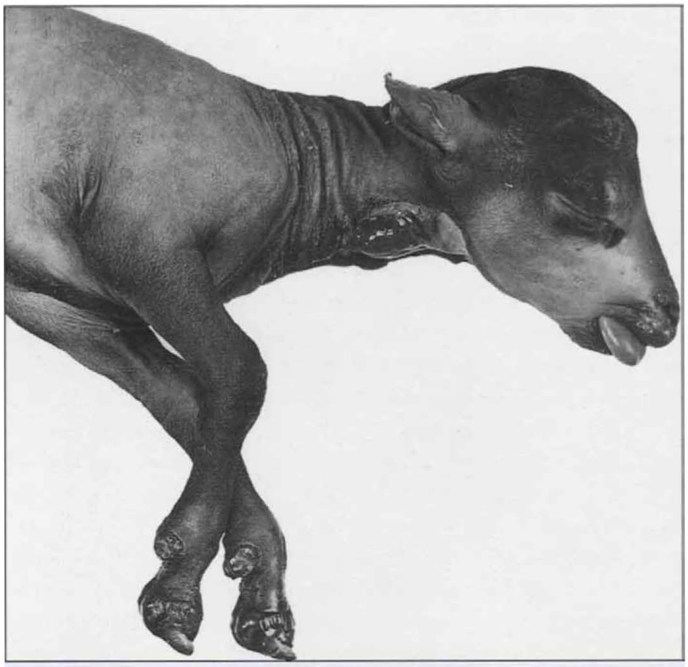

Figure 3.60 Congenital goiter due to iodine deficiency in a lamb. Note large thyroids, poor development of wool, and swollen tongue.

Iodine deficiency may be conditioned by other *antithyroid compounds* present in animal feeds and be responsible, in particular situations, for a high incidence of goiter. Prolonged low-level exposure to thiocyanates, which are produced by ruminal degradation of cyanogenetic glucosides from plants such as white clover (*Trifolium*), couch grass (*Cynoden*) and linseed meal, and by degradation of glucosinolates of the *Brassica* crops, is associated with congenital goiter in ruminants. *Goitrin* (5-vinyl-oxazolidine-2-thione) derived from the glucosinolates of *Brassica* spp. inhibits organification of iodine. *Leucaena leucocephala* and other legumes of the genus are native or cultivated in many subtrophical areas and contain the toxic aminoacid, *mimosine*. The effects of mimosine are discussed with Vol. 1, Skin and appendages. It is not directly goitrogenic but is converted in the rumen to 3-hydroxy-4(1*H*)-pyridone which prevents organic binding of iodine by the thyroid.

Goiter in adult animals usually is of little clinical significance and, except for occasional local pressure influences, the general health is not impaired. However, it does continue to be of significance as a disease of newborn animals, although the previous serious losses in endemic areas are now controlled by the prophylactic use of iodized salt.

Congenital hypothyroidism in domestic animals usually is associated with hyperplastic goiter, even though the dam may show no evidence of thyroid dysfunction. Gestation often is prolonged, the larger goiters may cause dystocia, and there is a tendency to retain the fetal placenta. Affected foals show extreme weakness and die within a few days after birth. The thyroids may be only slightly enlarged. Calves are somewhat more resistant to the effects of hypothyroidism. Although up to 70–80% may have large goiters in endemic areas, the majority survive and thrive. A few calves are partially or completely hairless, but these are either born dead or die soon after birth. Newborn goitrous pigs, goats, and lambs (Fig. 3.60) frequently have myxedema and alopecia. The mortality rate is high, with the majority being born dead or dying within a few hours of birth. Enlarged thyroid glands are readily palpable or visible in kids and lambs, but are not readily apparent in piglets because of the combination of a short neck and the development of myxedema. The tongue is swollen and there is edematous swelling of the fauces and larynx, which probably are contributory factors to death of the animals. Asphyxiation may result also from pressure by the enlarged thyroid gland on the trachea and adjacent structures. Young, goitrous animals that are treated and survive usually do not show permanent ill effects.

Congenital hyperplastic goiter with hypothyroidism is not a prominent feature of thyroid disease in *domestic carnivores*. However, degrees of follicular cell hyperplasia will be found that parallel changes in the maternal gland. In puppies, the thyroid enlargement

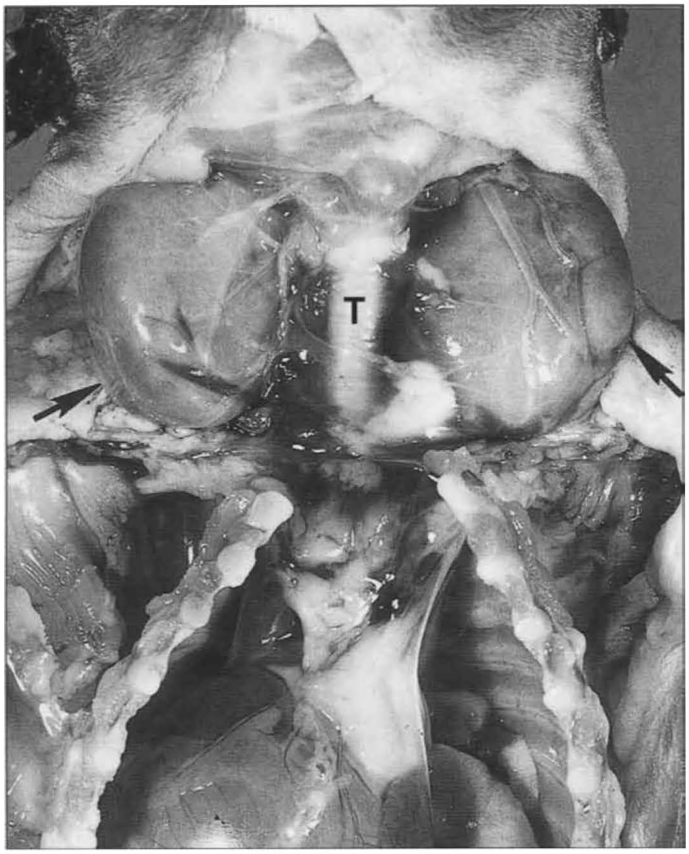

Figure 3.61 Symmetrical hyperplastic goiter (arrows) in a pup. T = trachea.

may be sufficient to cause dystocia or asphyxiation (Fig. 3.61). In the most severe form, death occurs shortly after birth and those affected have poorly developed coarse hair, anemia, and defective bone mineralization. Less severe forms are more common and affected pups often recover spontaneously. They are characterized by dry, coarse and sparse hair coat, narrow palpebral fissures, broad skulls and legs, which are relatively thicker and heavier than normal.

Both lobes of the thyroid are uniformly enlarged in young animals with diffuse hyperplastic goiter (Fig. 3.61) *due to extensive follicular cell hypertrophy and hyperplasia with enhanced endocytosis of colloid and collapse of follicles* (Fig. 3.62). The enlargements may be extensive and result in palpable swellings in the cranial cervical area. The affected lobes are firm and dark red because an extensive interfollicular capillary network develops under the influence of long-term TSH stimulation.

Colloid goiter *represents the involutionary phase of diffuse hyperplastic goiter and is usually seen in young adult and adult animals.* The markedly hyperplastic follicular cells continue to produce colloid, but endocytosis of colloid is decreased due to diminished pituitary TSH levels in response to the return of blood thyroxine and triiodothyronine to normal. Both thyroid lobes are diffusely enlarged but are more translucent and lighter in color than with hyperplastic goiter. The differences in macroscopic appearance are the result of reduced vascularity in colloid goiter and development of macrofollicles distended with colloid (Fig. 3.63A, B).

The changes in diffuse hyperplastic and colloid goiters are consistent throughout the diffusely enlarged thyroid lobes. The follicles are irregular in size and shape in hyperplastic goiter because of variable amounts of

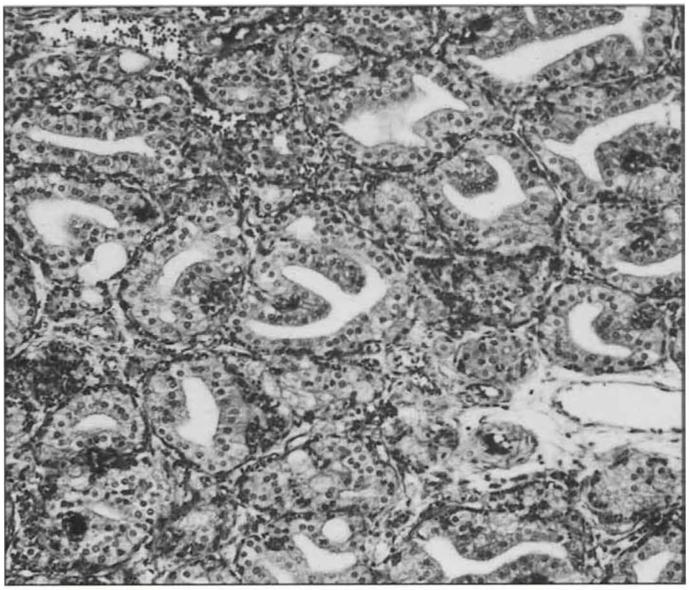

Figure 3.62 Hypertrophy and hyperplasia of thyroid follicular cells in **congenital hyperplastic goiter** with collapse of many follicles.

lightly eosinophilic and vacuolated colloid in the lumen. Some follicles are collapsed due to lack of colloid (Fig. 3.62). The lining epithelial cells are columnar with a deeply eosinophilic cytoplasm and small hyperchromatic nuclei that often are situated in the basilar part of the cell. The follicles are lined by single or multiple layers of hyperplastic follicular cells, which in some follicles may form papillary projections into the lumen. Similar proliferative changes are present in ectopic thyroid parenchyma in the neck or mediastinum.

Colloid goiter may develop either after sufficient amounts of iodide have been added to the diet of animals with iodine-deficient hyperplastic goiter or after the requirements for thyroid hormones have diminished in an older animal. Blood thyroid hormone levels return toward normal and the secretion of TSH by the pituitary gland is correspondingly decreased. Follicles are progressively distended with densely eosinophilic colloid due to diminished TSH-induced endocytosis. The follicular cells lining the macrofollicles are flattened and atrophic. The interface between the colloid and luminal surface of follicular cells is smooth and lacks the characteristic endocytotic vacuoles of actively secreting follicular cells (Fig. 3.63B). Some involuted follicles in colloid goiter have remnants of the papillary projections of follicular cells extending into their lumen. Interfollicular capillaries are less well developed than those with diffuse hyperplastic goiter as a result of the lower TSH levels.

Nodular hyperplasia

Nodular hyperplasia (goiter) in thyroid glands of old horses, cats, and dogs appears as multiple white to tan nodules of variable size (Fig. 3.64). The affected lobes are moderately enlarged and irregular in contour. *Nodular goiter in most animals is endocrinologically inactive and encountered as an incidental lesion at necropsy*; however, functional thyroid adenomas often develop in glands with multinodular follicular cell hyperplasia in old cats.

Nodular goiter consists of multiple foci of hyperplastic follicular cells that are sharply demarcated, but not encapsulated, and result in minimal compression of adjacent thyroid parenchyma. The microscopic appearance

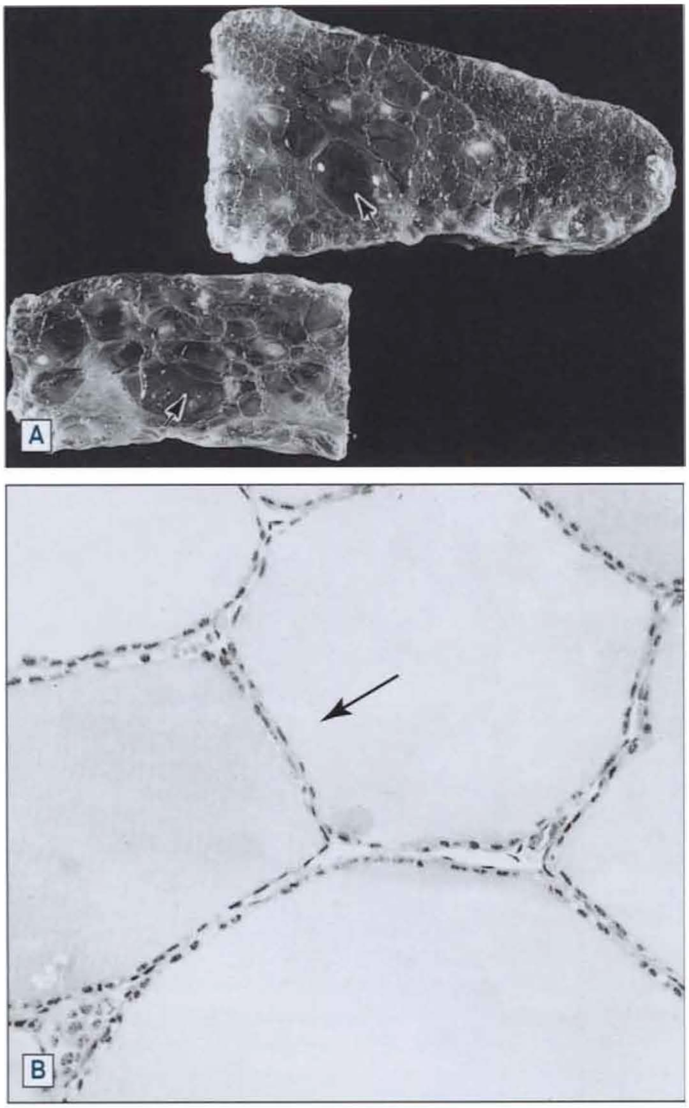

Figure 3.63 A. Colloid goiter in a lamb with large follicles (arrows) throughout sections of each lobe. **B.** Colloid goiter with distended follicles lined by flattened inactive cells (arrow).

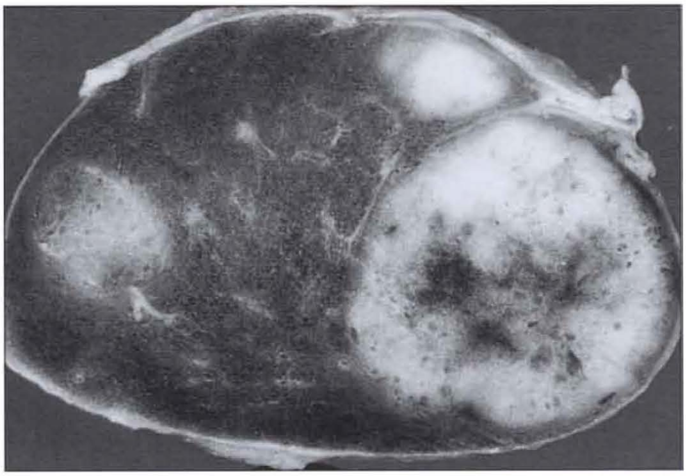

Figure 3.64 Nodular goiter with **multiple hyperplastic nodules** in a horse.

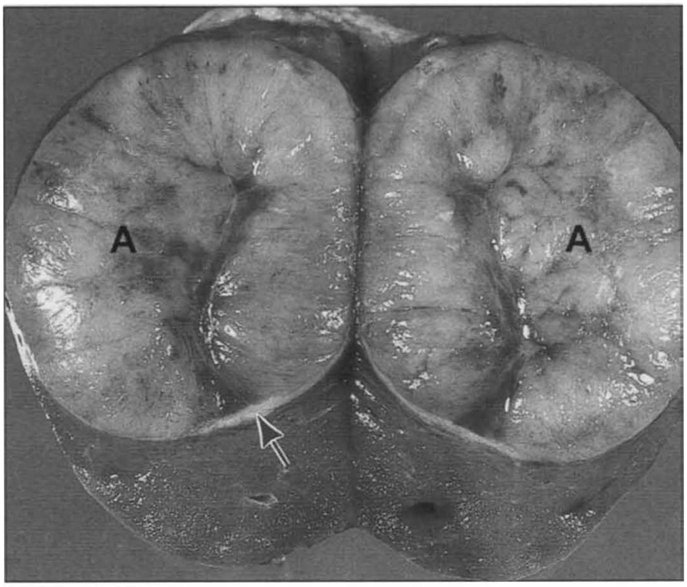

Figure 3.65 Solitary **thyroid follicular cell adenoma** (A) with prominent fibrous capsule (arrow) in a horse.

within a nodule is variable. Some hyperplastic cells form small follicles with little or no colloid. Other nodules are formed by larger irregularly shaped follicles lined by one or more layers of columnar cells that form papillary projections into the lumen. Some of the follicles are involuted and filled with densely eosinophilic colloid. These changes appear to be the result of alternating periods of hyperplasia and colloid involution in the thyroid glands of old animals. The areas of nodular hyperplasia may be microscopic, as in old cats, or grossly visible causing enlargement of the thyroid, as in old horses (Fig. 3.64).

There are no absolute morphologic criteria for distinguishing hyperplastic nodules and adenomas derived from thyroid follicular cells. As a general rule, hyperplastic nodules are multiple, poorly or not at all encapsulated, variable in their histologic structure, and do not cause compression of adjacent thyroid parenchyma. Adenomas on the other hand tend to be solitary, well encapsulated, fairly uniform in histologic structure, and cause compression of the surrounding parenchyma owing to progressive expansile growth (Fig. 3.65). Endocrinologically active thyroid adenomas result in colloid involution of follicles in the rim of surrounding thyroid due to inhibition of TSH secretion.

Inherited dyshormonogenetic goiter

An inability to synthesize and secrete adequate amounts of thyroid hormones beginning before or at birth has been documented in human infants and in several animal species. Congenital dyshormonogenetic goiter is inherited as an *autosomal recessive trait* in Corriedale, Dorset Horn, Merino, and Romney sheep; Afrikander cattle; and Saanen dwarf goats. The subnormal growth rate, absence of normal wool development or a rough sparse hair coat, myxedematous swellings of the subcutis, weakness, and sluggish behavior suggest that the affected young are *clinically hypothyroid.* Most lambs with congenital goiter either die shortly after birth or are highly sensitive to the effects of adverse environmental conditions.

Thyroid glands are symmetrically enlarged at birth due to intense diffuse hyperplasia of follicular cells (Fig. 3.66A). Thyroid follicles are lined by tall

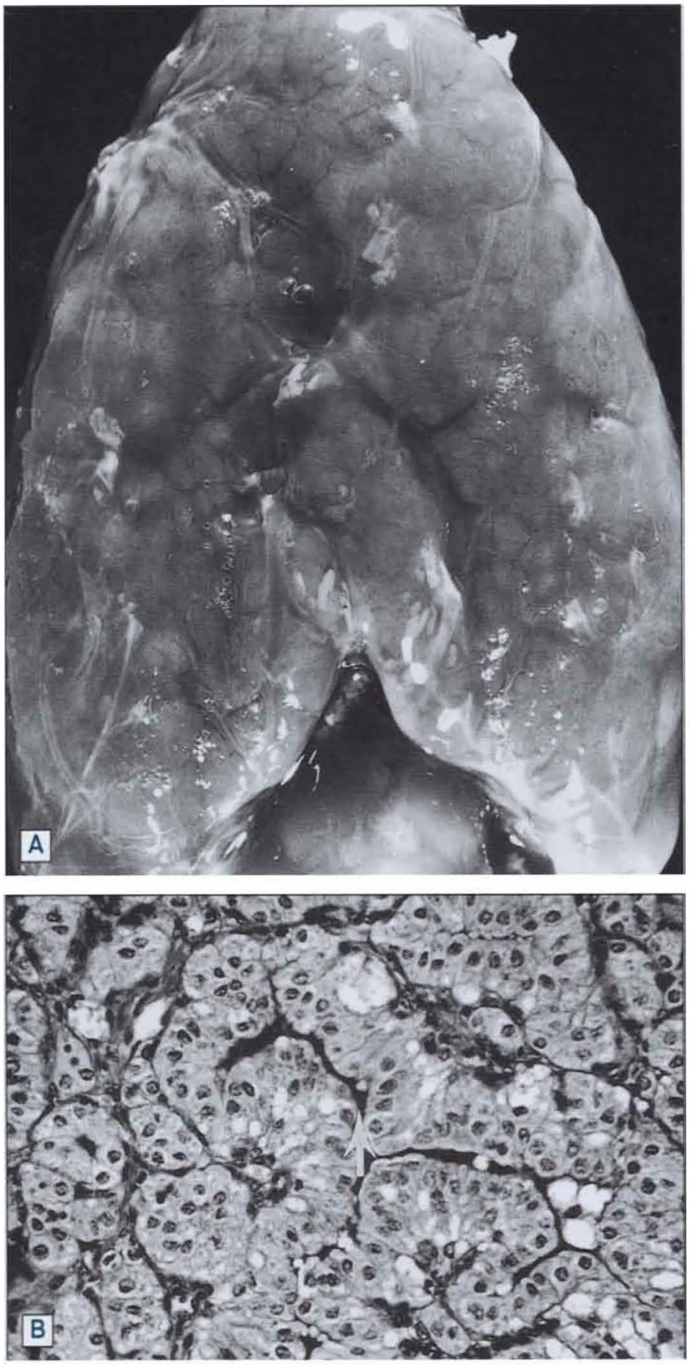

Figure 3.66 A. Congenital dyshormonogenetic goiter in a Corriedale lamb. **B.** Congenital goiter in a lamb with severe diffuse TSH-mediated follicular cell hypertrophy and hyperplasia. Thyroid follicles have collapsed and have slit-like lumens (arrow, PAS+ colloid) due to a lack of colloid resulting from the inability to synthesize thyroglobulin. (From Capen CC. Toxicol Pathol 2001;29:8–33.)

columnar cells, but often are collapsed because of lack of colloid resulting from the markedly increased endocytotic activity and diminished ability to synthesize thyroglobulin (Fig. 3.66B). The tall columnar follicular cells lining thyroid follicles have extensively dilated profiles of rough endoplasmic reticulum and large mitochondria, but there are relatively few dense granules associated with the Golgi apparatus and few apical vesicles near the luminal plasma membrane. Numerous long microvilli extend into the follicular lumen.

Although thyroidal uptake and turnover of ^{131}I are greatly increased compared with euthyroid controls, *levels of circulating* T_4 *and* T_3 *are consistently low*. The absence of a defect in the iodide transport mechanism and organification or dehalogenation, together with an absence of normal 19-S thyroglobulin in goitrous thyroids *suggests impairment in thyroglobulin biosynthesis* in animals with inherited congenital goiter. A closely related or similar defect appears operational in the examples of congenital goiter in sheep, cattle, and goats. The protein-bound iodine levels in sheep, cattle, and goats with inherited congenital goiter are markedly elevated. This appears to be the result of iodination of albumin and other plasma proteins by the thyroid gland under long-term TSH stimulation, since hormonal iodide levels (T_4 and T_3) are significantly lower than in controls. Hypothyroid goats with congenital goiter can be returned to a state of euthyroidism by the addition of iodide (1.0 mg/day) to the diet. Although the goats remain unable to synthesize thyroglobulin, supplementation with excess iodide results in sufficient formation of T_3 and T_4 in the abnormal iodoproteins to make the animals euthyroid.

The presence of messenger ribonucleic acid (mRNA) coding for thyroglobulin has been investigated to elucidate further the molecular basis for the impairment of thyroid hormone biosynthesis in congenital goiter. Although thyroglobulin-mRNA sequences are present in the goitrous tissue, their concentration is reduced to one-tenth to one-fortieth of normal, and the intracellular distribution is abnormal (nuclear: 42% of normal; cytoplasmic: 7%; membrane fraction: 1–2%). *The lack of thyroglobulin in these examples of congenital goiter in animals appears to be due to a defect in thyroglobulin-mRNA*, leading to aberrant processing of primary transcripts or transport of the thyroglobulin mRNA from the nucleus to the ribosomes of the endoplasmic reticulum.

Thyrotoxic effects of drugs and chemicals

Many of the significant physiologic and pathologic data in the literature on thyroid function and structure have come from studies in animals. Although the basic hypothalamic–pituitary–thyroid axis functions in a similar manner in animals and humans, *there are differences between species that are important when extrapolating animal data from toxicity and carcinogenicity studies for human risk assessment.*

Long-term perturbations of the pituitary–thyroid axis by various xenobiotics or physiologic alterations (e.g., iodine deficiency, partial thyroidectomy) are more likely to predispose laboratory animals to a higher incidence of proliferative lesions (e.g., hyperplasia and adenomas of follicular cells) than is the case in the human thyroid gland. This appears to be particularly true in male rats, in which there usually are higher circulating levels of TSH than in females. The greater sensitivity of the animal thyroid to derangement by drugs, chemicals and physiologic perturbations also is related to the shorter plasma half-life of T_4 (12–24 hours) than in humans (5–9 days) due, in part, to the considerable differences between species in the transport proteins for T_4.

There also are marked species differences in the sensitivity of the functionally important thyroperoxidase enzyme to inhibition by xenobiotics. *Thioamides* (e.g., sulfonamides) and other chemicals can selectively inhibit thyroperoxidase and significantly interfere with the iodination of tyrosyl residues incorporated in the thyroglobulin molecule, thereby disrupting the orderly synthesis of T_4 and T_3. Long-term administration of sulfonamides results in the development of thyroid "nodules" (e.g., focal hyperplasias and adenomas) frequently in the sensitive species (such as the rat, dog, and mice) but not in species resistant (e.g., monkey, guinea pig, chicken, and humans) to the inhibition of peroxidase in follicular cells.

The *goitrogenic effects of sulfonamides* have been known for more than 50 years, since the reports of the action of sulfaguanidine on the rat thyroid. Sulfamethoxazole and trimethroprim exert a potent goitrogenic effect in rats, resulting in marked decreases in circulating T_3 and T_4, a substantial compensatory increase in TSH, and increased thyroid weights due to follicular cell hypertrophy and hyperplasia. The dog also is a species sensitive to the effects of sulfonamides, resulting in markedly decreased serum T_4 and T_3 levels, hyperplasia of thyrotrophic basophils in the pituitary gland, and increased thyroid weights. By comparison, the thyroids of monkeys and human beings are resistant to the development of changes that sulfonamides produce in rodents (rats and mice) and the dog. Rhesus monkeys treated for 52 weeks with sulfamethoxazole with and without trimethroprim had no changes in thyroid weights and the thyroid histology was normal.

Studies comparing the effects of propylthiouracil (PTU) and a goitrogenic sulfonamide (sulfamonomethoxine) on the activity of thyroperoxidase in the rat and monkey (using the guaiacol peroxidation assay) demonstrated the concentration required for 50% inhibition of the peroxidase enzyme (inhibition constant$_{50}$ [IC_{50}]) was 50 times greater in the monkey than in the rat. Sulfamonomethoxine was almost as potent as PTU in inhibiting the thyroperoxidase in rats; however, it required 500 times the concentration to inhibit the enzyme in the monkey compared to the rat. Studies such as these with sulfonamides demonstrate *distinct species differences between rodents and primates in the response of the thyroid to chemical inhibition of hormone synthesis*; therefore, it is not surprising that the sensitive species (e.g., rats, mice, and dogs) are much more likely to develop follicular cell hyperplasia and thyroid tumors after long-term exposure to sulfonamides than the resistant species (e.g., subhuman primates, human beings, guinea pigs, and chickens).

The plasma thyroxine half-life in rats is considerably shorter (12–24 hours) than in humans (5–9 days). This is related in part to considerable differences between species in the transport proteins for T_4 and T_3. In humans and the monkey, circulating T_4 is bound primarily to thyroxine-binding globulin (TBG); however, this high affinity binding protein is not present in rodents, birds, amphibians or fish. Triiodothyronine (T_3) is transported bound to TBG and albumin in human beings, monkey, and dog, but only to albumin in mouse, rat, and chicken. In general, T_3 is bound less avidly to transport proteins than T_4, resulting in a faster turnover and shorter plasma half-life in most species.

In the evaluation of potential thyroid toxicity of various xenobiotics in animals, accurate quantitation of circulating levels of TSH is essential in order to determine whether proliferative lesions of follicular cells are mediated by a chronic hypersecretion of TSH. *The immunoassay for TSH is highly species-specific with considerable interanimal and interassay variations*. Xenobiotics that disrupt thyroid hormone synthesis, secretion, or peripheral metabolism often result in prompt increases in circulating TSH levels. Thyroid stimulating hormone levels are higher in male than female rats, and castration decreases both the baseline serum TSH and response to thyrotropin-releasing hormone (TRH) injection. Follicular cell height often is greater in male than female rats in response to the greater circulating TSH levels. The administration of exogenous testosterone to castrated male rats restores the TSH level to that of intact rats.

Chemical disruption of thyroid hormone synthesis and secretion in animals may occur at a number of different steps in thyroxinogenesis. These include blockage of iodine uptake, organification defects, blockage of hormone release, drug-induced thyroid pigmentation, inhibition of 5′-deiodinase, and induction of hepatic microsomal enzymes (Fig. 3.67).

Blockage of iodine uptake

The initial step in the biosynthesis of thyroid hormones is the uptake of iodide from the circulation, and transport against a gradient across follicular cells to the lumen of the follicle. A number of anions act as competitive inhibitors of iodide transport in the thyroid, including perchlorate (ClO_4^-), thiocyanate (SCN^-), and pertechnetate. Thiocyanate is a potent inhibitor of iodide transport and is a competitive substrate for thyroperoxidase, but it does not appear to be concentrated in the thyroid. Blockage of the iodide-trapping mechanism has a disruptive effect on the thyroid–pituitary axis similar to iodine deficiency. The blood levels of T_4 and T_3 decrease, resulting in a compensatory increase in the secretion of TSH by the pituitary gland (Fig. 3.67). The hypertrophy and hyperplasia of follicular cells that follows sustained exposure results in increased thyroid weight and the development of thyroid enlargement or goiter.

Organification defect

A wide variety of chemicals, drugs, and other xenobiotics affect the second step in thyroid hormone biosynthesis. The step-wise binding of iodide to the tyrosyl residues in thyroglobulin requires oxidation of inorganic iodide (I^-) to molecular (reactive) iodine (I_2) by thyroperoxidase present in the luminal aspect (microvillar membranes and apical cytoplasm) of follicular cells and adjacent colloid. Classes of chemicals that inhibit the organification of thyroglobulin include:

1. *thionamides* (such as thiourea, thiouracil, propylthiouracil, methimazole, carbimazole, and goitrin);
2. *aniline derivatives and related compounds* (e.g., sulfonamides, *para*-aminobenzoic acid, *para*-aminosalicylic acid, and amphenone);
3. *substituted phenols* (such as resorcinol, phloroglucinol, and 2,4-dihydroxybenzoic acid), and
4. *miscellaneous inhibitors* (e.g., aminotriazole, tricyanoaminopropene, antipyrine and its iodinated derivative (iodopyrine)).

These chemicals exert their action by inhibiting thyroperoxidase, which results in a disruption both of the iodination of tyrosyl residues in thyroglobulin but also the coupling reaction of inactive iodotyrosines (e.g., MIT and DIT) to form active iodothyronines (T_3 and T_4) (Fig. 3.67). Propylthiouracil (PTU) has been shown in rats to affect each step in thyroid hormone synthesis beyond iodide transport.

Blockage of thyroid hormone release

Relatively few chemicals selectively inhibit the secretion of thyroid hormone from the thyroid gland. An *excess of iodine* inhibits secretion of thyroid hormone and occasionally can result in goiter and hypothyroidism in animals and human patients. Several mechanisms have been suggested for this effect of high iodide levels on

Figure 3.67 Mechanism of action of goitrogenic chemicals on thyroid hormone synthesis and secretion. Chemicals can interfere with thyroid function by: (1) blocking iodide ion trapping, (2) inhibiting organic binding-coupling, or (3) disrupting proteolysis and release of T_4 and T_3 from colloid.

the thyroid hormone secretion, including a decrease in lysosomal protease activity (human glands), inhibition of colloid droplet formation (mice and rats), and inhibition of TSH-mediated increase in cAMP (dog thyroid slices). Rats fed an iodide-excess diet have hypertrophy of the cytoplasmic area of follicular cells with an accumulation of numerous colloid droplets and lysosomal bodies. There is limited evidence ultrastructurally of fusion of the membranes of these organelles and degradation of the colloid necessary for the release of T_4 and T_3 from the thyroglobulin (Fig. 3.67).

Lithium also has a striking inhibitory effect on thyroid hormone release. The widespread use of lithium carbonate in the treatment of manic states occasionally results in the development of thyroid enlargement with either euthyroidism or occasionally hypothyroidism in human patients.

Drug-induced thyroid pigmentation

The antibiotic *minocycline* produces a striking black discoloration of the thyroid lobes in laboratory animals and humans with the formation of brown pigment granules within follicular cells. The pigment granules stain similarly to melanin and are best visualized on thyroid sections stained with the Fontana-Masson procedure. Electron-dense material first accumulates in lysosome-like granules and in the rough endoplasmic reticulum. The pigment appears to be a metabolic derivative of minocycline, and administration of the antibiotic at high dose to rats for extended periods may result in disruption of thyroid function and development of goiter. The release of T_4 from perfused thyroids of minocycline-treated rats is significantly decreased, but follicular cells retain the ability to phagocytize colloid in response to TSH and have numerous colloid droplets in their cytoplasm.

Other chemicals (or their metabolites) selectively localize in the thyroid colloid resulting in abnormal clumping and increased basophilia to the colloid. Brown-to-black pigment granules may be present in follicular cells, colloid, and macrophages in the interthyroidal tissues resulting in macroscopic darkening of both thyroid lobes. The physicochemically altered colloid in the lumina of thyroid follicles appears to be less able than normal colloid either of reacting with organic iodine in a step-wise manner to result in the orderly synthesis of iodothyronines, or of being phagocytized by follicular cells and enzymatically processed to release active thyroid hormones into the circulation. Serum T_4 and T_3 are decreased, serum TSH levels are increased by an expanded population of pituitary thyrotrophs, and thyroid follicular cells undergo hypertrophy and hyperplasia and eventually develop tumors.

Inhibition of 5′-deiodinase

Erythrosine (FD&C red no. 3) is one the best characterized chemicals that acts as a 5′-deiodinase inhibitor and results in perturbations of thyroid function. It is a tetraiodinated derivative of fluorescein, with iodine accounting for ~58% of the molecular weight of the color. Erythrosine is a red dye used widely as a color additive in foods, cosmetics, and pharmaceuticals. *Amiodarone* is an organic

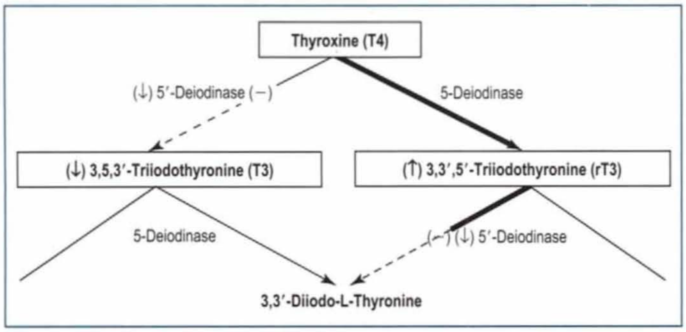

Figure 3.68 Effects of food color, erythrosine (FD&C red no. 3), on peripheral metabolism of thyroxine. Inhibition of 5′-deiodinase by erythrosine results in lowered serum T_3 and a compensatory increased secretion of TSH by the pituitary gland, leading to follicular cell stimulation. Preferential monodeiodination of thyroxine by 5-deiodinase results in markedly elevated blood levels of inactive reverse T_3 (rT3). (From Capen CC, Martin SL. Toxicol Pathol 1989;17:266–293.)

iodinated antiarrhythmic compound that also disrupts thyroid hormone economy by inhibiting 5′-deiodinase. *Iopanoic acid* and *flavonoids* also inhibit the enzyme in hepatocytes.

Erythrosine is an example of a xenobiotic that causes changes in circulating levels of thyroid hormones and morphologic evidence of follicular cell stimulation by producing alterations in the peripheral metabolism of T_4. *Inhibition of 5′-deiodinase in the liver and kidney by erythrosine explains the lower circulating T_3 levels.* The monodeiodination of T_4 by another enzyme (5-deiodinase) to reverse-T_3 and inhibition of 5′-deiodinase (which is necessary to further degrade this inactive iodothyronine to 3,3′-diiodothyronine (T_2)) results in the striking accumulation of serum reverse-T_3 (Fig. 3.68). The pituitary, sensing the lowered circulating levels of T_3, compensates by increasing the secretion of TSH, which results in the morphologic evidence of follicular cell stimulation (Fig. 3.68). Erythrosine does not appear to be a direct-acting thyroid oncogen. Rather, in massive doses (4% of diet over lifetime beginning in utero), it acts through a secondary mechanism to promote the development of benign thyroid tumors in laboratory animals.

Induction of hepatic microsomal enzymes

Hepatic microsomal enzymes play an important role in thyroid hormone economy since *glucuronidation is the rate-limiting step* in the biliary excretion of T_4, and sulfation, for the excretion of T_3 by phenol sulfotransferase. Long-term exposure to many chemicals may induce these enzyme pathways and result in chronic stimulation of the thyroid by disrupting the hypothalamic–pituitary–thyroid axis (Fig. 3.69). The resulting chronic stimulation of the thyroid by increased circulating levels of TSH often increases the risk of developing tumors derived from follicular cells in chronic studies with these compounds in certain species. **Xenobiotics** that induce liver microsomal enzymes and disrupt thyroid function include central nervous system drugs (e.g., phenobarbital, benzodiazepines); calcium channel blockers (e.g., nicardipine, bepridil); steroids (spironolactone); retinoids; chlorinated hydrocarbons (chlordane, DDT, TCDD), polyhalogenated biphenyls (PCB, PBB). Most of the hepatic microsomal enzyme inducers have no apparent intrinsic carcinogenic activity and produce little or no mutagenicity or DNA damage.

Phenobarbital has been studied extensively as the prototype for hepatic microsomal inducers that increase a similar spectrum of cytochrome P450 isoenzymes. *Polychlorinated biphenyls (PCBs)* also induce hepatic microsomal enzymes and disrupt thyroid function. PCBs are commonly used industrial compounds that are widespread environmental contaminants. Their disease-producing capability includes alterations in reproduction, growth, and development. PCBs cause a significant reduction in serum levels of thyroid hormones due to alterations in thyroid structure, in addition to the induction of hepatic UDP-glucuronyl transferase and increased secretion of thyroxine-glucuronide in the bile.

In contrast to the previous categories of indirect acting thyrotoxic compounds, *certain chemicals and irradiation appear to have a direct effect on the thyroid gland resulting in genetic damage that leads to cell transformation and tumor formation in animals.* Examples of thyroid initiators include 2-acetylaminofluorine (2-AAF), N-methyl-N-nitrosourea (MNU), N-bis(2-hydroxypropyl) nitrosamine (DHPN), methylcholanthrene, dichlorobenzidine, and polycyclic hydrocarbons. Chemicals in this group often increase the incidence of both benign and malignant thyroid tumors. Iodine deficiency is a strong promoter of MNU-initiated thyroid tumors in rats.

Understanding the mechanism of action of xenobiotics on the thyroid gland provides a rational basis for extrapolation of findings from long-term rodent studies to the assessment of a particular compound's safety for humans. Many chemicals and drugs disrupt one or more steps in the synthesis and secretion of thyroid hormones, resulting in subnormal levels of T_4 and T_3, associated with a compensatory increased secretion of pituitary TSH (Fig. 3.69). When tested in highly sensitive species, such as rats and mice, early on these compounds resulted in follicular cell hypertrophy/hyperplasia and increased thyroid weights, and in long-term studies they produced an increased incidence of thyroid tumors by a secondary (indirect) mechanism associated with hormonal inbalances. In the secondary mechanism of thyroid oncogenesis in rodents, the specific xenobiotic chemical or physiological perturbation evokes another stimulus (e.g., chronic hypersecretion of TSH) that promotes the development of nodular proliferative lesions (initially hypertrophy, followed by hyperplasia, subsequently adenomas, infrequently carcinomas) derived from follicular cells. Compounds acting by this indirect (secondary) mechanism with hormonal imbalances usually show little or no evidence for mutagenicity or for producing DNA damage. The literature suggests that prolonged stimulation of the human thyroid by TSH will induce neoplasia only in exceptional circumstances, possibly by acting together with some other metabolic or immunologic abnormality.

Neoplasms of the thyroid gland

Most thyroid tumors are of follicular origin. They are common in dogs and cats, moderately so in horses, and distinctly rare in cattle, sheep, and swine. These tumors usually develop in animals that often are permitted to live to an advanced age such as dogs, cats and horses.

Follicular cell adenoma

Adenomas are usually white to tan, relatively small, solid nodules that are well demarcated from the adjacent thyroid parenchyma. The affected thyroid lobe is only moderately enlarged and distorted. A distinct

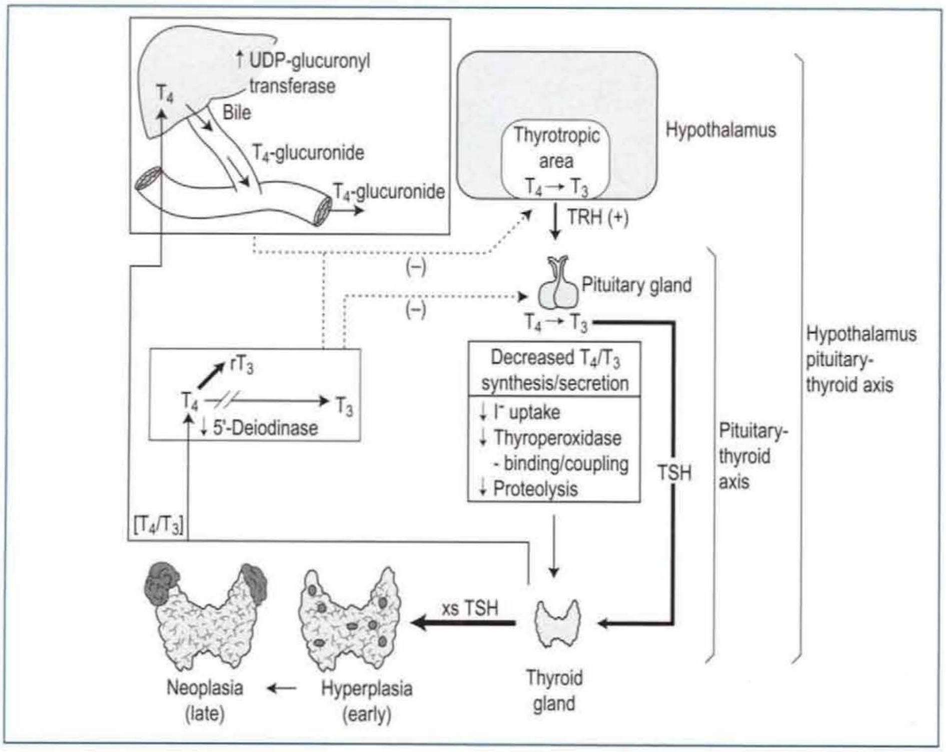

Figure 3.69 Multiple sites of disruption of the hypothalamic-pituitary-thyroid axis by xenobiotics. Chemicals can exert direct effects by disrupting thyroid hormone synthesis or secretion and indirectly influence the thyroid through inhibition of 5′-deiodinase or by inducing hepatic microsomal enzymes (e.g., T_4-UDP-glucuronyl transferase). All of these mechanisms can lower circulating levels of thyroid hormones (T_4 and T_3), resulting in a release from negative feedback inhibition and increased secretion of TSH by the pituitary gland. The chronic hypersecretion of TSH predisposes the sensitive rodent thyroid to develop an increased incidence of focal hyperplastic and neoplastic (predominantly adenomas) lesions by a secondary (epigenetic) mechanism due to hormonal imbalances. (From Capen CC. Toxicol Pathol 1997;25:39–48.)

white fibrous capsule of variable thickness separates the adenoma from the compressed parenchyma. Only a single adenoma usually is present in a thyroid lobe (see Fig. 3.65). Other thyroid adenomas are composed of fluctant thin-walled cysts filled with a yellow to red fluid. The external surface of **cystadenomas** is smooth and covered by an extensive network of blood vessels. Small masses of neoplastic tissue remain in the wall and form rugose projections into the cyst lumen. The thyroid parenchyma of the affected lobe may be completely obliterated.

Adenomas are classified into *follicular and papillary types.* They are sharply demarcated and encapsulated from the adjacent compressed thyroid parenchyma by a partial or complete fibrous capsule of variable thickness. *Adenomas derived from follicular cells that retain the ability to form follicles, according to one of several patterns, are considerably more common than papillary adenomas in animals.* Each **follicular adenoma** tends to have a consistent growth pattern within itself.

There are several different patterns of growth for follicles, similar to those of the normal thyroid. *Microfollicular adenomas* consist of tumor cells arranged in miniature follicles with small amounts of colloid or an absence of colloid. *Macrofollicular adenomas* are comprised of irregularly shaped large follicles that are greatly distended with colloid and lined by flattened follicular cells. There often is extensive hemorrhage and desquamation of follicular cells into the lumina of the distended follicles.

Cystic adenomas consist of one or two large cavities filled with proteinaceous fluid, necrotic debris, and erythrocytes. Focal accumulations of tumor cells, forming either follicles or solid nests, are present in the capsule of dense fibrous connective tissue. These adenomas may develop by progressive cystic degeneration of one of the several types of follicular adenomas. **Trabecular adenomas** are the most poorly differentiated of the follicular type. The tumor cells are small and are arranged in narrow columns separated by an edematous fibrous stroma. There is little evidence of follicle formation.

Oxyphilic adenomas are composed (predominantly or entirely) of large cells with densely eosinophilic granular cytoplasm arranged in indistinct follicles with little or no colloid formation. Oxyphilic (Hürthle) cells appear to be metabolically altered follicular cells that accumulate abnormally large numbers of mitochondria in their cytoplasm.

Papillary adenomas of thyroid origin are recognized infrequently in most animal species. Columnar or cuboidal follicular cells are arranged in a single layer about a thin vascular connective tissue stalk. *These papillary projections extend into the lumina of cystic spaces of various sizes.* The cysts contain desquamated tumor cells, colloid, erythrocytes, and occasionally laminated foci of mineralization resembling psammoma bodies.

Hyperthyroidism associated with thyroid tumors

Multinodular hyperplasia and follicular cell adenomas are common lesions in thyroid glands of adult to aged cats that develop a clinical syndrome of hyperthyroidism. Follicular cell adenomas, often developing in a thyroid with multinodular hyperplasia, are encountered more commonly than thyroid carcinomas. Adenomas and carcinomas are most likely to be encountered in aged cats, whereas nodular hyperplasia can occur at any age. The mean age of cats with benign tumors has been reported to be 12.4 years, and thyroid carcinomas as 15.8 years.

There has been a dramatic increase in the incidence of thyroid neoplasms and other focal proliferative lesions in cats resulting in hyperthyroidism since the late 1970s and at present it is one of the two most common endocrine diseases in adult cats (diabetes mellitus being the other). Prior to 1980, clinical hyperthyroidism was diagnosed infrequently in cats. The reason for the apparent increased incidence is uncertain, but appears to be related, in part, to: (1) a larger population of older cats seeking veterinary medical care since 1980, (2) improved assays for thyroid hormones, and (3) detailed characterization of the clinical syndrome and increased awareness of its common occurrence in adult-to-aged cats by veterinary clinicians. In addition, there does appear to be a "real" increase in the incidence of feline hyperthyroidism over the last 30 years. *Potential risk factors* have been reported to include a predominantly indoor environment, regular treatment with flea powders, exposures to herbicides and fertilizers, a diet primarily of canned food, and non-Siamese breeds (10 times greater occurrence). It has been suggested that wide variations (excessive to inadequate) in dietary iodine intake over prolonged periods may play a role in the pathogenesis of thyroid disorders in cats.

The disease in cats is mechanistically different from the clinically important *Grave's disease in humans*, as hyperthyroid cats do not have elevated circulating levels of thyroid-stimulating immunoglobulins comparable to long-acting thyroid stimulator (LATS) (an autoantibody that binds to the TSH receptor and activates follicular cells). Purified immunoglobulin G (IgG) preparations from hyperthyroid cats significantly increased ^{3}H-thymidine incorporation into DNA and stimulated cell proliferation 15-fold but did not stimulate intracellular cAMP. The former could be inhibited completely by a specific TSH receptor-blocking antibody. These data suggest that elevated titers of thyroid growth IgG's are present in cats with hyperthyroidism and most likely act by the TSH receptor. This important thyroid disease in cats most closely *resembles toxic nodular goiter in humans*. Hyperplastic and neoplastic thyroid tissue from cats is transplantable into athymic (nude) mice and continues to overproduce T4 and T3 in a subcuticular location.

Studies utilizing primary cultures of enzymatically dissociated follicles from thyroid proliferative lesions from cats with hyperthyroidism have reported that organification and ^{3}H-thymidine labeling continue in the absence of TSH, in contrast to follicles from normal cat thyroids. *These findings suggest that an intrinsic alteration in follicular cell function occurs in thyroids of cats with multinodular goiter leading to autonomy of cell growth and persistent overproduction of thyroid hormones.* A recent study reported an over-expression of the c-ras oncogene in areas of nodular hyperplasia and adenomas derived from follicular cells in cats with hyperthyroidism, suggesting that *mutations in this oncogene may play a role in the pathogenesis of these proliferative lesions.*

Point mutations in the thyrotropin receptor (TSHR) gene cause two forms of thyrotoxicosis in humans, namely, autonomously functioning toxic follicular adenomas and hereditary (autosomal dominant) toxic thyroid hyperplasia. The normal feline TSHR sequence between codons 480 and 640 is highly homologous to that of other mammalian TSHRs, with 95, 92, and 90% amino acid identity between the feline, canine, human, and bovine TSHRs, respectively. Analysis of single-stranded conformational polymorphisms in thyroid DNA from sporadic cases of feline thyrotoxicosis and leukocyte DNA from two cases of familial hyperthyroidism in cats failed to identify mutations between codons 480 and 640 of the TSHR gene. These interesting findings suggest that TSHR gene mutations are not a common cause of the focal proliferative lesions of thyroid follicular cells that result in feline thyrotoxicosis.

The syndrome of hyperthyroidism in aged cats can be associated with adenomas, multinodular hyperplasia, or adenocarcinomas derived from follicular cells. The most common clinical sign is *weight loss*, in spite of normal or increased appetite (Fig. 3.70). Polydipsia and polyuria, increased frequency of defecation, increased volume of stools, and increased activity occur. A common functional disturbance is tachycardia accompanied by premature beats and/or a systolic murmur. Cardiomegaly due to left ventricular hypertrophy may be evident on radiographs or at necropsy.

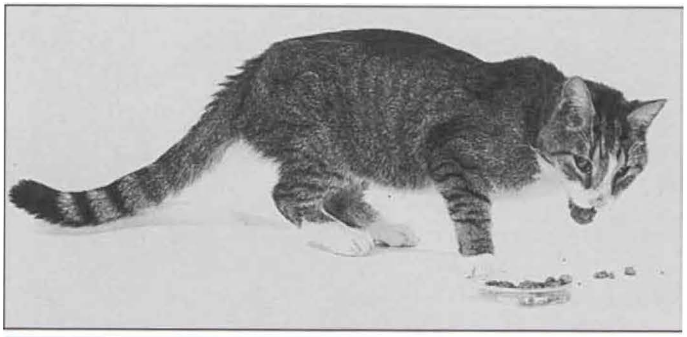

Figure 3.70 Hyperthyroidism in a cat with a functional adenoma derived from thyroid follicular cells. The cat progressively lost weight in spite of increased food consumption.

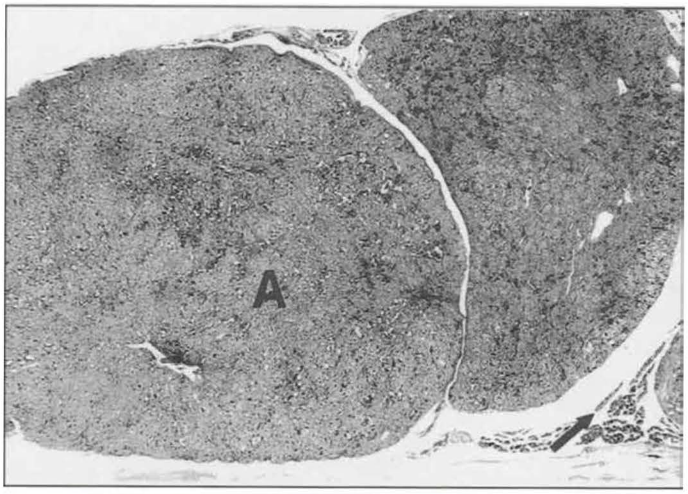

Figure 3.71 Follicular cell adenoma (A) in a cat with hyperthyroidism. The adenoma is lobulated, reflecting its likely development from coalescence of multifocal areas of adenomatous hyperplasia. The tumor is sharply demarcated from a rim of normal thyroid (arrow). (From Capen CC. Toxicol Pathol 2001;29:8–33.)

Thyroid adenomas in cats usually appear as solitary, soft, often lobulated nodules that enlarge and distort the contour of the affected lobe (Fig. 3.71). A thin, partial fibrous capsule separates the adenoma from the adjacent, often compressed, thyroid parenchyma (Fig. 3.72). Follicles in the surrounding rim of suppressed thyroid are markedly enlarged and distended by colloid, a lesion referred to as "*colloid involution*." The follicular cells are low cuboidal and atrophied with little evidence of endocytotic activity in response to the elevated levels of thyroid hormones produced by the adenoma resulting in suppressed levels of TSH (Fig. 3.72). Focal areas of necrosis, mineralization, and cystic degeneration are present in larger adenomas. Functional follicular adenomas often develop in thyroids that have multinodular hyperplasia of follicular cells in both lobes.

Functional thyroid adenomas are composed of cuboidal to columnar follicular cells with occasional papillary infoldings that form follicles containing variable amounts of colloid. The follicles usually are partially collapsed and contain little colloid due to the intense endocytotic activity of neoplastic follicular cells. Long

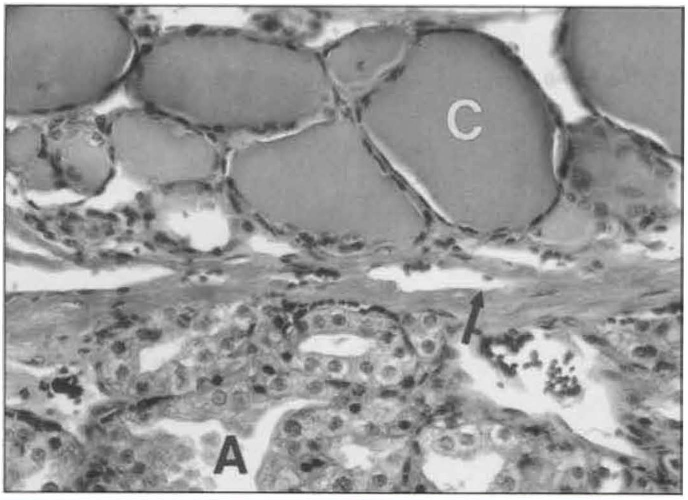

Figure 3.72 Follicular cell adenoma (A) composed of follicles with little stored colloid as a result of autonomous and excessive secretion of thyroid hormones. Follicles in the rim of normal thyroid have undergone colloid involution (C) and are distended with colloid as a morphologic response to suppressed TSH levels. A thin fibrous capsule (arrow) separates the adenoma from the peripheral rim of normal thyroid. (From Capen CC. Toxicol Pathol 2001;29:8–33.)

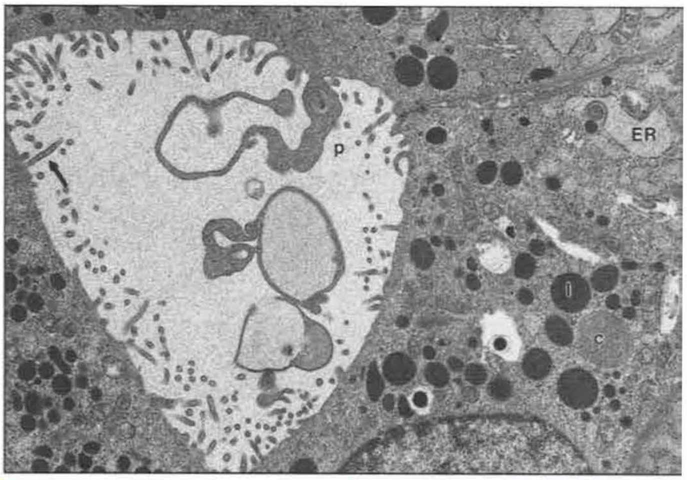

Figure 3.73 Functional follicular cell adenoma in a cat. Numerous cytoplasmic processes (p) extend from the luminal surface of neoplastic follicular cells to engulf colloid by endocytosis. Note lysosomal (l) bodies associated with colloid droplets (c) and long microvilli (arrow) on surfaces bordering colloid. Profiles of rough endoplasmic reticulum (ER) are dilated by finely granular material.

cytoplasmic projections extend from the follicular cells into the lumen to endocytose colloid (Fig. 3.73). As a result of the marked endocytotic activity, numerous colloid droplets are present in the apical cytoplasm of follicular cells in close proximity to the many lysosomal bodies.

Hyperthyroidism in cats also occurs in association with bilateral multinodular ("adenomatous") hyperplasia. These multiple areas of thyroid hyperplasia usually do not appreciably enlarge the affected lobe(s) (Fig. 3.74). The hyperplastic nodules are composed of irregularly shaped, colloid-filled follicles lined by cuboidal follicular cells. The multiple nodules of follicular cell hyperplasia eventually may coalesce to form macroscopically observable thyroid adenomas.

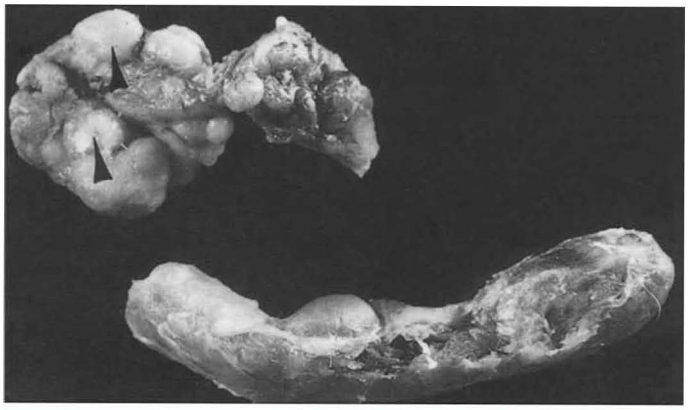

Figure 3.74 Multinodular follicular cell hyperplasia (arrowheads) in both thyroid lobes from a cat with hyperthyroidism.

Cats with hyperthyroidism usually have markedly elevated serum thyroxine and triiodothyronine levels. Normal feline serum levels of T_4 measured by radioimmunoassay are ~1.5–5.0 μg/dL (19–64 nmol/L) and serum T_3 levels are 60–200 ng/dL (0.9–3.1 nmol/L). The serum T_4 levels in cats with hyperthyroidism range from 5.0 to >50 μg/dL (64–640 nmol/L) and serum T_3 levels range from 100 to 1000 ng/dL (1.5–150 nmol/L). Moderately increased liver-derived serum enzyme levels, including AST (SGOT), ALT (SGPT), and especially alkaline phosphatase, occur in hyperthyroid cats.

The likelihood of developing clinical hyperthyroidism associated with thyroid neoplasms in animals depends upon: (1) the capability of tumor cells to synthesize T_4 and T_3 (e.g., well-differentiated thyroid tumors that form follicles and produce colloid are more likely to synthesize thyroid hormones than poorly differentiated solid neoplasms), and (2) the degree of elevation of circulating levels of T_4 and T_3, which depends upon a balance between the rate of secretion of thyroid hormones by the tumor and the rate of degradation of thyroid hormones. For example, *dogs have a much more efficient enterohepatic excretory mechanism for thyroid hormones than cats and infrequently have clinical signs associated with functional thyroid tumors.* Cats are very sensitive to phenol and phenol-derivatives, and have a poor ability to conjugate phenolic compounds (such as T_4) with glucuronic acid and excrete the T_4-glucuronide into the bile. The capacity of conjugation of T_3 with sulfate is limited and easily overloaded. Therefore, *cats with relatively small functional proliferative lesions of thyroid follicular cells often have marked elevations in circulating levels of T_4 and T_3 with clinical signs of hyperthyroidism,* whereas dogs with functional thyroid tumors have only slight elevations of serum T_4 and T_3 and less frequently develop clinical hyperthyroidism.

When first evaluated, a small percentage of hyperthyroid cats have T_4 concentrations within the upper limits of the reference range. This most likely is due to early detection of the disease attributable to clinician awareness and readily available screening tests. Hyperthyroidism usually can be confirmed in these cats by repeating the thyroid hormone assays or performing a T_3 suppression test. In addition, a wide variety of nonthyroidal illnesses in hyperthyroid cats also may suppress the serum T_4 concentration into the normal range. Hyperthyroid cats with increased circulating T_4 and T_3 levels do not respond to exogenous TSH stimulation by increasing hormone levels two or three fold as in normal cats. The neoplastic follicular cells are unable to respond to the exogenous TSH, and follicular cells in the adjacent normal rim of thyroid have undergone trophic atrophy with colloid involution of follicles and are unable to increase blood T_4 and T_3 levels after only short-term stimulation by TSH.

Hyperthyroid cats often have disturbances of calcium homeostasis and diffuse chief cell hyperplasia in the parathyroid glands. Compared to reference intervals, blood ionized (not total) calcium and plasma creatinine concentrations often are significantly decreased and plasma phosphate and intact parathyroid hormone levels are increased. Hyperparathyroidism occurred in 77% of hyperthyroid cats, with parathyroid hormone levels elevated up to 19 times the upper limit of the reference range. Hyperphosphatemia was present in approximately 40% of hyperthyroid cats. The mechanisms for the development of hyperphosphatemia in feline hyperthyroidism are uncertain but may be related, in part, to polyphagia with increased intestinal phosphate absorption, increased catabolism of muscle proteins and release of phosphate due to the gluconeogenic effects of the elevated thyroid hormone levels, and increased bone resorption with release of phosphate into the blood. The hyperparathyroidism and chief cell hyperplasia appear to be related to the reciprocal decline in circulating levels of ionized calcium in response to the hyperphosphatemia. An elevated blood phosphate also could inhibit the renal 1 α-hydroxylase and decrease the production of the active form of vitamin D thereby reducing intestinal calcium absorption; however, circulating levels of $1,25(OH)_2D_3$ were not decreased in the limited number of hyperthyroid cats evaluated.

Serum levels of the bone isoenzyme of alkaline phosphatase are elevated consistently in cats with hyperthyroidism; however, there is no correlation between the magnitude of increase of alkaline phosphatase, osteocalcin, and serum T_4 concentrations. Although the total calcium usually is within the reference interval, the serum ionized calcium is reduced in approximately 50% of cases. *These findings suggest that hyperthyroid cats have altered bone metabolism*; however, the bone disease usually is not clinically significant in adult-to-aged cats with hyperthyroidism.

Surgical excision of affected thyroid lobe(s), medical management by thyroid blocking drugs (e.g., methimazole, propylthiouracil), and radioactive iodine are effective treatments available for cats with hyperthyroidism. Bilateral thyroidectomy is necessary if both glands are abnormal in appearance at surgery. At least one parathyroid gland should be left with an intact blood supply if bilateral thyroidectomy is performed. A thyroid-blocking agent, such as methimazole or propylthiouracil, can be used before surgery to alleviate some of the severe clinical effects (e.g., tachycardia and cardiomegaly) of hyperthyroidism.

Follicular cell carcinoma

Thyroid carcinomas are palpable masses in the ventral cervical region and they may be unilateral or bilateral. Most thyroid tumors are palpated near the larynx, but larger ones may extend toward the thoracic inlet. The tumor may be firm or soft. Respiratory distress occurs if the tumor encroaches upon the larynx or trachea. Carcinomas become fixed in position by extensive local invasion of adjacent structures, whereas adenomas are freely movable under the skin.

In dogs, thyroid carcinomas occur more often than adenomas, but in cats adenomas occur more frequently than carcinomas. No sex prevalence has been observed in dogs. It has been reported that Boxers develop thyroid carcinomas more frequently than any other breed of dog. There also are data indicating that Beagles, Boxers, and Golden Retrievers have a significantly greater risk for thyroid carcinoma than all other breeds of dogs combined.

Adenocarcinomas of the thyroid are larger than adenomas, are coarsely multinodular, and often have large central areas of hemorrhage and necrosis. Unilateral involvement is about twice as frequent in dogs as is involvement of both thyroid lobes. Carcinomas are poorly encapsulated and invade locally into the wall of the trachea, cervical muscles, esophagus, larynx, nerves, and vessels. Early invasion into branches of the cranial and caudal thyroid veins with the formation of *tumor cell thrombi* (Fig 3.75A, C) leads to multiple *pulmonary metastases* (Fig. 3.75D, E), often before involvement of the retropharyngeal and caudal cervical lymph nodes. Focal white gritty areas of mineralization or bone formation are scattered throughout some tumors. Although adenomas and carcinomas derived from follicular cells usually arise in the neck from the thyroid lobes, they may develop from *ectopic thyroid parenchyma in the mediastinum* and must be included in the differential diagnosis of "*heart-base tumors*" in dogs.

Malignant tumors of thyroid follicular cells generally are more highly cellular and have a greater degree of cellular pleomorphism than adenomas. On the basis of the predominant histologic pattern of growth, *"differentiated" thyroid adenocarcinomas are subdivided into follicular, papillary, and compact cellular (solid) types.* In dogs, where thyroid carcinomas are seen most frequently, they often have both a follicular and compact cellular growth pattern (Fig. 3.75B), whereas papillary carcinomas are uncommon.

In **follicular adenocarcinomas**, *the majority of tumor cells are arranged in a recognizable follicular pattern.* It is possible to subdivide follicular carcinomas further on the basis of size of follicles, as described for follicular adenomas, but this often is difficult because of the admixture of growth patterns present in any one tumor. Such subdivisions appear to be of little prognostic value in animals with thyroid cancer. The tumor cells are tall cuboidal to columnar, and form follicles of variable size, shape, and colloid content. Mitotic activity in the tumor cells is minimal. The colloid in follicular lumina occasionally is clumped and extensively mineralized.

In **compact cellular carcinoma**, tumor cells form aggregations or solid sheets of cells often separated by fibrous stroma with little or no attempt at follicle formation and colloid secretion. The polyhedral cells are closely apposed and have eosinophilic cytoplasm that is finely granulated or vacuolated. Immunocytochemical and ultrastructural studies have demonstrated that compact cellular ("solid") carcinomas in dogs are derived from follicular cells and not from C cells.

Follicular-compact cellular carcinoma *is the most common type of malignant thyroid tumor in dogs*, having approximately equal follicular and compact cellular growth patterns (Fig. 3.75B). The follicles formed often are smaller and contain less colloid than do pure follicular carcinomas. The tumor cells arranged in compact or solid areas appear to be morphologically and functionally less differentiated than those that form follicles and secrete colloid.

Papillary carcinomas in which tumor cells form papillae extending into cystic spaces are *uncommon in animals*. Single or multiple layers of cuboidal cells surround fibrovascular stalks that project into cystic spaces. Their nuclei are vesicular and pleomorphic with prominent nucleoli. The nuclear vacuoles seen by light

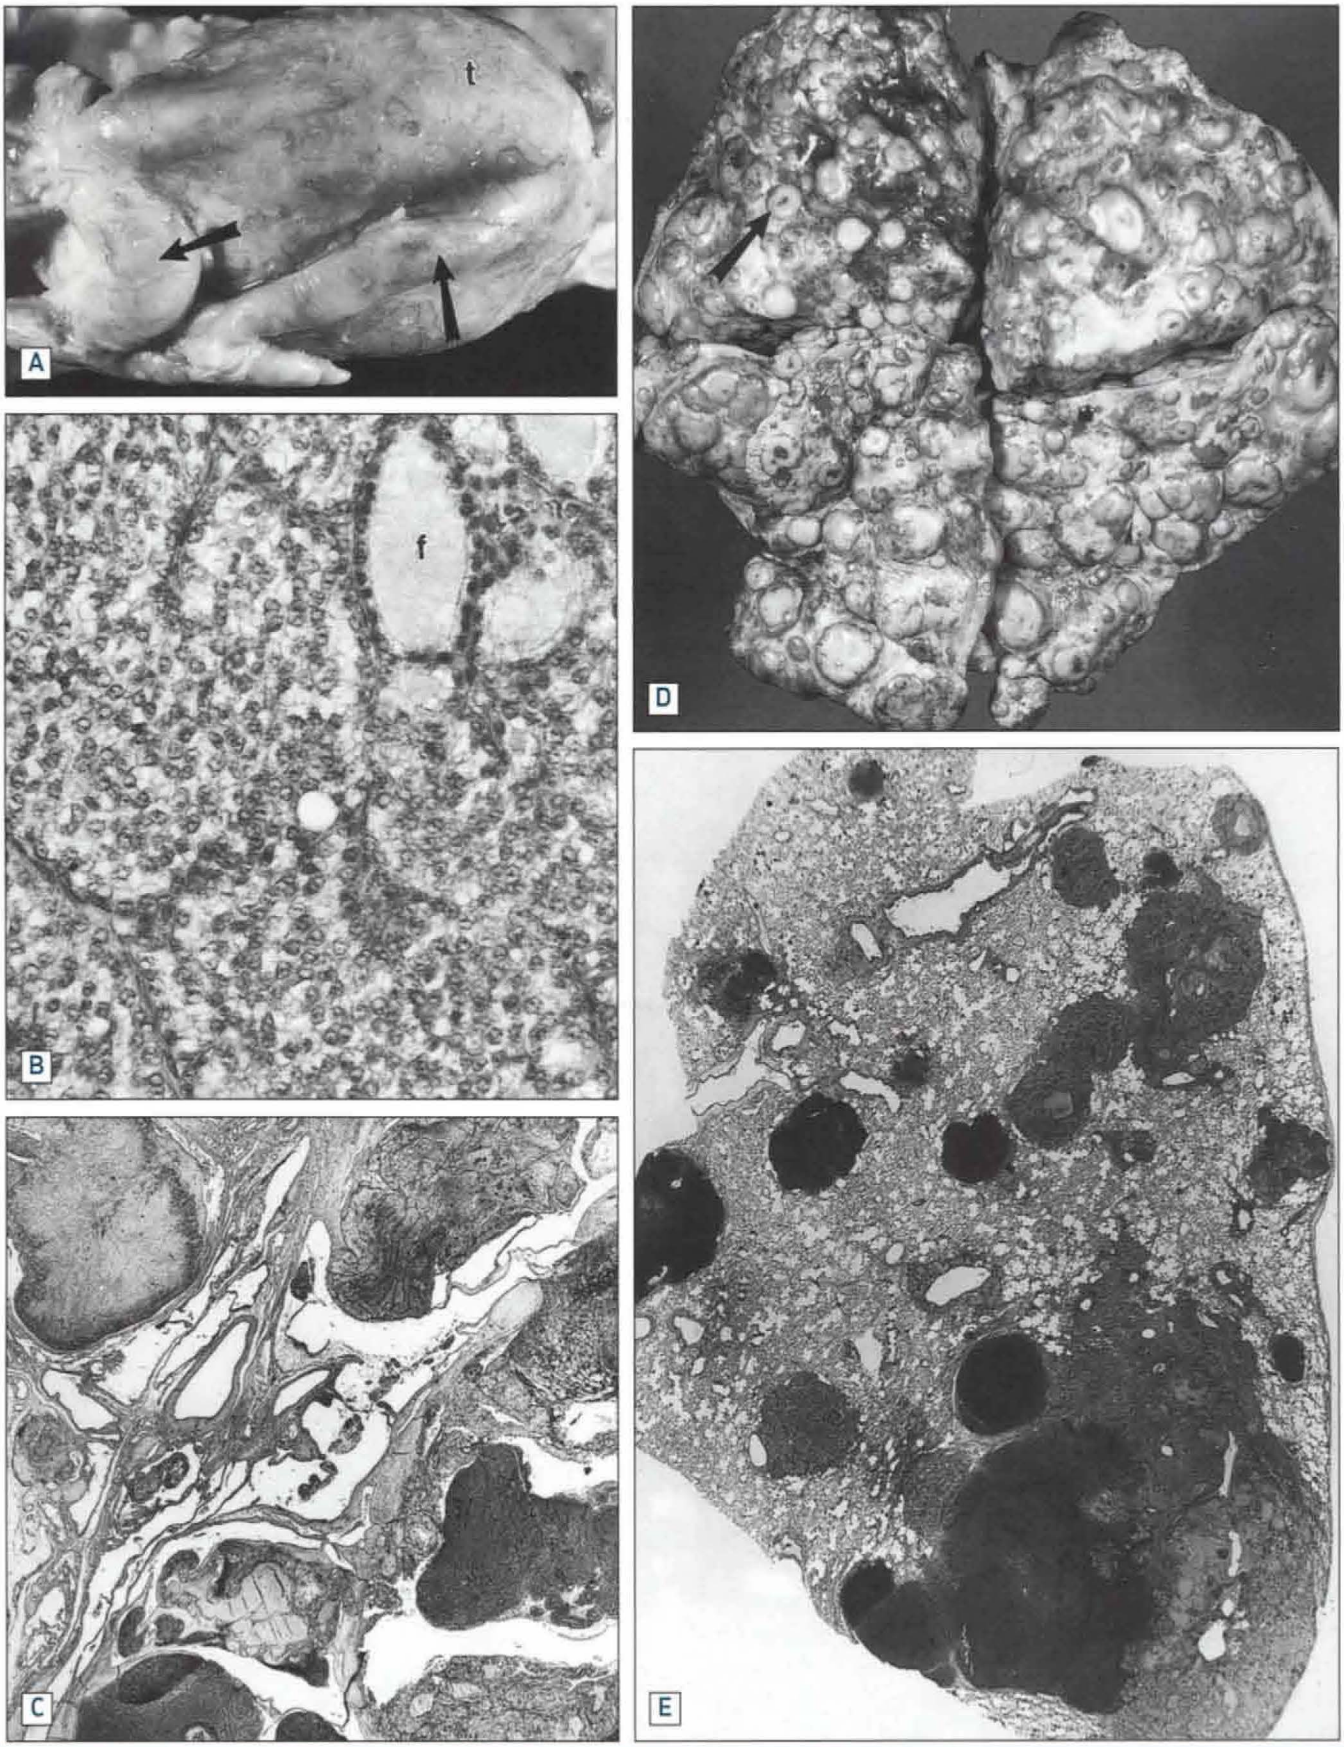

Figure 3.75 Adenocarcinoma of thyroid follicular cells, dog. **A.** Prominent tumor thrombi distending thyroid veins (arrows) adjacent to the enlarged thyroid (t). **B.** Follicular-compact cellular pattern. microscopy have been shown by electron microscopy to represent cytoplasmic evaginations into the nucleus. Infiltration of tumor cells through the fibrous connective tissue capsule and into adjacent tissues is frequent in thyroid adenocarcinomas.

Undifferentiated thyroid carcinomas *lack a characteristic architectural pattern of arrangement of tumor cells.* They are an uncommon form of thyroid carcinoma in animals. **Small-cell carcinoma** is one type of undifferentiated thyroid carcinoma. They are composed of highly malignant follicular cells with either a diffuse or compact pattern of growth. The small tumor cells are uniform in appearance and are closely packed within clusters separated by fibrous stroma. The scant cytoplasm is eosinophilic, and the oval nucleus is densely hyperchromatic. Mitotic figures are frequent.

Giant cell carcinoma is a highly malignant thyroid tumor derived from poorly differentiated follicular cells. *The anaplastic tumor cells are large, pleomorphic, and often spindle-shaped, making differentiation from a fibrosarcoma difficult.* The demonstration of identifiable epithelial structures may require multiple sections from several areas of the tumor. Follicular remnants of transitional forms suggest that giant cell carcinomas are derived from thyroid follicular cells.

Malignant mixed thyroid tumors have been reported in the dog. The tumors contain both malignant thyroid follicular cells and mesenchymal elements, usually osteogenic or cartilaginous.

Thyroid carcinomas often grow rapidly, invading adjacent structures such as the trachea, esophagus, and larynx, and usually are fixed in position. *The earliest and most frequent site of metastasis is the lung* (Fig. 3.75D, E), because thyroid carcinomas tend to invade branches of the thyroid vein. Tumor cords may be palpated in the thyroid or jugular veins in some animals with thyroid carcinoma. The retropharyngeal and caudal cervical lymph nodes are less frequent sites of metastasis.

Some thyroid tumors in the dog secrete sufficient thyroid hormone to produce mild clinical signs of *hyperthyroidism*. It is surprising that hyperthyroidism occurs even with functional tumors since experimental induction of hyperthyroidism in the dog requires daily administration of ~25 times the normal replacement dose of desiccated thyroid or *l*-thyroxine. The clinical signs of hyperthyroidism in dogs with functional thyroid tumors include weight loss, polyphagia, polyuria, polydipsia, weakness and fatigue with exercise, intolerance to heat, and nervousness.

Thyroid carcinomas occur much less frequently in **cats** than either adenomas or multinodular hyperplasia. They often result in considerable enlargement of one or both thyroid lobes and may invade adjacent structures. Thyroid carcinomas are characterized by neoplastic invasion of vessels and connective tissue capsule. Metastases to regional lymph nodes (retropharyngeal, mandibular, deep cervical) and distant sites have been reported infrequently in thyroid carcinomas of cats. The well-differentiated thyroid adenocarcinomas are composed of a uniform pattern of small follicles containing variable amounts of colloid. Strands of dense connective tissue with an abundant capillary network and foci of lymphocytes subdivide the neoplastic cells into small lobules.

Thyroid carcinogenesis and radiation. Epidemiologic investigations in humans and animal studies have indicated that the risk of developing thyroid cancer is increased following exposure to external (localized) X-rays (especially to the cervical region) or to internal ^{131}I irradiation. For example, results of a large study in female Long-Evans rats revealed that the proportion of rats with thyroid carcinomas was similar for ^{131}I and X-irradiation within the dose range of 0–1000 rads. There was a significant dose-dependent increase in follicular cell carcinomas in rats administered ^{131}I or exposed to external X-radiation.

Neoplasms of thyroglossal duct remnants

Tumors arising in cystic remnants of the thyroglossal duct are *rare in animals* but have been reported in dogs. They appear as well-circumscribed, fluctuant, movable enlargements (~2–4 cm diameter) on the ventral midline in the cranial cervical region. The clinical history usually indicates a slowly progressive expansion of the cervical mass. On cross-section, multilocular cystic areas containing translucent proteinaceous fluid alternate with white solid areas. The thyroid glands appear to be normal in the few cases studied in dogs. These tumors appear to develop from the epithelium of the thyroglossal duct and are not a cystic metastasis from a primary carcinoma in the thyroid gland.

Neoplasms of thyroglossal duct remnants are well-differentiated papillary carcinomas. Multiple papillary outgrowths covered by multiple layers of tall cuboidal to columnar epithelial cells extend from the cyst wall into the lumen (Fig. 3.76). The cyst wall is composed of dense fibrous connective tissue with focal areas of hemorrhage and cholesterol clefts. Aggregations of thyroidogenic epithelium in the form of small follicles and cell cords are present within the fibrous capsule and in surrounding connective tissue. These follicles are lined by low cuboidal epithelium and contain variable amounts of colloid. Carcinomas of thyroglossal duct remnants appear to be well-differentiated and slow growing with limited evidence of local tissue invasion.

Thyroid C (parafollicular) cell tumors

Tumors derived from C (parafollicular) cells of the thyroid gland are most frequently encountered in adult-to-aged bulls (ultimobranchial body origin), certain strains of laboratory rats, adult-to-aged horses, but infrequently in other species. A high percentage of aged bulls have been reported to develop C-cell tumors (30%) or hyperplasia of C cells and ultimobranchial derivatives (15–20%) when they were fed diets with a high calcium content similar to that fed to cows. *These frequently occurring hyperplastic and neoplastic lesions of C cells have been observed only in bulls and not in cows.* The incidence

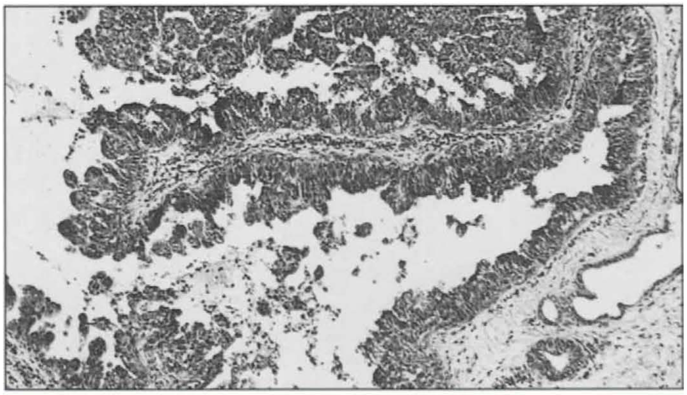

Figure 3.76 Papillary cystadenocarcinoma derived from thyroglossal duct remnants in a dog.

of C-cell tumors increases with advancing age in bulls, and may be associated with the development of vertebral osteophytes.

The syndrome of C-cell tumors in bulls shares many similarities with medullary thyroid carcinoma in humans. *Multiple endocrine tumors*, especially bilateral pheochromocytomas and occasionally pituitary adenomas, are detected coincidentally in bulls and human patients with C-cell tumors. This may represent a simultaneous neoplastic transformation of multiple endocrine cell populations of neural crest origin in the same individual. A high frequency of thyroid C-cell tumors and pheochromocytomas has been reported in a family of Guernsey bulls, suggesting an autosomal dominant pattern of inheritance. Diffuse or nodular hyperplasia of secretory cells in the adrenal medulla appears to precede the development of pheochromocytoma.

The calcitonin-producing C cells were described initially in dogs as light or gray cells and are particularly prominent in this species. Nodular aggregations of C cells are especially prominent in dogs, either near the thyroid hilus in the perithyroidal connective tissues, or within the thyroid lobes along the course of the major branches of the thyroid artery. The ultimobranchial body (last, usually fifth pharyngeal pouch) that delivers the neural crest-derived C cells to the postnatal thyroid gland fuses with each thyroid lobe at the hilus and distributes C cells throughout each lobe to various degrees in different species. In the dog, nodular aggregations of C cells frequently persist along the course of the major vessels to the thyroid; therefore, *C-cell hyperplasia in dogs should be diagnosed only when there is a definite increase in C-cell numbers throughout each thyroid lobe compared to age-matched controls.* Both thyroid lobes should be sectioned longitudinally in a consistent manner for microscopic evaluation. This will minimize the prominent regional differences of C cells in the thyroid glands of normal dogs that can result in the over-interpretation of these focal aggregations of C cells as a significant lesion. The C cells in the focal aggregations have abundant, lightly eosinophilic, finely granular, cytoplasm and a spherical-oval nucleus. There are occasional ultimobranchial-derived, colloid-containing follicles lined by more basophilic cells within the focal accumulations of C cells along the course of vessels within the thyroid lobe or in the connective tissues of the thyroid hilus in dogs.

Focal (nodular) hyperplasia of C cells often precedes the development of C-cell neoplasms in animal and humans. *The histological distinction between focal hyperplasia and adenoma of C cells often is difficult and somewhat arbitrary.* The diagnosis of C-cell hyperplasia refers to a focal or diffuse increase of C cells between thyroid follicles and/or within the follicular basement membrane. The C cells appear normal, with abundant, lightly eosinophilic, granular cytoplasm and a round-to-oval nucleus with finely stippled chromatin (Fig. 3.77). Cell boundaries often are indistinct. Focal hyperplasia of C cells forms a nodule with an approximate diameter equal to or less than 5 average colloid-containing thyroid follicles with minimal evidence of compression of adjacent follicles (guidelines for rat thyroids). Hyperplastic C cells within the basement membrane may compress individual thyroid follicles. Calcitonin immunoreactivity is localized to the cytoplasm of hyperplastic C cells.

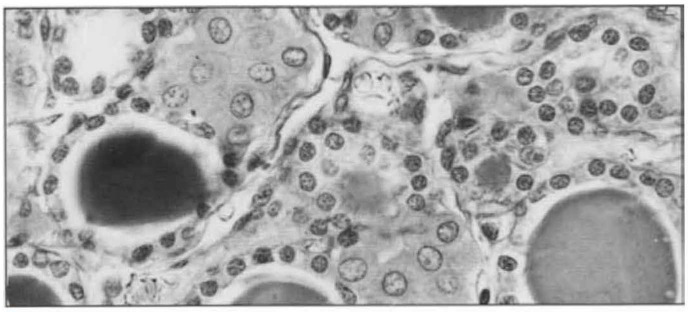

Figure 3.77 Hyperplasia of thyroid C cells in a dog.

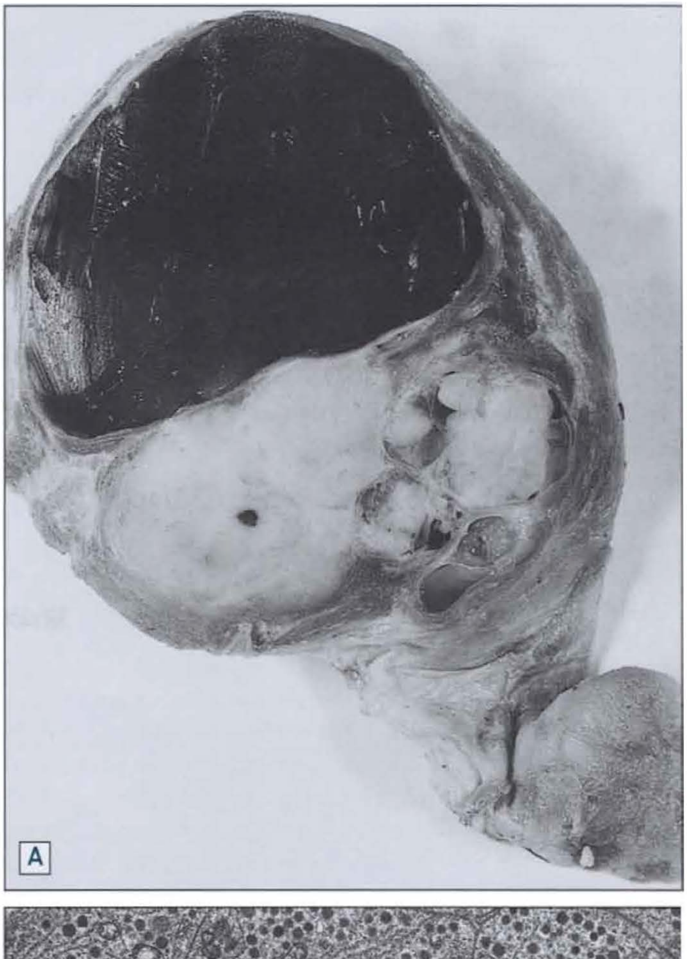
C-cell adenomas appear as discrete, single or multiple, gray to tan nodules in one or both thyroid lobes (Fig. 3.78A). Adenomas are smaller (~1–3 cm diameter) than carcinomas, and are separated from the thyroid parenchyma by a thin, partial to complete, fibrous



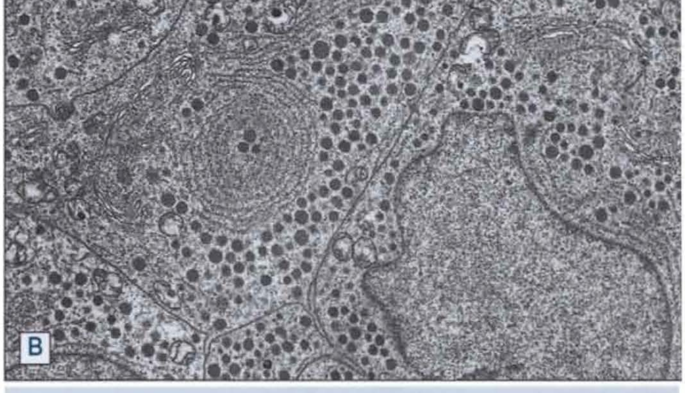


Figure 3.78 A. C-cell adenoma with cyst formation in a bull. **B.** C-cell adenoma in a horse, composed of well-differentiated cells that contain numerous membrane-limited secretory granules, circular profiles of rough endoplasmic reticulum, and prominent Golgi apparatuses.

connective tissue capsule. The adjacent thyroid is compressed but not invaded by neoplastic C cells. In horses, C-cell adenomas may result in a palpable enlargement in the cranial cervical region. Larger C-cell adenomas incorporate most of the thyroid lobe, but a rim of dark brown-red thyroid often is present on one side.

Thyroid C-cell adenomas microscopically are discrete, expansive masses of cells greater in diameter than 5 average colloid-containing thyroid follicles. They are well circumscribed or partially encapsulated from adjacent follicles that are compressed to various degrees. C-cell adenomas may be sub-divided into packets of cells by fine or coarse connective tissue septa and capillaries. The neoplastic C cells are well differentiated and have abundant cytoplasm that is lightly eosinophilic or clear. Areas of subendothelial growth of neoplastic C cells should not be over-interpreted as vascular invasion and evidence of malignancy. The well-differentiated cells comprising C-cell adenomas have numerous membrane-limited secretory granules, circular and lamellar profiles of rough endoplasmic reticulum, and prominent Golgi complexes (Fig. 3.78B). Some C-cell adenomas are composed of larger cells with amphophilic cytoplasm, large nuclei with coarsely clumped chromatin, and prominent nucleoli. These cells bear a histological resemblance to ganglion cells and the potential of primitive neuroectodermal cells that give rise to the adrenal medulla to differentiate into either sympathetic ganglion cells or catecholamine-secreting endocrine cells. Occasional amyloid deposits may be found both in nodular hyperplasia and in adenomas.

Thyroid **C-cell carcinomas** result in more extensive multinodular enlargements of one or both thyroid lobes. The proliferating neoplastic tissue may incorporate the entire thyroid gland. Multiple metastases in cranial cervical lymph nodes may be large and have areas of necrosis and hemorrhage. Pulmonary metastases are present infrequently and appear as discrete tan nodules throughout all lobes of the lung. C-cell carcinomas are more highly cellular and the tumor cells are more pleomorphic than are C-cell adenomas. They often have evidence of intrathyroidal and/or extracapsular invasion, occasionally with metastasis to distant sites. The neoplastic cells are polyhedral to spindle-shaped with lightly eosinophilic, finely granular, indistinct cytoplasm (Fig. 3.79). The vesicular nuclei are oval or elongate and have more frequent mitotic figures than do adenomas. Malignant C cells often are subdivided into small groups by fine connective tissue septa that contain small capillaries.

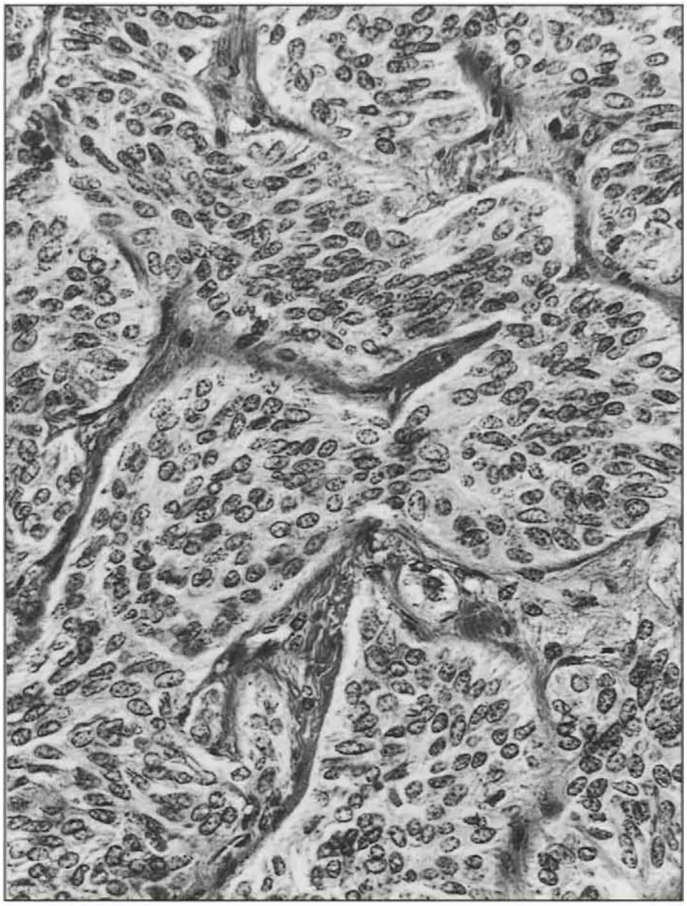

Figure 3.79 C-cell carcinoma illustrating neuroendocrine pattern in a bull.

Thyroid C-cell tumors in bulls, other animals and humans often are firm and in some areas the stroma consists of dense bands of fibrous connective tissue. In both adenomas and carcinomas, there may be deposits of homogeneous eosinophilic material that stains positively for *amyloid*. Ultrastructurally, large aggregations of fine amyloid fibrils are observed between the bundles of collagen fibers. The etiology of the localized amyloid deposition in thyroid C-cell neoplasms is uncertain but it is not associated with chronic suppurative lesions in other organs. Amyloid production is consistently associated with medullary thyroid carcinoma in humans and also has been reported in certain other endocrine tumors. Chemical differences exist between amyloid fibrils of immunoglobulin origin and those produced by endocrine tumors.

Bioassay of C-cell adenomas and carcinomas from bulls has demonstrated the presence of *calcitonin activity in tumor tissue* and calcitonin has been detected at higher than normal levels in plasma of bulls by immunoassay. Calcium infusion to raise serum calcium increases plasma calcitonin-like activity. Mean serum calcium levels in bulls with calcitonin-secreting thyroid tumors are only slightly lower than in adult control bulls. The near normal or mild decrease in serum electrolyte values in animals with chronic hypersecretion of calcitonin probably is a result of the low turnover rate of bone and compensatory mechanisms of other endocrine organs such as the parathyroid glands.

The etiology of C-cells neoplasms is unknown, but a possible relationship has been suggested between the long-term dietary intake of excessive calcium and the high incidence of these tumors in bulls. Depending upon the feeding regimen, adult bulls may ingest 3.5–6.0 times the amount of calcium normally recommended for maintenance. *The chronic stimulation of C cells by high levels of calcium absorbed from the digestive tract may be related to the pathogenesis of C-cell neoplasms.* A significant decline in the incidence of C-cell tumors has been reported when bulls are switched from a high-calcium intake to a reduced calcium intake. Cows do not develop proliferative lesions of C cells under similar dietary conditions, possibly because of the high physiologic requirements for calcium imposed by pregnancy and lactation.

Ultimobranchial tumors in the thyroid glands of bulls often have a more complex histologic structure than the typical C-cell (medullary) neoplasms in human patients, horses, dogs, and certain strains of laboratory rats. Focal areas in the tumor are composed of more differentiated C cells that have abundant lightly eosinophilic cytoplasm and are located either in the wall of thyroid and ultimobranchial follicles or as larger nodules with a solid histologic structure. This often is accompanied by multifocal hyperplasia of

C cells in other parts of the thyroid lobes and hilus. The neoplastic C cells often are embedded in an increased amount of hyalinized stroma that may contain amyloid. Other areas of this unique thyroid neoplasm in bulls appear to be derived from less differentiated ultimobranchial remnants and consist of follicle-like structures, cysts, and tubules composed of immature small basophilic cells. They closely resemble undifferentiated or stem cells of the normal ultimobranchial body in bulls and other species that have the potential to differentiate into both C and follicular cells. Thyroid follicles and cribriform structures with colloid-like material formed by cells resembling differentiated follicular cells often are present in the neoplasms in close association with these more primitive ultimobranchial-derived structures. The heterogeneous histologic structure of ultimobranchial neoplasms in bulls resembles an unusual type of thyroid carcinoma of human patients. This variant, designated as an **intermediate type of differentiated thyroid carcinoma**, has structural and immunocytochemical characteristics of both medullary (C-cell) and follicular carcinomas.

ADRENAL CORTEX

Development, structure, and function

Embryonic development of adrenal gland

The adrenal glands of mammals consist of two distinct parts that differ not only in morphology and function but also in origin. Because of their close structural relationships, the outer cortex and inner medulla of the adrenal gland usually have been considered parts of one organ (Fig. 3.80). The **adrenal cortex** develops from cells of the celomic epithelium that are of mesodermal origin. The chromaffin tissue and sympathetic ganglion cells of the **adrenal medulla** are derived from ectoderm of the neural crest. It is not until relatively late in fetal development that a definitive relationship between the two primordia occurs.

Structure of adrenal gland

The adrenal glands are richly vascularized, receiving arterial branches either directly from the aorta or from the phrenic, renal and lumbar arteries. The arteries form a vascular plexus in the capsule that eventually supplies the entire adrenal gland through separate channels to the capsule, cortex, and medulla. A sinusoidal network is formed about the cell columns of the adrenal cortex that empties into the venous tree at the periphery of the medulla. The larger branches of the venous tree empty into the adrenal vein.

The adrenal cortex classically is subdivided into three layers or zones, although the demarcation between zones often is not distinct.

- The **zona glomerulosa** (multiformis, arcuata) is composed of columns of cells that have a sigmoid arrangement next to the capsule. It represents ~15% of the cortex and is responsible for the secretion of *mineralocorticoid hormones*.

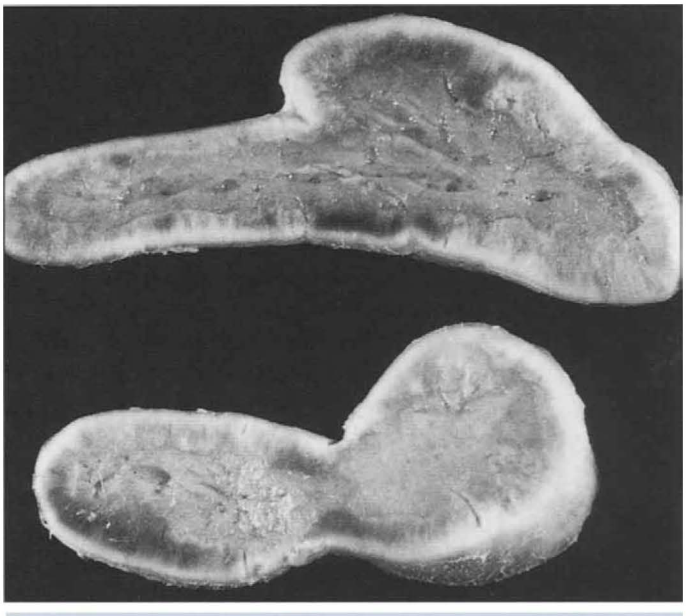

Figure 3.80 Normal adrenal glands (top = right adrenal; bottom = left adrenal) from a dog. Cortical:medullary ratio is approximately 2:1.

- The secretory cells of the **zona fasciculata** are arranged in long anastomosing cords separated by numerous small capillaries. This middle zone, which comprises ~70% of the cortex, is composed of cells that contain abundant cytoplasmic lipid and are responsible for the secretion of the *glucocorticoid hormones*.
- The **zona reticularis** accounts for the remaining 15% of the cortex. The secretory cells are arranged in small groups surrounded by capillaries. This inner layer is responsible for the secretion of *sex steroids* by the adrenal gland.

Cortical cells may project for a short distance into the medulla.

Biosynthesis and action of adrenal cortical hormones

Mineralocorticoids *are adrenal steroids that have their principal effects on ion transport by epithelial cells, resulting in a loss of potassium and conservation of sodium.* The most potent and important naturally occurring mineralocorticoid is *aldosterone*. The enzymatically controlled electrolyte "pumps" in epithelial cells of the renal tubule and sweat glands respond to mineralocorticoids by conserving sodium and chloride and by excreting potassium. In the distal convoluted tubule of the mammalian nephron, a cation exchange mechanism exists for the resorption of sodium from the glomerular filtrate and secretion of potassium into the lumen. These reactions are accelerated by mineralocorticoids but proceed at a much slower rate in their absence. A lack of secretion of mineralocorticoids (such as in idiopathic adrenal atrophy of dogs) may result in a lethal retention of potassium and loss of sodium.

Glucocorticoid hormones secreted by the adrenal cortex are concerned with the intermediary metabolism of glucose. *Cortisol* and lesser amounts of *corticosterone* are the most important naturally occurring glucocorticoids secreted by the adrenal gland in domestic animals. *In general, the actions of glucocortocoids on carbohydrate, protein, and lipid metabolism result in sparing of glucose and a tendency to hyperglycemia and increased glucose production.* The acute effects of glucocorticoids are observed within 15–30 min prior to when the compensatory effects of insulin become prominent. There is a decrease in glucose uptake in adipose tissue, skin, fibroblasts, and lymphoid tissue followed shortly by increased catabolism in these tissues and muscle. This provides the amino acids for gluconeogenesis, which is increased mainly in the liver. In addition, glucocorticoids decrease lipogenesis and increase lipolysis in adipose tissue, which results in release of glycerol and free fatty acids.

Glucocorticoids also function to *suppress inflammatory and immunologic responses* and thereby attenuate the associated tissue destruction and fibroplasia. However, under the influence of high levels of glucocorticoids there is an enhancement of the spread of infections and reduced resistance to a number of bacterial, viral, and fungal diseases. Glucocorticoids may impair the immunologic response at any stage from the initial interaction and processing of antigens by cells of the monocyte–macrophage system through the induction and proliferation of immunocompetent lymphocytes and subsequent antibody production. Inhibition of a number of lymphoid cell functions by glucocorticoids forms part of the basis for suppression of the immunologic response.

Glucocorticoids also *decrease the initial inflammatory reaction* and its classic manifestations of heat, swelling, and pain. The degree of hyperemia, extravasation, cellular migration, and infiltration at the site of injury is decreased. Especially important are the effects of glucocorticoids on the usual vascular responses of increased permeability, diapedesis, and extravasation. Capillary blood flow is decreased and there is less endothelial swelling. In addition, a number of *phagocytic mechanisms are inhibited* by glucocorticoids and clearance of particulate substances from the blood and lymph is impaired. The accumulation of engulfed antigens in macrophages probably is related in part to the *enhanced stability of lysosomal membranes* caused by glucocorticoids. There is a diminished capacity of lysosomes to interact with phagocytized material and to release hydrolytic enzymes involved in intracellular digestion.

Glucocorticoids exert a *profound negative effect on wound healing*. Dogs receiving high therapeutic levels of adrenal corticosteroids or animal patients with hypercortisolism may have wound dehiscence following surgery. The basis mechanism involved is inhibition of fibroblast proliferation and collagen synthesis leading to a decrease in scar tissue formation.

Secretion of **adrenal sex hormones** by cells of the zona reticularis occurs under normal conditions but in minute amounts that probably are of minor physiologic significance. Secretory cells of the inner zone of the cortex synthesize progesterone, estrogens, and androgens. Under pathologic conditions, excessive secretion of adrenal sex steroids infrequently may occur associated with a neoplasm arising in the zona reticularis. The clinical manifestations of virilism, precocious sexual development or feminization depend upon which steroid is secreted in excess, sex of the patient, and the age of onset.

The **renin–angiotensin system** is the major regulator of *aldosterone* production by the zona glomerulosa of the adrenal cortex. Renin is an enzyme secreted into the circulation by cells of the juxtaglomerular apparatus in the kidney. It acts to cleave the plasma globulin, angiotensinogen, to form angiotensin I. This decapeptide is further hydrolyzed to angiotensin II by a converting enzyme. Angiotensin II is both a potent vasoconstrictor and a trophic hormone for the zona glomerulosa of the adrenal cortex, resulting in the synthesis and secretion of aldosterone. It is a very labile peptide that is quickly inactivated in plasma and tissues by angiotensinases.

A number of factors are concerned with the regulation of renin secretion by the kidney. The "short loop" of negative feedback control is the direct inhibition exerted by circulating levels of angiotensin II. The "long loop" of this servo-mechanism is exerted by an indirect feedback inhibition by aldosterone on renin secretion. Renin release and eventually aldosterone secretion are increased by conditions that compromise blood flow and pressure to the kidney, severe dehydration that results in decreased intravascular blood volume, and sodium depletion.

Adrenocorticotropin (ACTH) secreted by the adenohypophysis is the principal regulator of adrenal cortical growth and secretory activity, particularly of cells in the zonae fasciculata and reticularis. The adrenal cortex secretes physiologic quantities of cortisol only in response to ACTH stimulation. ACTH is one of many polypeptide hormones known to exert its action on target cells through receptor-mediated activation of adenylate cyclase and generation of the intracellular mediator 3′,5′-adenosine monophosphate (cyclic AMP). Cyclic AMP serves as the intracellular mediator of ACTH action by stimulating certain key enzymes (e.g., protein kinases) to initiate the biochemical events leading to the biosynthesis of corticosteroid hormones.

Control of the secretion of ACTH by the adenohypophysis is governed by the hypothalamus largely through the secretion of **corticotropin-releasing factor (CRH)**. This peptide is secreted by neurons of the hypothalamus into capillaries that form the *hypothalamic–pituitary portal system* and convey CRH to corticotrophs of the pituitary. Corticotropin-releasing factor acts by stimulating cyclic AMP formation within ACTH-secreting cells resulting in the rapid release of preformed secretory granules containing ACTH.

Negative feedback control of ACTH secretion is exerted primarily by the circulating level of cortisol acting on secretory cells in the hypothalamus or adenohypophysis gland or both. When plasma cortisol levels are elevated beyond the normal physiologic range (as occurs following the exogenous administration or with cortisol-producing adrenal tumor), ACTH secretion is suppressed, secretory cells in the zonae fasciculata and reticularis decrease the rate of synthesis and release of corticosteroid hormones, and the adrenal cortex undergoes trophic atrophy. Conversely, when cortisol levels are subnormal, there is increased release of ACTH from the pituitary gland in an attempt to increase cortisol secretion and return blood levels towards normal.

Diseases of the adrenal cortex

Developmental disturbances of the adrenal cortex

The adrenal glands are composites of steroid hormone-secreting cells of mesodermal origin and catecholamine hormone-secreting cells of neural crest origin that become associated anatomically to varying degrees in different animals. The development of one component does not depend on the development of the other, nor does it depend on the presence or absence of the kidney.

Unilateral agenesis of an adrenal gland occurs occasionally in dogs, most frequently on the left side. **Total agenesis** of the adrenal cortex is fatal in all species due to the inability to produce mineralocorticoids, but the medulla is not essential for life. Developmental anomalies or diseases that decrease or prevent the production or release of ACTH from the fetal pituitary result in hypoplasia or atrophy of the zonae fasciculata and reticularis but not the zona glomerulosa. **Accessory adrenal cortical** tissue is frequent in many species. It may be found in the capsule of adrenal, in the periadrenal or perirenal adipose tissue, and in the mesorchium. Accessory adrenocortical tissue is seen frequently in the vicinity of the equine testis.

Hypoplasia of the adrenal cortex is associated with maldevelopment of the hypophysis associated with anencephaly, in some cases of cyclopia, and in hypophyseal aplasia. The adrenal cortices are small and histologically have nests of cortical cells without distinct zonal development, similar to the arrangement of the fetal adrenal cortex (see Fig. 3.3). The adrenal medulla is normal.

Foci of hematopoietic cells are found incidentally in the adrenal glands and usually are not associated with anemia or other evidence of bone marrow depression or extramedullary myelopoiesis. They are observed most commonly in cattle as round white foci (up to 3–4 mm in diameter) and histologically are composed predominantly of eosinophils. Foci of lymphopoiesis are seen in the cortex of both sheep and cattle and also may be present in the medulla.

Congenital enzyme defects of adrenal cortical steroidogenesis

Several genetically determined enzyme defects in the adrenal cortex of humans interfere with the synthesis of certain cortical steroids and lead to various degrees of hypoadrenocorticism. For example, a lack of 3-hydroxycorticosteroid dehydrogenase blocks the synthesis of cortisol, aldosterone, and adrenal sex steroids. It is uncertain whether any of these congenital enzyme defects occurs in domestic animals.

Rabbits (III VD/J strain) with a congenital (autosomal recessive gene) deficiency of cholesterol-20α -hydroxylase in the adrenal cortex and testis have marked adrenal cortical hyperplasia and feminization at birth. This is a lethal trait and results in death soon after birth. The blockage at an early stage of steroidogenesis in the adrenal cortex interferes with the ability to synthesize cortisol (probably other corticosteroids as well) and leads to a marked accumulation of substrate (e.g., cholesterol) in cortical cells. The marked hyperplasia of the zonae fasciculata and reticularis in the adrenal cortex is a response to the elevated ACTH levels stimulated by the low blood cortisol. The hyperplastic cortical cells are vacuolated and lipid-laden due to the accumulation of cholesterol. The lack of cholesterol-20α -hydroxylase in the testis interferes with the synthesis of androgenic steroids. Inadequate androgen levels during development result in failure of virilization of structures derived from the urogenital sinus and account for the finding of female external genitalia in ~80% of rabbits with the hyperplasia (ah/ah) genotype.

Degenerative changes of the adrenal cortex

Mineralization of the adrenal glands with extensive deposits of calcium salts occurs frequently in adult cats. A 30% incidence has been reported for cats compared with <6% for dogs. Mineralization also is common in adrenal glands of monkeys. *The cause is unknown.* The mineral deposits, although often bilateral and extensive, usually are not associated with clinical signs attributable to hypoadrenocorticism. The mineralized adrenals may be detected at necropsy or during routine radiographic evaluation of the abdomen.

Extensively mineralized adrenal glands are coarsely nodular, firm and mottled with multiple yellow-white foci throughout the cortex and extending into the medulla. They are gritty and difficult to cut. Histologically, there are large areas of necrosis with mineral deposition adjacent to areas of nodular regenerative hyperplasia of remaining viable cortical cells. These hypertrophic cortical cells have abundant lipid in their expanded cytoplasmic area and appear to be able to maintain near normal blood cortisol levels in response to an apparent increased secretion of ACTH.

Capsular sclerosis affects the adrenal glands of old cows often with ovarian follicular cysts. The connective tissue changes often proceed to collagenous and osseous metaplasia in old bulls. There may be an associated moderate reduction in the width of the cortex.

Amyloid deposition in the adrenal glands usually involves the cortex but not the medulla. It occurs in all species and is regularly part of the syndrome of generalized amyloidosis in cattle. Affected adrenal cortices often are widened and the amyloid deposits may be grossly visible as translucent areas. Amyloid deposition begins around the sinusoids in the inner portions of the zona fasciculata and often is largely confined to this zone. Signs of adrenal cortical insufficiency usually do not develop.

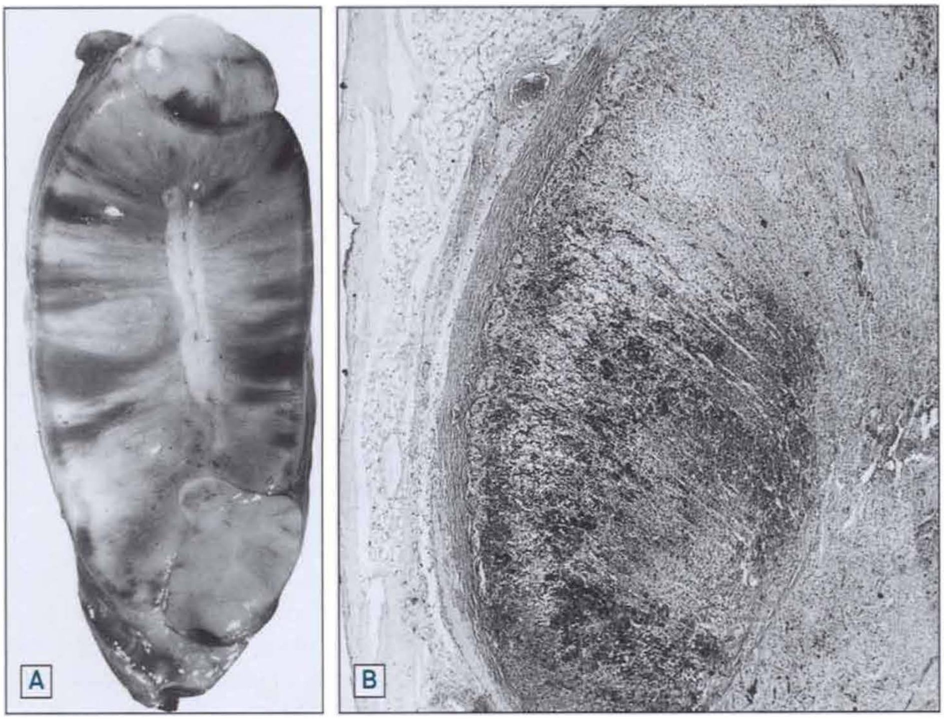

Figure 3.81 A. Multiple hemorrhages in the adrenal cortex in a severely stressed horse. **B.** Necrosis with hemorrhage in adrenal cortex of a lamb with coliform septicemia.

Hemorrhages in the adrenals occur in the newborn of any species. They are presumed to be due to *birth trauma*. Widespread hemorrhage and early degeneration occurs in the adrenal cortex as part of the exhaustion phase of the "*stress response*." It is seen in wild animals that die suddenly during restraint and horses that die from *overexertion* (e.g., struggling to free themselves from being trapped in a fence). *Toxemia* (e.g., intestinal torsion in horses) and *septicemia* also may injure the endothelial lining of adrenal sinusoids and result in extensive cortical hemorrhage (Fig. 3.81A) or the formation of hematomas.

Telangiectasis of the adrenal cortex occurs in middle-aged or older animals as single or multiple dark foci near the corticomedullary junction. These areas typically are depressed on cut surfaces. Areas of telangiectasis appear to develop subsequent to degeneration and loss of cortical cells and ectasia of adrenal sinusoids in the area. Persisting parenchymal cells in these foci either may be hypertrophied and contain much lipid or be small and atrophic.

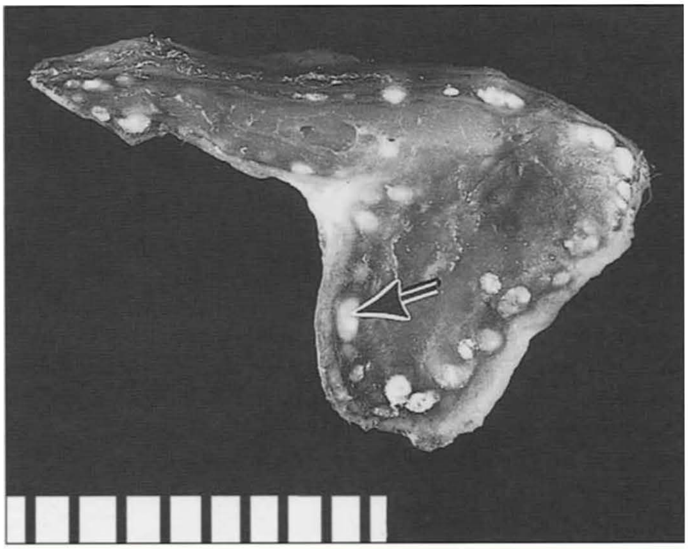

Figure 3.82 Multifocal granulomatous adrenalitis in a dog. The cortices are thin with multiple granulomas (arrow). Scale in mm.

Inflammation of the adrenal cortex (adrenalitis)

Infectious and parasitic agents frequently localize in the adrenal gland and elicit various degrees of inflammation and necrosis. *There is good experimental evidence that the high local concentration of anti-inflammatory steroids in the adrenal cortex suppresses local cell-mediated immunity and permits the preferential progressive growth of certain fungi, protozoa, and bacteria in the adrenal gland.* Focal inflammations usually are suppurative arising in the course of bacterial septicemia. The adrenal capsule provides an effective barrier against direct invasion by inflammatory processes in adjacent tissue. Gram-negative bacteria, especially coliforms, produce suppurative inflammation with necrosis as part of septicemia in many species (Fig. 3.81B). Emboli often lodge in the adrenal sinusoids to produce focal necrosis and suppurative infection. Tuberculosis of the adrenal is encountered mainly in cattle and humans. *Toxoplasma gondii* localizes in the adrenal cortex of many animals and produces focal areas of necrosis with minimal inflammation. Granulomatous inflammation due to *Histoplasma capsulatum*, *Coccidioides immitis*, or *Cryptococcus neoformans* occasionally occurs in dogs and cats in areas where these fungi are endemic. Multiple distinct granulomas with central areas of necrosis and mineralization may nearly destroy the entire cortex (Fig. 3.82). Small nodules of viable hypertrophic cortical cells are present between the granulomas. The reaction to *Cryptococcus* in the adrenal may vary from no reaction to extensive infiltration by macrophages.

Several *viruses* affect the adrenals and focal lesions are expected in herpesviral infections such as pseudorabies. The adrenal lesions are characterized by intranuclear viral inclusion bodies, necrosis, and hemorrhage in the cortex and medulla. Lymphocytes and macrophages infiltrate the necrotic and hemorrhagic foci in the later stages of the infection.

Inflammatory edema of the adrenal glands occurs in older animals with acute infectious diseases. These conditions would be more likely to cause cortical hemorrhages in young animals. The glands are enlarged due to swelling of the cortex from hyperemia and edema. The cortical cells are swollen, granular, depleted of lipid, and dissociated by the inflammatory edema.

Mechanisms of toxicity of the adrenal cortex

Adrenal cortical cells contain large stores of lipid used as substrate for steroidogenesis. Many compounds that are toxic for the adrenal cortex are lipophilic and accumulate in these lipid-rich cells. **Mechanisms of toxicity** include:

- **Impairment of steroidogenesis**, which is an important mechanism of toxicity in the adrenal cortex that can occur by inhibition of cholesterol biosynthesis or metabolism, and by disruption of cytochrome P450 enzymes. Both of these mechanisms will lead to the accumulation of increased cytoplasmic lipid in the form of discrete droplets.
- **Toxin activation by mitochondrial cytochrome P450 (CYP450) enzymes** in the cortical cells. Activation of toxins can result in the generation of reactive oxygen metabolites, result in membrane damage, and produce phospholipidosis in the cells.
- **Exogenous steroids**, which can disrupt normal function and structure of the adrenal cortex. Agonists will induce negative feedback inhibition of ACTH secretion by the pituitary and will result in atrophy of the zonae fasciculata and reticularis. Some steroids, such as the sex steroids, can induce proliferative lesions in the adrenal cortex. Antagonists will block steroid hormone action, lead to increased ACTH secretion, and diffuse hyperplasia of the cortex.
- **DNA damage,** by agents such as carcinogens or radiation, may induce neoplasia of the adrenal cortex.

There is considerable *species variation* in the response of the adrenal cortex to exogenous chemicals. This is due to both inherent differences in the sensitivity to certain drugs and differences in the metabolic pathways of steroidogenesis. An interesting example is o,p′-DDD (mitotane) which was originally developed to treat metastatic adrenal cortical cancer in humans. However, humans are relatively insensitive to the effects of o,p′-DDD and the drug was not effective in the treatment of adrenal cancer. In contrast, dogs are considerably more sensitive to the effects of o,p′-DDD and it has been used effectively in a dose-dependent manner in the medical management of pituitary-dependent hyperadrenocorticism due to autonomous secretion of ACTH by pituitary (corticotroph) tumors. o,p′-DDD is a selective toxin for the zona fasciculata and reticularis; thereby, sparing the important life-sustaining functions of the zona glomerulosa and production of aldosterone.

Classes of chemicals known to be toxic for the adrenal cortex include short chain (3 or 4 carbon) aliphatic compounds, lipidosis inducers, and amphiphilic compounds. A variety of other compounds also may affect the medulla. The most potent aliphatic compounds are of 3-carbon length with electronegative groups at both ends. These compounds frequently produce necrosis, particularly in the zonae fasciculata and reticularis. Examples include acrylonitrile, 3-aminopropionitrile, 3-bromopropionitrile, 1-butanethiol, and 1,4-butanedithiol. By comparison, lipidosis inducers can cause the accumulations, often coalescing, of neutral fats that may be of sufficient quantity to cause reduction or loss of organellar function and eventual cell destruction. Cholesterol is the precursor substrate required to synthesize steroid hormones. Steroidogenic cells obtain cholesterol exogenously from serum lipoproteins and endogenously from de novo synthesis via the acetyl coenzyme A pathway (Fig. 3.83A). The adrenal cortical cells and ovarian interstitial (OI) cells in the rat preferentially utilize serum high-density lipoproteins (HDLs) for their primary source of cholesterol and resort to de novo synthesis if HDL does not meet the demand of steroidogenesis. This is in contrast to Leydig cells of the testis, which preferentially utilize de novo synthesis of cholesterol and use an exogenous source only when intracellular synthesis does not meet the demand and the cholesterol pool has been depleted.

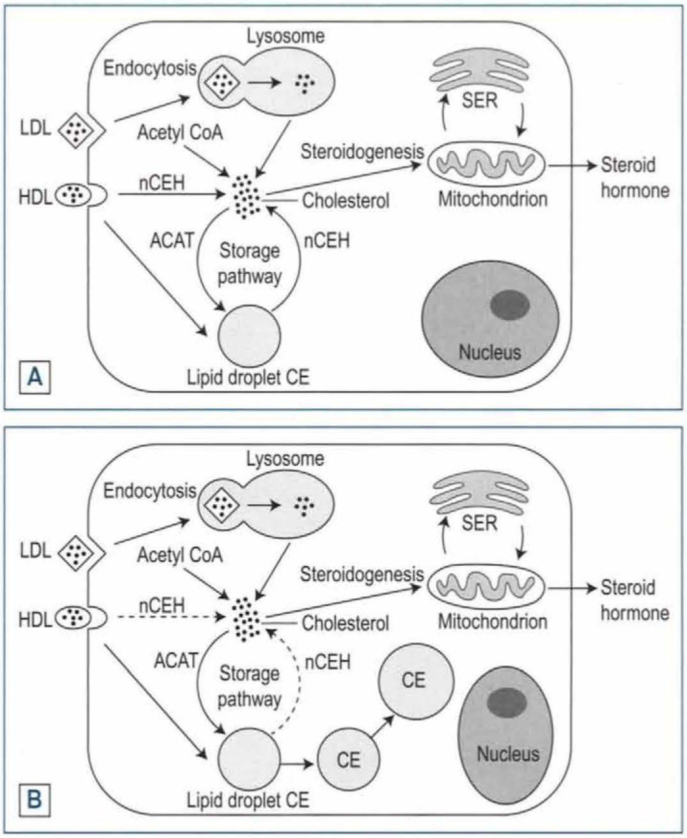

Figure 3.83 A. Cholesterol metabolism and steroid hormone biosynthesis in adrenocortical cells. Cholesterol is the substrate for steroid hormone biosynthesis. Conversion of cholesterol to pregnenolone occurs in the mitochondria, and oxidative reactions catalyzed by P450 enzymes occur in the smooth endoplasmic reticulum (SER) and mitochrondia. Sources of cholesterol include lipoprotein (LDL and HDL) uptake from serum, de novo synthesis from acetate via the acetyl coenzyme A pathway, and hydrolysis of cholesteryl ester (CE) by neutral CE hydrolase (nCEH). The storage pool in the form of lipid droplets is derived principally from the conversion of free cholesterol to CE catalyzed by acyl coenzyme A:cholesterol acyltransferase (ACAT). **B. Pathogenesis of cholesteryl lipidosis in adrenocortical cells.** Inhibition of nCEH by a xenobiotic can result in the accumulation of CE in the form of lipid droplets in the cytoplasm. The levels of ACAT that catalyze the formation of CE from cholesterol activity remain near normal. (From Latendresse JR, et al. Toxicol Appl Pharmacol 1993;122:281–289.)

The zonae reticularis and fasciculata appear to be the principal targets of xenobiotics in the adrenal cortex. Examples of the compounds causing lipidosis include aminoglutethimide, amphenone, and anilines. Tricresyl phosphate (TCP) and other triaryl phosphates cause a defect in cholesterol metabolism by blocking both the uptake from serum and storage pathways. An inhibition of cytosolic neutral cholesteryl ester hydroxylase (nCEH) by triaryl phosphate results in the progressive accumulation of cholesteryl ester in the form of lipid droplets in the cytoplasm of adrenal cortical and OI cells (Fig. 3.83B) but not in testicular Leydig cells of rats. Acyl coenzyme A: cholesterol acyl transferase (ACAT), an enzyme that esterifies cholesterol to make cholesteryl ester, was depressed to a lesser extent but contributed to the elevated intracellular storage of cholesterol in the form of lipid droplets by the triaryl phosphate (Fig. 3.83B).

Biologically active cationic amphiphilic compounds produce generalized phospholipidosis that involves primarily the zonae reticularis and fasciculata and results in the development of microscopic phospholipid-rich inclusions. These compounds affect the functional integrity of lysosomes, which appear ultrastructurally to be enlarged and filled with membranous lamellae or myelin figures. Examples of compounds known to induce phospholipidosis include chloroquine, triparanol, and chlorphentermine.

Adrenal lesions associated with hypoadrenocorticism

Idiopathic adrenocortical atrophy. *The most frequently observed lesion in dogs with* **hypoadrenocorticism** *is bilateral idiopathic adrenocortical atrophy in which all layers of the cortex are markedly reduced in thickness* (Fig. 3.84A, B). There usually is deficient production of all classes of corticosteroids (mineralocorticoids, glucocorticoids, and adrenal sex steroids). The adrenal cortex is reduced to one-tenth or less its normal thickness and consists primarily of the adrenal capsule. The adrenal medulla is relatively more prominent and with the capsule makes up the bulk of the remaining adrenal glands. The pathogenesis of idiopathic adrenocortical atrophy is unknown, but it has been *proposed that the lesion is immune-mediated.* Multiple foci of lymphocytes and plasma cells often are seen interspersed between adrenal sinusoids and groups of fibroblasts in the earlier stages of the disease. The entire three zones of the cortex are nearly absent in dogs that die from untreated hypoadrenocorticism. The capsule appears thickened due to collapse of the adrenal cortex plus fibroblastic proliferation.

No obvious pituitary lesions other than compensatory hyperplasia of corticotrophs have been observed in dogs with idiopathic adrenal cortical atrophy. All zones of the adrenal cortex are involved, including the zona glomerulosa, which is not under ACTH control. In comparison, trophic atrophy of the adrenal cortex secondary to a destructive pituitary lesion that decreases ACTH secretion is characterized by severe atrophy only of the inner two cortical zones. These animals do not have the characteristic electrolyte abnormalities present in hypoadrenocorticism since the secretion of aldosterone remains within normal limits.

Causes of adrenocortical insufficiency in the dog include granulomatous inflammation caused by such diseases as histoplasmosis, blastomycosis or tuberculosis that destroy the cortex; thrombosis of adrenal vessels with infarction of the cortex associated with disseminated intravascular coagulopathies; invasion and destruction of adrenal cortex by metastatic neoplasms; hemorrhage and necrosis

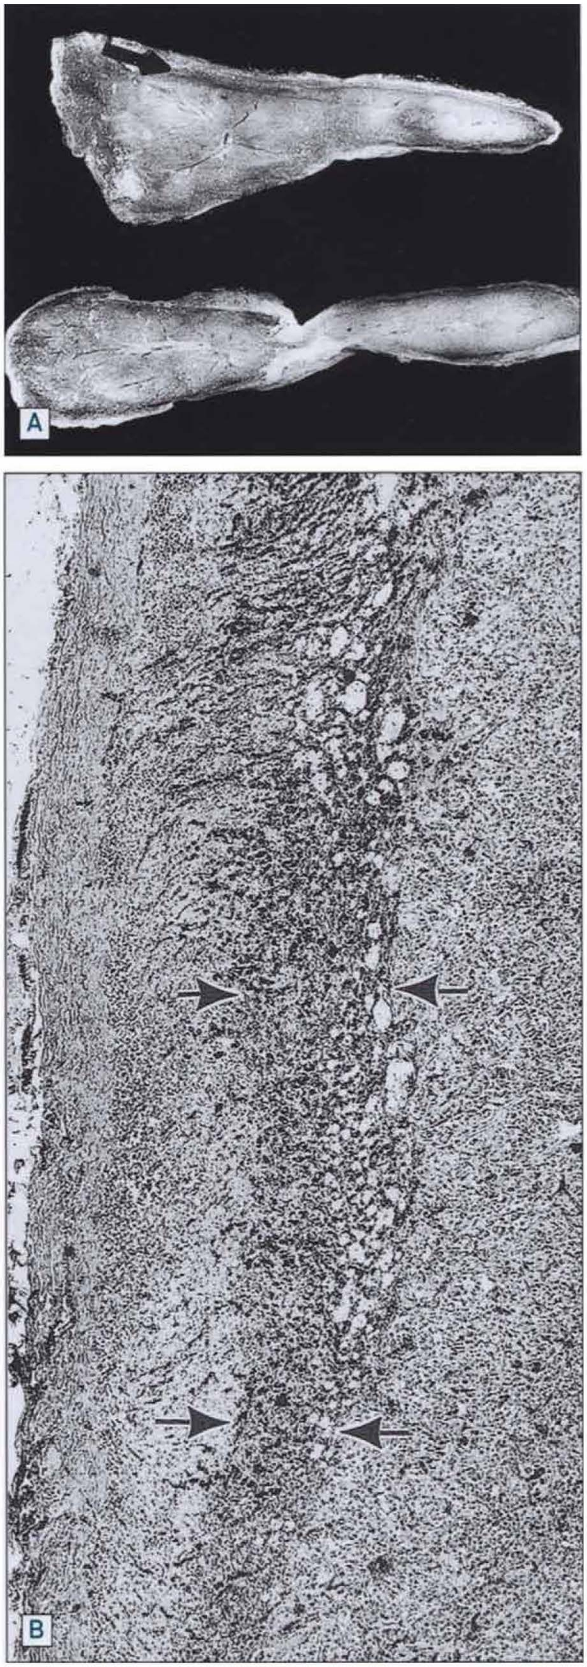

Figure 3.84 A. Idiopathic adrenal cortical atrophy in a dog. All three layers of the adrenal cortex from both glands are markedly reduced in thickness (arrow) due to atrophy as a sequela of immune-mediated adrenalitis and destruction of parenchymal cells. **B.** Severe adrenal cortical atrophy in a dog with hypoadrenocorticism. Medulla lies between arrows.

with subsequent replacement by fibrous connective tissue; and extensive amyloid deposition along adrenal sinusoids.

Many of the *functional disturbances* of hypoadrenocorticism associated with chronic adrenal insufficiency are not specific and include recurrent episodes of gastroenteritis, slowly progressive loss of body condition, and failure to respond appropriately in stressful situations such as minor illnesses or surgery. Less commonly, the dog is presented in a shock-like coma with no history of previous illness. Although hypoadrenocorticism occurs in dogs of any breed or sex and at any age, idiopathic adrenocortical insufficiency occurs more frequently in *young adult dogs*. This may be related to its likely immune-mediated pathogenesis with the generation of autoantibody against cortical cells, progressive degeneration of parenchymal cells, and lymphoplasmacytic adrenalitis.

Reduction in the synthesis and secretion of mineralocorticoids, primarily aldosterone, results in marked alterations of serum potassium, sodium, and chloride levels. Less potassium is excreted by the kidney, resulting in a progressive rise in serum potassium levels and *severe hyperkalemia* (5.5–9.0 mmol/L, 5.5–9.0 meq/L). Less sodium and chloride are reabsorbed from renal tubules, leading to various degrees of hypernatriuria and hyperchloruria and a corresponding decline in blood levels. The severe hyperkalemia frequently produces marked cardiovascular disturbances that are reflected by changes in the electrocardiogram.

Although the development of clinical signs often is insidious and not readily apparent, the dog frequently is presented with *acute circulatory collapse* and evidence of *renal failure*. Progressive decrease in blood volume contributes to hypotension, weakness, and microcardia. Peripheral circulatory collapse may result from progressive hemoconcentration. Increased excretion of water by the kidney, due to hyponatremia and hypochloremia, results in progressive dehydration and hemoconcentration. *Emesis, diarrhea, and anorexia* are common in dogs with hypoadrenocorticism and they contribute to the animal's deterioration. *Weight loss* is frequently severe.

Decreased production of glucocorticoids results in several characteristic functional disturbances of hypoadrenocorticism. Failure of gluconeogenesis and increased sensitivity to insulin contribute to development of *moderate hypoglycemia*. *Hyperpigmentation* of the skin occurs in some dogs with long-standing adrenocortical insufficiency. This change results from lack of negative feedback on the pituitary gland, increased release of ACTH, and "specificity spillover" with binding to melanocyte-stimulating hormone (MSH) receptors on melanocytes in the skin.

Peripheral lymph nodes may be moderately increased in size due to *lymphoid hyperplasia*. Histologically, prominent germinal centers are observed in lymph nodes, and substantial numbers of eosinophils may infiltrate the peripheral lymph sinus. There often are increased numbers of eosinophils and lymphocytes in the circulation as a result of the diminished cortisol levels.

Hematologic alterations that occur in hypoadrenocorticism include *hemoconcentration* due to dehydration and loss of intravascular fluid volume. In some dogs, the numbers of eosinophils and lymphocytes in the blood are not increased above normal, but the differential count is not consistent with the animal's severely "stressed" appearance. Blood urea and creatinine levels begin to rise as renal perfusion and urine output decrease. The serum glucose level ranges from low normal to moderately subnormal in affected dogs, but this usually is not responsible for functional disturbances.

Hypercalcemia (up to 3.75 mmol/L, 15 mg/dL) occurs in approximately 30% of dogs with hypoadrenocorticism. The elevated serum calcium concentration returns to normal when the adrenal cortical disease is treated with adequate corticosteroid replacement therapy. The mechanism of hypercalcemia is not understood completely, but the ionized fraction of serum calcium remains normal whereas the nonionized fraction increases and there is inappropriate hypocalciuria for the degree of hypercalcemia. Since the ionized serum calcium concentration is not increased, the hypercalcemia often is not deleterious to the animal; however, some of the clinical signs of hypoadrenocorticism (vomiting, anorexia, polyuria, and polydipsia) are similar to those of hypercalcemia.

The *plasma cortisol levels* in dogs with hypoadrenocorticism range from 28 to 41 nmol/L (0.1–1.5 μg/dL). Due to the severe atrophy or destruction of the adrenal cortex, there is little or no increase in blood cortisol levels following administration of exogenous ACTH.

Carbadox (Mecadox) is a synthetic antibacterial agent and growth promotant belonging to the family of quinoxaline-di-*N*-oxide compounds. It has been used in young pigs as a growth promotant at 50 ppm in feed and as a preventive or therapeutic agent for diarrhea up to 100–150 ppm. Exposure to 150–200 ppm of carbadox in the feed for 2–3 weeks or 100 ppm for 4–5 weeks can produce a disease in pigs that is characterized by growth retardation and dehydration associated with *lesions in the adrenal zona glomerulosa* and in the kidney. Prolonged exposure to even 50 ppm can produce disease, the only safe level being 25 ppm or less. The related compounds olaquindox and cyadox have similar effects to carbadox but the latter drug is somewhat less toxic.

The adrenal changes consist of disorganization of the zona glomerulosa with loss of distinction from the zona fasciculata. The cells of the glomerulosa develop hydropic degeneration and eventually there is atrophy, mild diffuse fibrosis and mononuclear cell infiltrates in the zone and fibrosis of the capsule, which consistently contains cells with PAS-positive cytoplasmic granules. Depending on duration and severity of exposure, adrenal lesions may persist following removal of the drug. In the kidney, there is degeneration and desquamation of epithelium in the collecting tubules of the medulla and in the pelvic epithelium. Plasma aldosterone and sodium levels are reduced significantly after 2 weeks exposure to toxic levels of carbadox, and potassium is increased.

Hyperplasia of the adrenal cortex

Accessory cortical nodules are common in the adrenal glands of adult to aged animals and are found in the capsule, cortex, and medulla (Fig. 3.85A). Many accessory cortical nodules either arise as evaginations of outer cortex into the capsule and surrounding periadrenal fat or invaginations of the cortex into the medulla.

Nodular hyperplasia (measuring from <1.0 to 2.0 cm) also is common in the adrenal as well-defined spherical nodules in the cortex or attached to the capsule. Hyperplastic nodules are usually multiple and bilateral, yellow, and may involve any of the three zones of the cortex. Histologically, the nodules near the capsule *resemble zona glomerulosa*, sometimes with areas like zona fasciculata. The cells either are about the same size as those of the adrenal cortex or hypertrophied. The lipid content in these hyperplastic nodules is not depleted in circumstances that reduce the amount of lipid in the rest of the

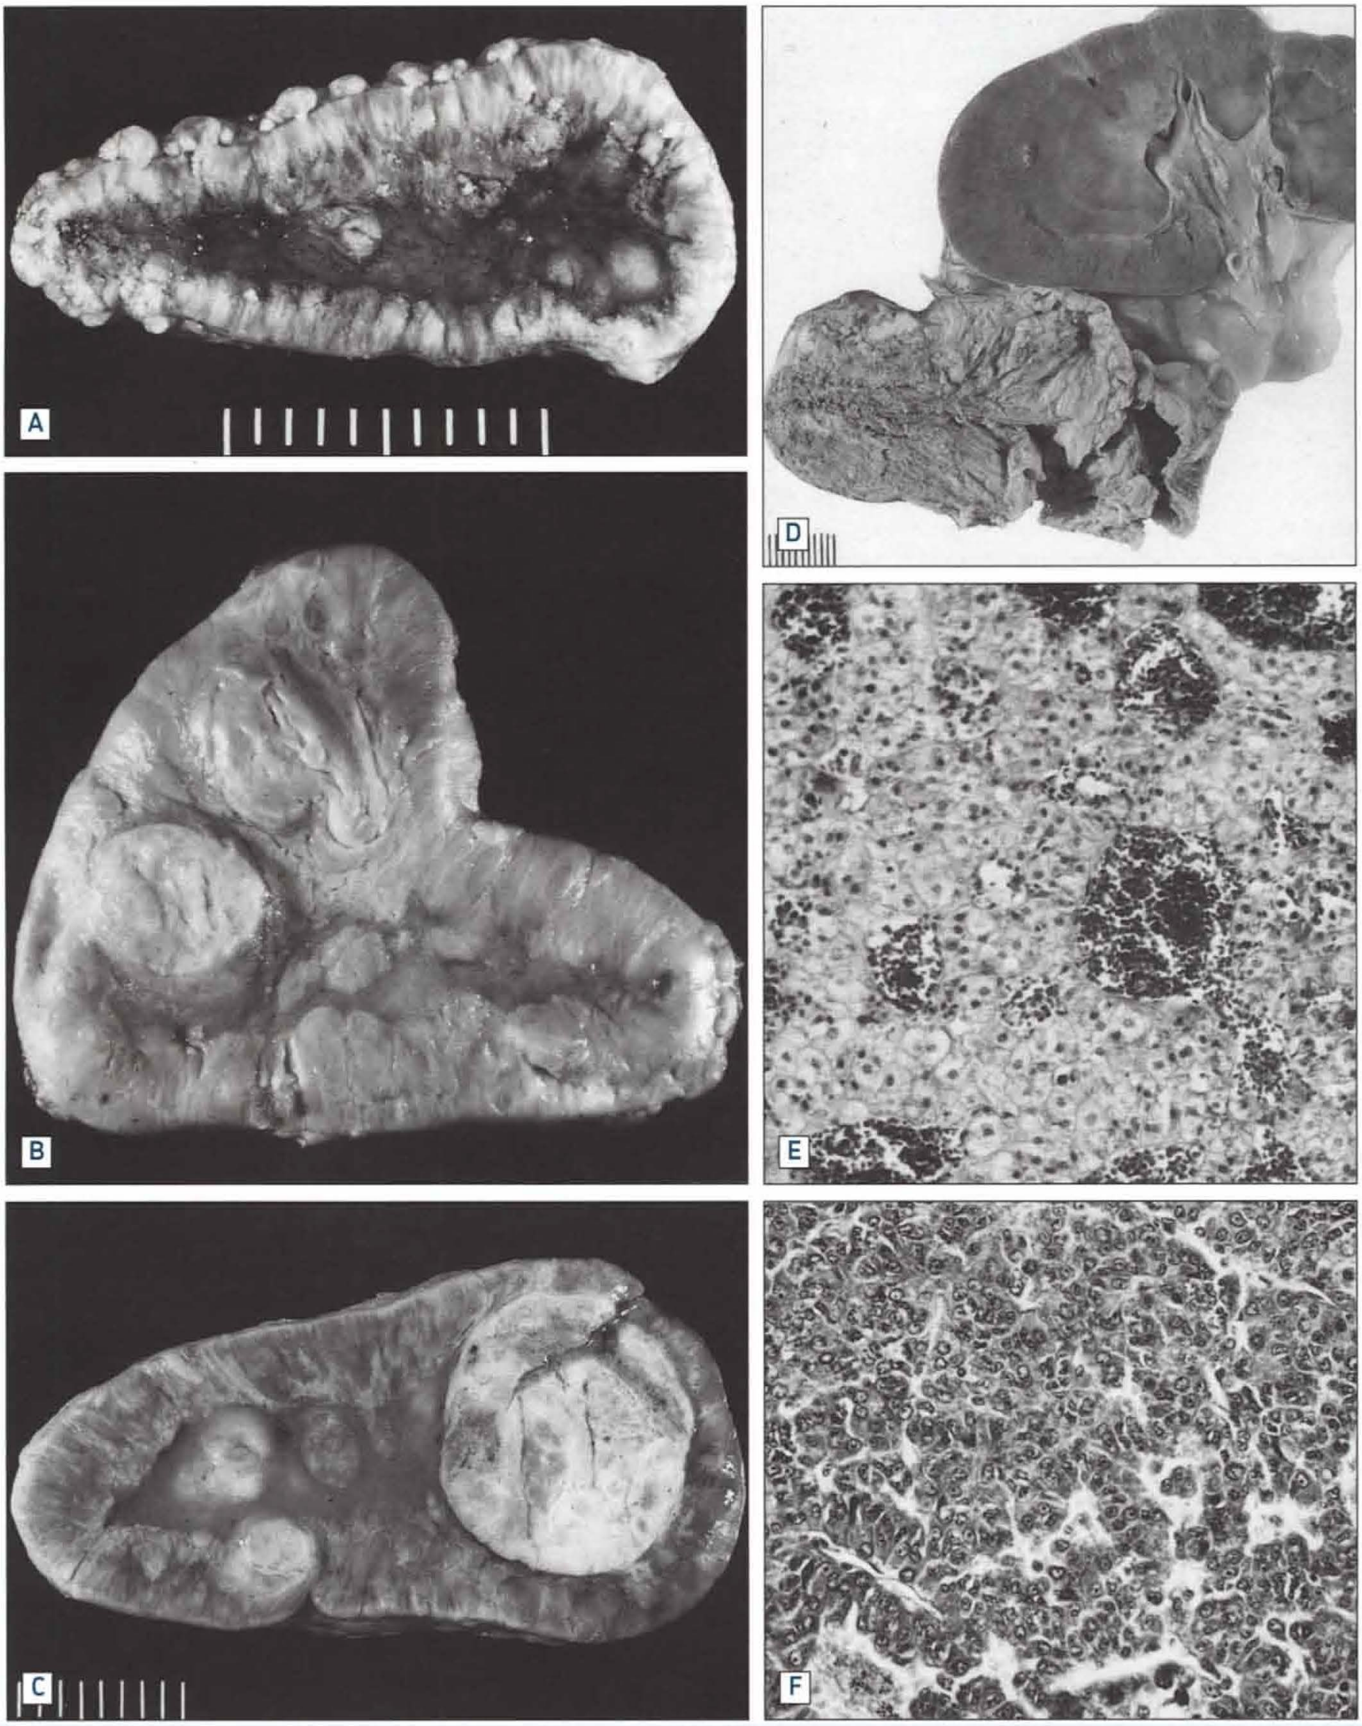

Figure 3.85 A. Discrete **accessory adrenal cortical nodules** in capsule and medulla in a dog. **B.** Discrete area of **nodular hyperplasia** in a diffusely hyperplastic adrenal cortex. Dog with pituitary corticotroph adenoma and hypercortisolism. **C. Cortical adenoma** (right) in an adrenal with multinodular hyperplasia (left) from a dog. **D.** Functional **adrenal cortical carcinoma** in a dog with the syndrome of cortisol-excess. The adrenal gland was completely incorporated within the mass at the cranial pole of the kidney (top). **E. Adrenal cortical adenoma** with hematopoiesis. **F. Adrenal cortical carcinoma** from a dog. Scale in mm in (**A**), (**C**), (**D**).

cortex. Hyperplastic cortical nodules are most common in *older horses, dogs, and cats*.

Nodular hyperplasia of the zona reticularis may appear as discrete foci of cortical parenchyma extending into the medulla and result in an irregular corticomedullary junction. This adrenal lesion has been seen in animals with functional disturbances suggesting androgen excess (e.g., greater muscle mass, well-developed crest, hypertrophy of clitoris, and involution of mammary glands).

Diffuse cortical hyperplasia results in uniform, usually bilateral, enlargement of the adrenal cortex. There is a marked hypertrophy and hyperplasia of cells in the zonae fasciculata and reticularis in response to autonomous hypersecretion of ACTH by a corticotroph adenoma of the pituitary. The hyperplastic cells in the zona fasciculata are vacuolated (lipid-rich) and arranged in straight columns separated by sinusoids. Cells in the outer zona glomerulosa often are compressed by the expanded inner two zones. The corticomedullary junction is irregular in diffuse hyperplasia, and projections of cortical cells often extend into the medulla. Areas of discrete nodular hyperplasia may be present in a diffusely hyperplastic cortex (Fig. 3.85B).

Hyperplasia of zona glomerulosa occurs as part of the compensatory mechanism of the body to a variety of factors that stimulate long-term release of renin from the juxtaglomerular apparatus of the kidney. Chronic sodium depletion or potassium excess, decreased blood volume to the kidney, or a sustained reduction in systemic blood pressure all will increase aldosterone production by stimulating renin release. Renin results in the formation of angiotensin II, a trophic hormone for the zona glomerulosa of the adrenal cortex.

Neoplasms of the adrenal cortex

Myelolipoma

This is a *benign lesion* encountered in the adrenals of cattle, nonhuman primates, and infrequently in other animals. It is composed of accumulations of well-differentiated adipose connective tissue cells and hematopoietic tissue, including both myeloid and lymphoid elements. Focal areas of mineralization or bone formation may occur in the tumor. Although the origin of these nodular aggregations of fat, bone and myeloid cells is uncertain, they appear to develop by *metaplastic transformation* of cells in the adrenal cortex.

Cortical adenoma

Adenomas of the adrenal cortex are seen most frequently in *old dogs* (8 years and older) and sporadically in horses, cattle, and sheep. They usually are encountered as *incidental findings* at autopsy. Castrated male goats are reported to have a higher incidence of cortical adenomas than intact males.

Cortical adenomas are well-demarcated, usually single, nodules in one adrenal gland, but may be bilateral. Larger cortical adenomas are yellow to red, distort the external contour of the affected gland, and are partially or completely encapsulated. Adjacent cortical parenchyma is compressed and the tumor may extend into the medulla.

Discrete cortical adenomas often develop in an adrenal with multiple areas of nodular hyperplasia (Fig. 3.85C). Smaller cortical adenomas are more yellow and similar in color to the normal adrenal cortex because of the high lipid content. They are surrounded on all sides by mildly compressed cortex with attempts at encapsulation, and may be difficult to distinguish from nodular cortical hyperplasia in old dogs. However, nodular hyperplasia consists of multiple small foci usually in both adrenals with no evidence of encapsulation and often is associated with extracapsular nodules of hyperplastic cortical tissue.

Cortical adenomas are composed of well-differentiated cells that resemble secretory cells of the normal zonae fasciculata or reticularis. Tumor cells are arranged in broad trabeculae or nests separated by small vascular spaces. The abundant cytoplasmic area of tumor cells is lightly eosinophilic, often vacuolated, and filled with many lipid droplets. Adenomas are partially or completely surrounded by a fibrous connective tissue capsule of variable thickness and a rim of compressed cortical parenchyma. Focal areas of mineralization, hematopoiesis (Fig. 3.85D), and accumulations of fat cells may be found in cortical adenomas.

Cortical carcinoma

Adrenal cortical carcinomas occur less often than adenomas and have been reported most often in *cattle* and *older dogs*, but infrequently in other species. Carcinomas develop in adult to older individuals, and there is no apparent breed or sex predisposition.

Adrenal carcinomas are larger than adenomas and more likely to be bilateral. In dogs, they are composed of variegated, yellow-red, friable tissue that incorporates the affected adrenal gland (Fig. 3.85E). They are often fixed in location because of extensive invasion of surrounding tissues with *extension into the caudal vena cava*, forming large tumor-cell thrombi. Carcinomas may attain considerable size in cattle (up to 10 cm or more in diameter) and have multiple areas of mineralization or ossification.

Carcinomas are composed of more highly pleomorphic secretory cells than adenomas that are subdivided into small groups by fibrovascular stroma of variable thickness. The architecture of the affected adrenal usually is completely obliterated by the carcinoma. The pattern of growth varies between individual tumors and within the same carcinoma. Tumor cells usually are large and polyhedral with prominent nucleoi and densely eosinophilic or vacuolated cytoplasm (Fig. 3.85F). Areas of hemorrhage within the tumors are common because of rupture of thin-walled sinusoids.

Carcinomas and adenomas of the adrenal cortex in dogs occasionally are functional and secrete excessive amounts of hormone, usually cortisol. The clinical picture of adrenal cortical carcinoma may be complicated by compression of adjacent organs by the large tumor, invasion into the aorta or caudal vena cava leading to intra-abdominal hemorrhage, and metastases to distant sites.

Functional cortical adenomas and carcinomas are associated with atrophy of the contralateral cortex because of negative feedback inhibition of pituitary ACTH secretion by the elevated blood cortisol levels. The atrophic cortex consists primarily of the adrenal capsule and zona glomerulosa. Few secretory cells remain in the zonae fasciculata and reticularis. A similar atrophy may be present in the remnants of compressed adrenal cortex around functional adenomas. The adrenal medulla in the contralateral gland appears expanded and relatively more conspicuous because of the lack of cortical parenchyma.

Hypercortisolism

The manifestations and lesions associated with hyperadenocorticism, mainly in dogs, result from long-term overproduction of cortisol by hyperactive adrenal cortices. As a result of the cortisol excess,

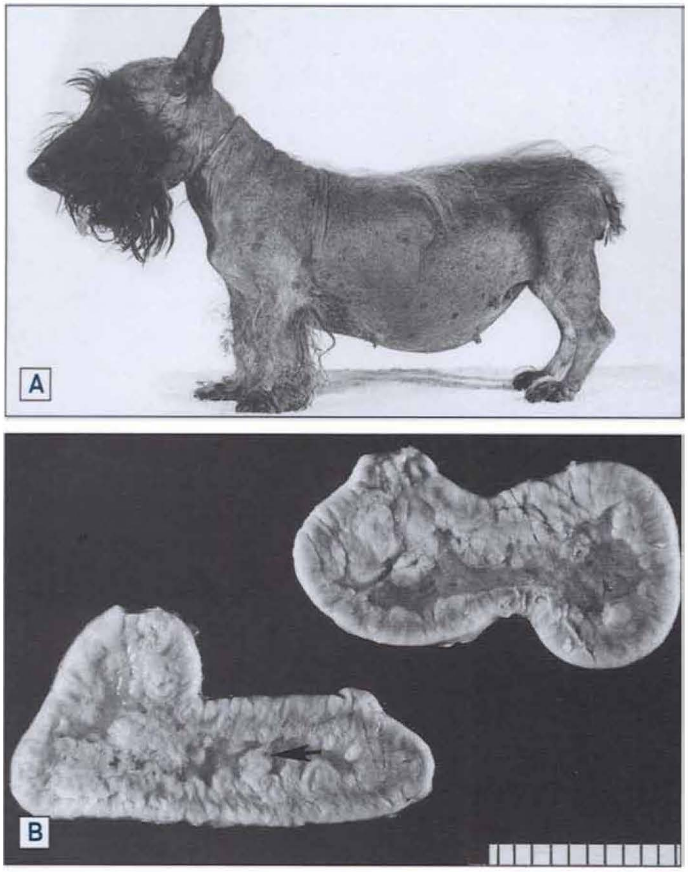

Figure 3.86 Hypercortisolism in a dog. **A.** Hypercortisolism with alopecia extending over most of the body. The skin is thin, wrinkled, and hyperpigmented. Muscle asthenia is evident from the pendulous abdomen and swayed back. **B.** Idiopathic adrenocortical hyperplasia with bilateral cortical thickening and irregularity of corticomedullary junction (arrow). Scale in mm.

affected dogs develop a spectrum of functional disturbances and lesions from the combined gluconeogenic, lipolytic, protein catabolic, and anti-inflammatory effects of the glucocorticoid hormones on many organs. The course of the disease is insidious and slowly progressive. *Cortisol excess is one of the most frequent endocrinopathies in adult to aged dogs*, occurs occasionally in cats, but is encountered infrequently in other species of domestic animals.

The elevation in circulating cortisol levels in dogs with hyperadrenocorticism may result from one of several different pathogenetic mechanisms. The most common mechanism is a *functional corticotroph (ACTH-secreting) adenoma of the pituitary gland* (pars distalis or pars intermedia in dogs) that causes bilateral adrenal cortical hypertrophy and hyperplasia (see Fig. 3.10). Hypercortisolism associated with *idiopathic adrenal cortical hyperplasia* occurs most frequently in poodles and occasionally in other breeds (Figs 3.86A, 3.87). The cortex of both adrenal glands is thickened considerably owing to diffuse or nodular hyperplasia of secretory cells, primarily in the zona fasciculata, and the corticomedullary junction is irregular (Figs. 3.86B, 3.87E).

Functional adrenal neoplasms are infrequent (10–15% of cases) causes of the syndrome of cortisol excess in the dog. Many of the clinical signs and lesions of naturally occurring hyperadrenocorticism can be induced by the long-term, daily administration of large doses of corticosteroids for the treatment of other diseases.

The appetite and intake of food often are increased as a direct result of either the hypercortisolism or the destruction of hypothalamic centers that control appetite by a dorsally expanding pituitary tumor. The muscles of the extremities and abdomen are weakened and atrophied. The loss in tone of the abdominal muscles and muscles of the appendicular skeleton results in gradual abdominal enlargement, lordosis, muscle trembling, and a straight-legged, skeletal-braced posture (Fig. 3.86A). Profound atrophy of the temporal muscles may result in obvious concave indentations and readily palpable prominences of underlying skull bones. Hepatomegaly due to increased fat and glycogen deposition may contribute to the development of the distended, often pendulous, abdomen. The muscular asthenia and wasting is the result of increased catabolism of structural proteins, combined with diminished protein synthesis, under the influence of long-term cortisol excess.

Skin lesions occur in a high percentage of dogs with hypercortisolism. The initial changes in the skin often are observed over points of wear such as neck, flanks, behind the ears, and over bony prominences. These initial skin changes spread in a bilaterally symmetrical pattern to involve a significant percentage of the body surface. The basic skin lesion of cortisol excess is atrophy of the epidermis and pilosebaceous apparatus, combined with loss of collagen and elastin fibers in the dermis and subcutis (Fig. 3.87D). The skin is of fine texture and often paper-thin. Most of the hair follicles are inactive and in the telogen phase. Accumulation of keratin in the atrophic hair follicles disrupts the base of attachment of the hair shaft, thereby permitting easy dislodgement from the follicle. The epidermis usually is markedly thinned and consists of only one or two cell layers derived from the basilar stratum germinativum. However, the stratum corneum is considerably thickened owing to the accumulation of multiple layers of keratin on the surface (Fig. 3.88).

Cutaneous mineralization is a characteristic lesion in dogs with hypercortisolism, but occurs only in long-standing cases. Although mineral deposition may occur in any region of the body, the dorsal midline, ventral abdomen, and inguinal region are frequently affected sites. Numerous mineral crystals are deposited along collagen and elastin fibers in the dermis and may protrude through the atrophic and thinned epidermis (Fig. 3.87B). The epidermis remains intact in less severe cases and appears irregularly elevated by the opaque white deposits of mineral. A narrow rim of hyperemia and foreign-body granulomatous inflammation often surrounds the areas of mineralization. The mineral deposits occur in dogs with normal blood calcium and phosphorus levels. The pathogenesis of this manifestation of hypercortisolism most likely is related to the gluconeogenic and protein catabolic action of cortisol, resulting in the rearrangement of the molecular structure of proteins such as collagen and elastin, and the formation of an organic matrix that attracts and binds calcium.

Severe mineralization also occurs in several other tissues. The lungs are most frequently affected (>90%) (Fig. 3.87A) but active skeletal muscles (Fig. 3.87C) and the wall of the stomach also may have extensive areas of mineralization. Large, basophilic mineral crystals are deposited in interalveolar and bronchiolar walls with little accompanying inflammation. Pulmonary function may be compromised when mineralization is extensive.

The syndrome of long-term cortisol excess often is complicated by *increased susceptibility to bacterial infections of the skin, urinary tract, conjunctiva, and lung.* Multifocal areas of suppurative folliculitis and

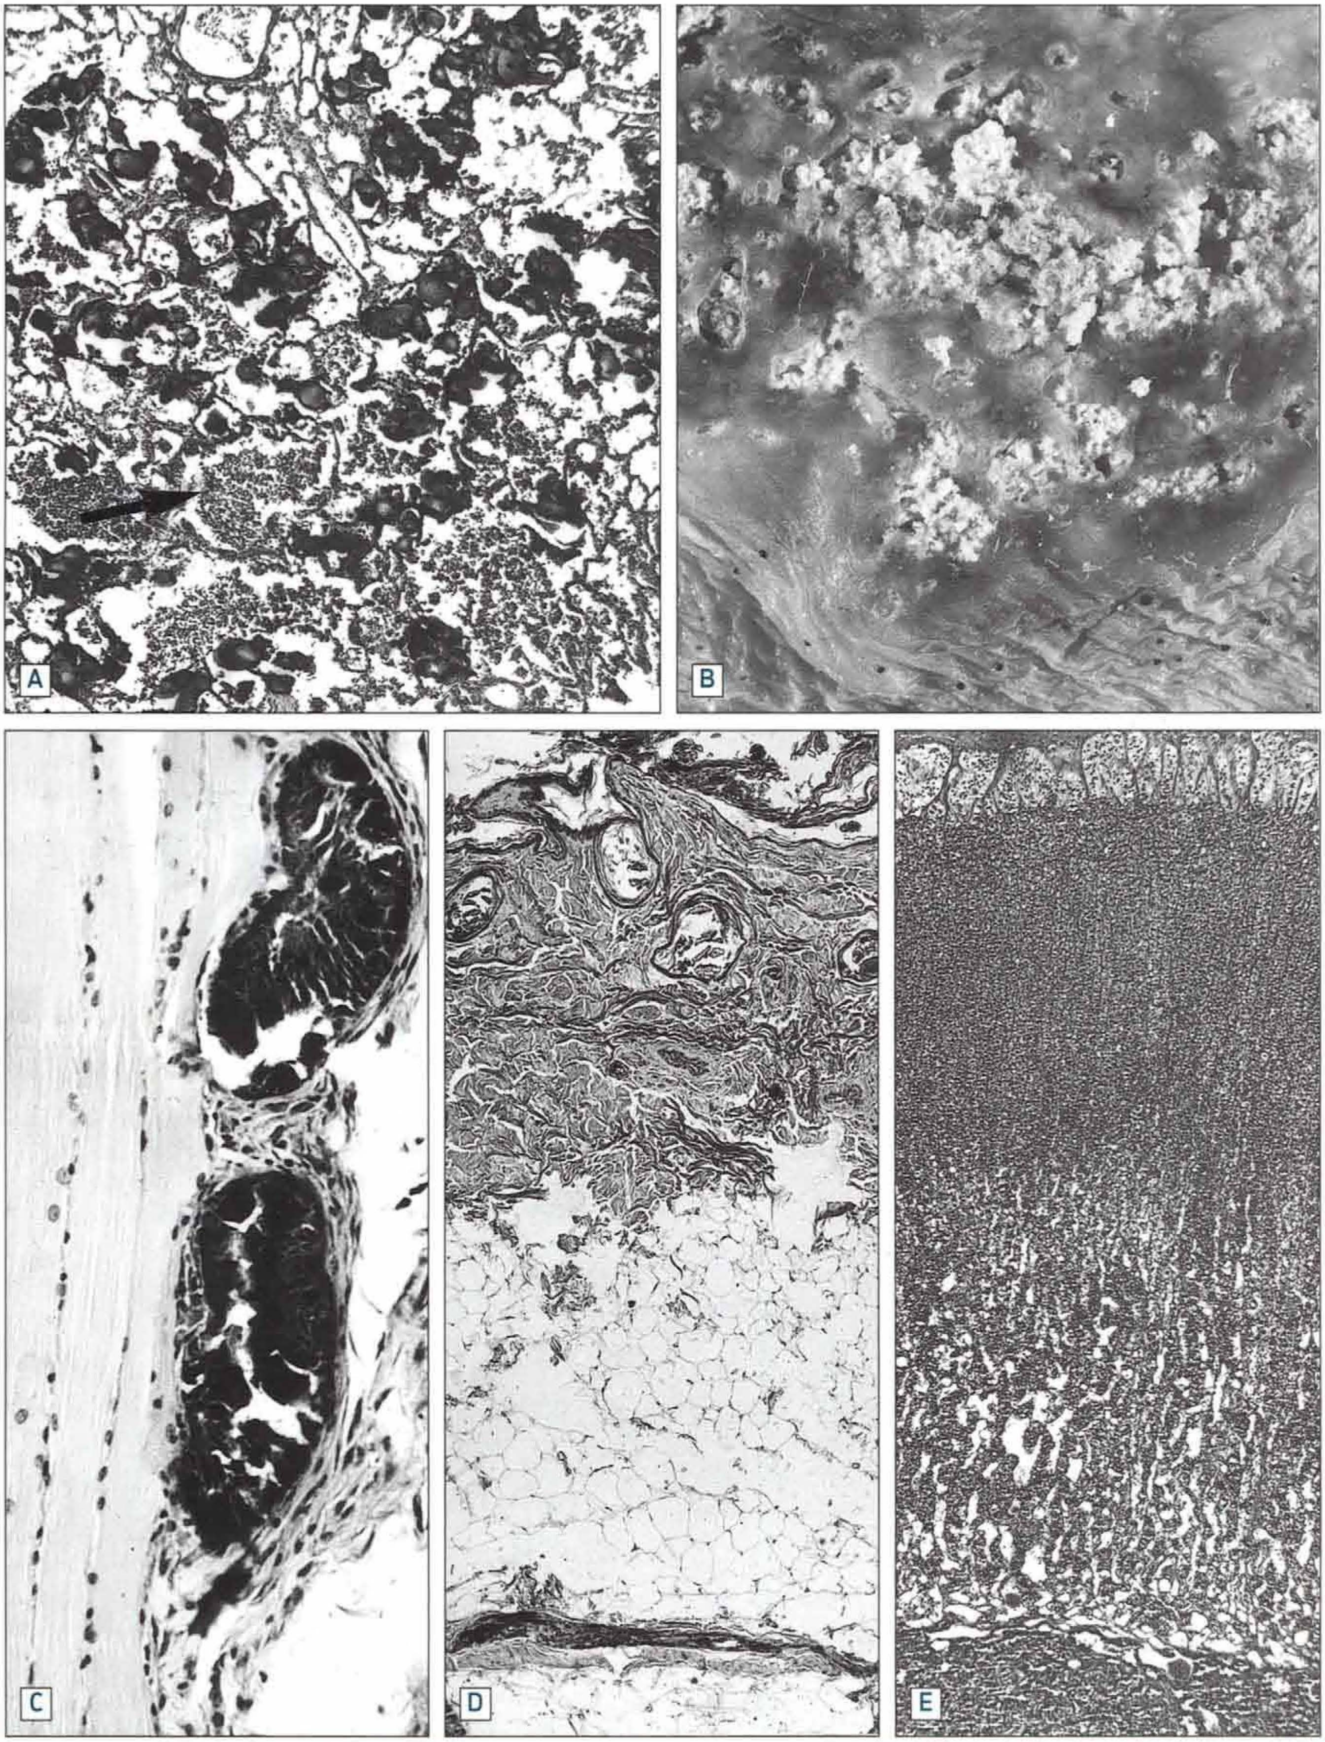

Figure 3.87 Hypercortisolism in a dog. **A.** Pulmonary mineralization and suppurative bronchopneumonia (accumulation of leukocytes, arrow). **B.** Severe mineralization of the skin. Note empty hair follicles and mineral crystals protruding through atrophic epidermis. **C.** Mineralization of connective tissue between muscle bundles. **D.** Atrophy of epidermis with accumulation of layers of keratin and follicular keratosis, and loss of collagen and elastin fibers in subcutis. **E.** Hyperplasia of zonae fasciculata and reticularis in adrenal cortex of a dog with a corticotroph adenoma of the pituitary. Outer zona glomerulosa (top) is approximately normal thickness or slightly compressed.

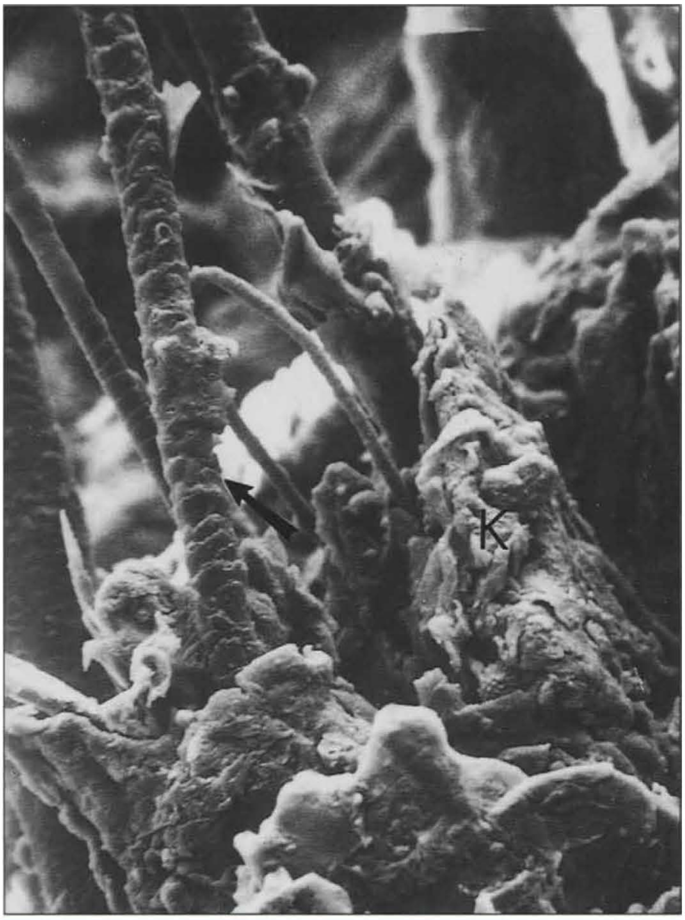

Figure 3.88 Skin of a dog with **hypercortisolism**. The skin surface is rough and scaly due to the accumulation of interlapping plates of keratin (K) in the stratum corneum. A few hair shafts (arrow) are emerging from the hair follicles. Scanning electron micrograph.

dermatitis develop near the lip folds and footpads and elsewhere in the skin. Suppurative bronchopneumonia frequently is a serious, life-threatening, complication since it develops in lungs whose function is already partially impaired by extensive mineralization of alveolar walls and terminal bronchioles.

The consistent effects that elevated blood levels of corticosteroids have on the hematopoietic system may help establish a diagnosis of adrenal cortical disease. Involution of lymphatic tissue results in significant *lymphopenia*. There is intravascular destruction of eosinophils or sequestration of circulating eosinophils in the lung and spleen, which leads to *eosinopenia*. An excess of corticosteroids can cause neutrophilia and hence leukocytosis by stimulating the formation of neutrophils and decreasing the migration of these cells into areas of infection. The nuclei of neutrophils in dogs and cats with naturally occurring or iatrogenic hyperadrenocorticism may become hypersegmented as a reflection of their prolonged lifespan in the circulation.

Laboratory confirmation *of the syndrome of cortisol excess is accomplished by a combination of suppression and stimulation tests of the hypothalamic–pituitary–adrenocortical axis.* A single blood cortisol determination usually is not diagnostic due to the wide range of normal in "stressed" dogs in an abnormal environment (such as a veterinary hospital). Low doses of dexamethasone (15 μg/kg) suppress ACTH production and subsequently plasma cortisol levels in normal dogs, but do not suppress cortisol levels in dogs with pituitary-dependent hyperadrenocorticism or functional adrenal cortical neoplasms. High doses of dexamethasone (1.0 mg/kg) usually suppress plasma cortisol levels in dogs with pituitary-dependent hyperadrenocorticism but do not significantly influence levels in dogs with cortisol-producing adrenal cortical neoplasms. Radioimmunoassays developed to measure plasma ACTH in the dog have demonstrated a mean concentration of 10 pmol/L, range 3.7–21.6 pmol/L (45.8 pg/mL, range 17–98 pg/mL). Assays for plasma ACTH are useful in differentiating pituitary-dependent (elevated) and adrenal-dependent (suppressed) causes of the syndrome of cortisol excess. Dogs with functional adrenal cortical neoplasms have plasma ACTH concentrations two standard deviations or more below the mean value for normal dogs.

Dogs with the syndrome of cortisol excess caused by diffuse cortical hyperplasia (corticotroph adenoma of pituitary or idiopathic adrenal hyperplasia) can be managed medically by the oral administration of the drug *ortho,-para*′-2,2-bis (2-chlorophenyl-4-chlorophenyl)-1,1-dichlorethane (**o,p′-DDD**, mitotane). The drug is an isomer of the insecticide DDD and is selectively cytotoxic, at the recommended dosage, for the zonae fasciculata and reticularis of the canine adrenal cortex. In dogs, the cells of these zones are highly susceptible to the cytotoxic effects of o,p′-DDD. After 5–10 days of daily treatment (50 mg/kg), the secretory cells of the inner two zones are swollen, vacuolated, and undergo necrosis. Mitochondria are vacuolated, profiles of smooth endoplasmic reticulum are disrupted, and lipid accumulates in secretory cells of the zona fasciculata after o,p′-DDD administration. Necrosis is followed progressively by collapse of the two inner zones, reduction in cortical thickness, and dilation of vascular sinusoids. After several months of treatment with o,p′-DDD, the cortex is markedly thinned and consists of an intact zona glomerulosa surrounded by a fibrous capsule. The levels of plasma cortisol decline progressively in dogs with hyperadrenocorticism treated with o,p′-DDD. The exaggerated increase in plasma corticosteroids in response to ACTH stimulation in dogs with adrenal cortical hyperplasia is eliminated after treatment with o,p′-DDD. The weekly doses of o,p′-DDD must be continued for the life of the dog in order to prevent recurrence of the functional disturbances and lesions of hypercortisolism. If the intermittent doses of o,p′-DDD are discontinued, small nests of viable cortical cells which remain in the zonae fasciculata and reticularis will regenerate the pretreatment diffuse cortical hyperplasia, with the return of the functional disturbances and the biochemical alterations. Dose levels of o,p′-DDD that are effectively cytotoxic to hyperplastic adrenal cortices usually will not destroy functional adrenal cortical adenomas and carcinomas in the dog unless high doses of drug are used. Higher dose levels of the drug can be toxic to several parenchymal organs.

Adrenal tumors in ferrets

Adrenal tumors are being recognized with greater frequency in ferrets as they are being kept as household pets and living to a more advanced age. The adrenal enlargements are either bilateral (approximately 45%) due to diffuse (most frequent) or nodular hyperplasia, or unilateral (approximately 55%) due to adrenal cortical carcinoma (more common) or cortical adenoma. Clinical signs in ferrets with adrenal cortical tumors include *vulvar enlargement*, *bilaterally symmetrical alopecia* especially on the ventral abdomen and medial aspects of the rear legs, *polyuria*, *polydipsia*, and the presence of a *palpable mass at the cranial pole of the kidney* (left side has a greater frequency than the right).

Adrenal tumors develop in adult-aged ferrets (mean age 5 years) with females more frequently affected than males (sex ratio of 2:1 or greater). The history frequently indicates the ferrets were gonadectomized at an early age (5 or 6 weeks). Other functional disturbances including anemia, thrombocytopenia, pyometra, and endometrial hyperplasia are consistent with *overproduction of estrogenic steroids by the adrenal tumors*. Some of the functional disturbances resemble intact females with persistent or prolonged estrus; ferrets being seasonally polyestrous and induced ovulators. About one third of ferrets with adrenal cortical tumors also have neoplasms derived from the insulin-producing beta cells of the pancreatic islets that can be associated with hypoglycemia and elevated levels of serum insulin, resulting in seizures, episodic lethargy, ptyalism, ataxia, and hind leg weakness.

The most consistent endocrinologic change in ferrets with adrenal tumors is *elevation of plasma levels of estradiol-17β*. It is presumed that the estradiol-17β is produced by the tumor directly, but an alternative possibility would be that the adrenal tumors secrete androgenic steroids that are aromatized in the skin and possibly elsewhere to estrogenic steroids. There is no increase in circulating estradiol-17β levels in response to exogenous ACTH, but plasma levels decrease following adrenalectomy. Plasma cortisol and corticosterone levels in ferrets with adrenal tumors either are in the range of normal or below, and do not show an exaggerated increase in response to exogenous ACTH. There is not a decrease in plasma cortisol following unilateral adrenalectomy, and the contralateral adrenal cortex is not atrophic as would be expected if the adrenal tumor were secreting excess cortisol. However, the urinary cortisol:creatinine ratio has been reported to be elevated in ferrets with adrenal cortical tumors. The clinical signs in ferrets with adrenal cortical tumors can be effectively reversed by adrenalectomy (especially of the left side if there is no macroscopic enlargement) but not by chemotherapy with o,p′-DDD. Complete regrowth of hair usually occurs by 2–3 months postadrenalectomy.

ADRENAL MEDULLA

Development, structure, and function

Embryonic development and structure

The adrenal medulla has a different embryonic derivation than the cortical portion of the adrenal gland. It is derived from neuroectoderm of the neural crest. Secretory cells in the adrenal medulla are involved in biosynthesis of the *catecholamine group of hormones*.

The medulla is completely surrounded by the adrenal cortex in mammals, and venous drainage from the cortex bathes the medullary cells with blood containing the highest concentration of corticosteroids of any fluid in the body. This close anatomic association between the adrenal cortex and medulla in mammals is not fortuitous, because the N-methylating enzyme (phenylethanolamine-*N*-methyl transferase), which converts norepinephrine to epinephrine, is corticosteroid hormone-dependent.

A variety of techniques may be used for the demonstration of catecholamines in tissue sections. The chromaffin reaction is the oxidation of catecholamines by potassium dichromate solutions and results in the formation of a brown-to-yellow pigment in medullary tissue. The chromaffin reaction as traditionally performed has a low level of sensitivity and should not be used for the definitive demonstration of the presence of catecholamines in tissues. Similarly, both the argentaffin and argyrophil reactions, which have been used extensively in the past for the demonstration of chromaffin cells, have low sensitivity and specificity. *Fluorescence techniques using formaldehyde or glyoxylic acid represent the methods of choice for the demonstration of catecholamines at the cellular level.* These aldehydes form highly fluorescent derivatives with catecholamines, which can be visualized by ultraviolet microscopy. *Immunohistochemistry* provides an alternative approach for the localization of catecholamines in chromaffin cells and other cell types. Antibodies are available that permit epinephrine- and norepinephrine-containing cells to be distinguished in routinely fixed and embedded tissue samples. Several of the important enzymes involved in the biosynthesis of catecholamine hormones also may be demonstrated by immunohistochemical procedures. Antibodies to chromogranin-A can be used for the demonstration of this unique protein in chromaffin cells.

Biosynthesis of catecholamine hormones
